# EDITORIAL ADVISORY BOARD

# FOREWORD

In bygone centuries, our physical world appeared to be filled to the brim with mysteries. Divine powers could provide for genuine miracles; water and sunlight could turn arid land into fertile pastures, but the same powers could lead to miseries and disasters. The force of life, the *vis vitalis*, was assumed to be the special agent responsible for all living things. The heavens, whatever they were for, contained stars and other heavenly bodies that were the exclusive domain of the Gods.

Mathematics did exist, of course. Indeed, there was one aspect of our physical world that was recognised to be controlled by precise, mathematical logic: the geometric structure of space, elaborated to become a genuine form of art by the ancient Greeks. From my perspective, the Greeks were the first practitioners of 'mathematical physics', when they discovered that all geometric features of space could be reduced to a small number of axioms. Today, these would be called 'fundamental laws of physics'. The fact that the flow of *time* could be addressed with similar exactitude, and that it could be handled geometrically together with space, was only recognised much later. And, yes, there were a few crazy people who were interested in the magic of numbers, but the real world around us seemed to contain so much more that was way beyond our capacities of analysis.

Gradually, all this changed. The Moon and the planets appeared to follow geometrical laws. Galilei and Newton managed to identify their logical rules of motion, and by noting that the concept of mass could be applied to things in the sky just like apples and cannon balls on Earth, they made the sky a little bit more accessible to us. Electricity, magnetism, light and sound were also found to behave in complete accordance with mathematical equations.

Yet all of this was just a beginning. The real changes came with the twentieth century. A completely new way of thinking, by emphasizing mathematical, logical analysis rather than empirical evidence, was pioneered by Albert Einstein. Applying advanced mathematical concepts, only known to a few pure mathematicians, to notions as mundane as space and time, was new to the physicists of his time. Einstein himself had a hard time struggling through the logic of connections and curvatures, notions that were totally new to him, but are only too familiar to students of mathematical physics today. Indeed, there is no better testimony of Einstein's deep insights at that time, than the fact that we now teach these things regularly in our university classrooms.

Special and general relativity are only small corners of the realm of modern physics that is presently being studied using advanced mathematical methods. We have notoriously complex subjects such as phase transitions in condensed matter physics, superconductivity, Bose–Einstein condensation, the quantum Hall effect, particularly the fractional quantum Hall effect, and numerous topics from elementary particle physics, ranging from fibre bundles and renormalization groups to supergravity, algebraic topology, superstring theory, Calabi–Yau spaces and what not, all of which require the utmost of our mental skills to comprehend them.

The most bewildering observation that we make today is that it seems that our *entire* physical world appears to be controlled by mathematical equations, and these are not just sloppy and debatable models, but precisely documented properties of materials, of systems, and of phenomena in all echelons of our universe.

Does this really apply to our entire world, or only to parts of it? Do features, notions, entities exist that are emphatically *not* mathematical? What about intuition, or dreams, and what about consciousness? What about religion? Here, most of us would say, one should not even try to apply mathematical analysis, although even here, some brave social scientists are making attempts at coordinating rational approaches.

No, there are clear and important differences between the physical world and the mathematical world. Where the physical world stands out is the fact that it refers to 'reality', whatever 'reality' is. Mathematics is the world of pure logic and pure reasoning. In physics, it is the experimental evidence that ultimately decides whether a theory is acceptable or not. Also, the methodology in physics is different.

A beautiful example is the serendipitous discovery of superconductivity. In 1911, the Dutch physicist Heike Kamerlingh Onnes was the first to achieve the liquefaction of helium, for which a temperature below 4.25 K had to be realized. Heike decided to measure the specific conductivity of mercury, a metal that is frozen solid at such low temperatures. But something appeared to go wrong during the measurements, since the volt meter did not show any voltage at all. All experienced physicists in the team assumed that they were dealing with a malfunction. It would not have been the first time for a short circuit to occur in the electrical equipment, but, this time, in spite of several efforts, they failed to locate it. One of the assistants was responsible for keeping the temperature of the sample well within that of liquid helium, a dull job, requiring nothing else than continuously watching some dials. During one of the many tests, however, he dozed off. The temperature rose, and suddenly the measurements showed the normal values again. It then occurred to the investigators that the effect and its temperature dependence were completely reproducible. Below 4.19 degrees Kelvin the conductivity of mercury appeared to be strictly infinite. Above that temperature, it is finite, and the transition is a very sudden one. Superconductivity was discovered (D. van Delft, "Heike Kamerling Onnes", Uitgeverij Bert Bakker, Amsterdam, 2005 (in Dutch)).

This is not the way mathematical discoveries are made. Theorems are not produced by assistants falling asleep, even if examples do exist of incidents involving some miraculous fortune.

The hybrid science of mathematical physics is a very curious one. Some of the topics in this Encyclopedia are undoubtedly physical. High $T_c$ superconductivity, breaking water waves, and magneto-hydrodynamics, are definitely topics of physics where experimental data are considered more decisive than any high-brow theory. Cohomology theory, Donaldson–Witten theory, and AdS/CFT correspondence, however, are examples of purely mathematical exercises, even if these subjects, like all of the others in this compilation, are strongly inspired by, and related to, questions posed in physics.

It is inevitable, in a compilation of a large number of short articles with many different authors, to see quite a bit of variation in style and level. In this Encyclopedia, theoretical physicists as well as mathematicians together made a huge effort to present in a concise and understandable manner their vision on numerous important issues in advanced mathematical physics. All include references for further reading. We hope and expect that these efforts will serve a good purpose.

Gerard 't Hooft,
Spinoza Institute,
Utrecht University,
The Netherlands.

# PREFACE

Mathematical Physics as a distinct discipline is relatively new. The International Association of Mathematical Physics was founded only in 1976. The interaction between physics and mathematics has, of course, existed since ancient times, but the recent decades, perhaps partly because we are living through them, appear to have witnessed tremendous progress, yielding new results and insights at a dizzying pace, so much so that an encyclopedia seems now needed to collate the gathered knowledge.

Mathematical Physics brings together the two great disciplines of Mathematics and Physics to the benefit of both, the relationship between them being symbiotic. On the one hand, it uses mathematics as a tool to organize physical ideas of increasing precision and complexity, and on the other it draws on the questions that physicists pose as a source of inspiration to mathematicians. A classical example of this relationship exists in Einstein's theory of relativity, where differential geometry played an essential role in the formulation of the physical theory while the problems raised by the ensuing physics have in turn boosted the development of differential geometry. It is indeed a happy coincidence that we are writing now a preface to an encyclopedia of mathematical physics in the centenary of Einstein's annus mirabilis.

The project of putting together an encyclopedia of mathematical physics looked, and still looks, to us a formidable enterprise. We would never have had the courage to undertake such a task if we did not believe, first, that it is worthwhile and of benefit to the community, and second, that we would get the much-needed support from our colleagues. And this support we did get, in the form of advice, encouragement, and practical help too, from members of our Editorial Advisory Board, from our authors, and from others as well, who have given unstintingly so much of their time to help us shape this Encyclopedia.

Mathematical Physics being a relatively new subject, it is not yet clearly delineated and could mean different things to different people. In our choice of topics, we were guided in part by the programs of recent International Congresses on Mathematical Physics, but mainly by the advice from our Editorial Advisory Board and from our authors. The limitations of space and time, as well as our own limitations, necessitated the omission of certain topics, but we have tried to include all that we believe to be core subjects and to cover as much as possible the most active areas.

Our subject being interdisciplinary, we think it appropriate that the Encyclopedia should have certain special features. Applications of the same mathematical theory, for instance, to different problems in physics will have different emphasis and treatment. By the same token, the same problem in physics can draw upon resources from different mathematical fields. This is why we divide the Encyclopedia into two broad sections: physics subjects and related mathematical subjects. Articles in either section are deliberately allowed a fair amount of overlap with one another and many articles will appear under more than one heading, but all are linked together by elaborate cross referencing. We think this gives a better picture of the subject as a whole and will serve better a community of researchers from widely scattered yet related fields.

The Encyclopedia is intended primarily for experienced researchers but should be of use also to beginning graduate students. For the latter category of readers, we have included eight elementary introductory articles for easy reference, with those on mathematics aimed at physics graduates and those on physics aimed at mathematics graduates, so that these articles can serve as their first port of call to enable them to embark on any of the main articles without the need to consult other material beforehand. In fact, we think these articles may even form the

foundation of advanced undergraduate courses, as we know that some authors have already made such use of them.

In addition to the printed version, an on-line version of the Encyclopedia is planned, which will allow both the contents and the articles themselves to be updated if and when the occasion arises. This is probably a necessary provision in such a rapidly advancing field.

This project was some four years in the making. Our foremost thanks at its completion go to the members of our Editorial Advisory Board, who have advised, helped and encouraged us all along, and to all our authors who have so generously devoted so much of their time to writing these articles and given us much useful advice as well. We ourselves have learnt a lot from these colleagues, and made some wonderful contacts with some among them. Special thanks are due also to Arthur Greenspoon whose technical expertise was indispensable.

The project was started with Academic Press, which was later taken over by Elsevier. We thank warmly members of their staff who have made this transition admirably seamless and gone on to assist us greatly in our task: both Carey Chapman and Anne Guillaume, who were in charge of the whole project and have been with us since the beginning, and Edward Taylor responsible for the copy-editing. And Martin Ruck, who manages to keep an overwhelming amount of details constantly at his fingertips, and who is never known to have lost a single email, deserves a very special mention.

As a postscript, we would like to express our gratitude to the very large number of authors who generously agreed to donate their honorariums to support the Committee for Developing Countries of the European Mathematical Society in their work to help our less fortunate colleagues in the developing world.

# GUIDE TO USE OF THE ENCYCLOPEDIA

## Structure of the Encyclopedia

The material in this Encyclopedia is organised into two sections. At the start of Volume 1 are eight **Introductory Articles**. The introductory articles on mathematics are aimed at physics graduates; those on physics are aimed at mathematics graduates. It is intended that these articles should serve as the first port of call for graduate students, to enable them to embark on any of the main entries without the need to consult other material beforehand.

Following the Introductory Articles, the main body of the Encyclopedia is arranged as a series of entries in alphabetical order. These entries fill the remainder of Volume 1 and all of the subsequent volumes (2–5).

To help you realize the full potential of the material in the Encyclopedia we have provided four features to help you find the topic of your choice: a contents list by subject, an alphabetical contents list, cross-references, and a full subject index.

## 1. Contents List by Subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of mathematical physics. This will enable the reader to make quick connections between entries and to locate the entry of interest. The contents list by subject is divided into two main sections: *Physics Subjects* and *Related Mathematics Subjects*. Under each main section heading, you will find several subject areas (such as GENERAL RELATIVITY in Physics Subjects or NONCOMMUTATIVE GEOMETRY in Related Mathematics Subjects). Under each subject area is a list of those entries that cover aspects of that subject, together with the volume and page numbers on which these entries may be found.

Because mathematical physics is so highly interconnected, individual entries may appear under more than one subject area. For example, the entry GAUGE THEORY: MATHEMATICAL APPLICATIONS is listed under the Physics Subject GAUGE THEORY as well as in a broad range of Related Mathematics Subjects.

## 2. Alphabetical Contents List

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the order in which they appear in the Encyclopedia. This list provides both the volume number and the page number of the entry.

You will find "dummy entries" where obvious synonyms exist for entries or where we have grouped together related topics. Dummy entries appear in both the contents list and the body of the text.

*Example*
If you were attempting to locate material on path integral methods via the alphabetical contents list:

PATH INTEGRAL METHODS *see* Functional Integration in Quantum Physics; Feynman Path Integrals

The dummy entry directs you to two other entries in which path integral methods are covered. At the appropriate locations in the contents list, the volume and page numbers for these entries are given.

If you were trying to locate the material by browsing through the text and you had looked up Path Integral Methods, then the following information would be provided in the dummy entry:

| **Path Integral Methods** *see* Functional Integration in Quantum Physics; Feynman Path Integrals |
|---|

## 3. Cross-References

All of the articles in the Encyclopedia have been extensively cross-referenced. The cross-references, which appear at the end of an entry, serve three different functions:

i. To indicate if a topic is discussed in greater detail elsewhere.

ii. To draw the reader's attention to parallel discussions in other entries.

iii. To indicate material that broadens the discussion.

*Example*
The following list of cross-references appears at the end of the entry STOCHASTIC HYDRODYNAMICS

> *See also*: Cauchy Problem for Burgers-Type Equations; Hamiltonian Fluid Dynamics; Incompressible Euler Equations: Mathematical Theory; Malliavin Calculus; Non-Newtonian Fluids; Partial Differential Equations: Some Examples; Stochastic Differential Equations; Turbulence Theories; Viscous Incompressible Fluids: Mathematical Theory; Vortex Dynamics

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g. Incompressible Euler Equations: Mathematical Theory), parallel discussion in other entries (e.g. Stochastic Differential Equations) and reference to entries that broaden the discussion (e.g. Turbulence Theories).

The eight Introductory Articles are not cross-referenced from any of the main entries, as it is expected that introductory articles will be of general interest. As mentioned above, the Introductory Articles may be found at the start of Volume 1.

## 4. Index

The index will provide you with the volume and page number where the material is located. The index entries differentiate between material that is a whole entry, is part of an entry, or is data presented in a figure or table. Detailed notes are provided on the opening page of the index.

## 5. Contributors

A full list of contributors appears at the beginning of each volume.

## Introductory Article: Classical Mechanics

**G Gallavotti**, Università di Roma “La Sapienza,” Rome, Italy

### General Principles

Classical mechanics is a theory of motions of point particles. If $X=(x_1,\ldots,x_n)$ are the particle positions in a Cartesian inertial system of coordinates, the equations of motion are determined by their masses $(m_1,\ldots,m_n)$, $m_j>0$, and by the potential energy of interaction, $V(x_1,\ldots,x_n)$, as

$$m_i\ddot{x}_i=-\partial_{x_i}V(x_1,\ldots,x_n),\quad i=1,\ldots,n \qquad [1]$$

here $x_i=(x_{i1},\ldots,x_{id})$ are coordinates of the $i$th particle and $\partial_{x_i}$ is the gradient $(\partial_{x_{i1}},\ldots,\partial_{x_{id}})$; $d$ is the space dimension (i.e., $d=3$, usually). The potential energy function will be supposed “smooth,” that is, analytic except, possibly, when two positions coincide. The latter exception is necessary to include the important cases of gravitational attraction or, when dealing with electrically charged particles, of Coulomb interaction. A basic result is that if $V$ is bounded below, eqn [1] admits, given initial data $X_0=X(0),\dot{X}_0=\dot{X}(0)$, a unique global solution $t\to X(t)$, $t\in(-\infty,\infty)$; otherwise a solution can fail to be global if and only if, in a finite time, it reaches infinity or a singularity point (i.e., a configuration in which two or more particles occupy the same point: an event called a collision).

In eqn [1], $-\partial_{x_i}V(x_1,\ldots,x_n)$ is the force acting on the points. More general forces are often admitted. For instance, velocity-dependent friction forces: they are not considered here because of their phenomenological nature as models for microscopic phenomena which should also, in principle, be explained in terms of conservative forces (furthermore, even from a macroscopic viewpoint, they are rather incomplete models, as they should be considered together with the important heat generation phenomena that accompany them). Another interesting example of forces not corresponding to a potential are certain velocity-dependent forces like the Coriolis force (which, however, appears only in noninertial frames of reference) and the closely related Lorentz force (in electromagnetism): they could be easily accommodated in the Hamiltonian formulation of mechanics; see Appendix 2.

The action principle states that an equivalent formulation of the eqns [1] is that a motion $t\to X_0(t)$ satisfying [1] during a time interval $[t_1,t_2]$ and leading from $X^1=X_0(t_1)$ to $X^2=X_0(t_2)$, renders stationary the action

$$\mathcal{A}(\{X\})=\int_{t_1}^{t_2}\left(\sum_{i=1}^{n}\frac{1}{2}m_i\dot{X}_i(t)^2-V(X(t))\right)\mathrm{d}t \qquad [2]$$

within the class $\mathcal{M}_{t_1,t_2}(X^1,X^2)$ of smooth (i.e., analytic) “motions” $t\to X(t)$ defined for $t\in[t_1,t_2]$ and leading from $X^1$ to $X^2$.

The function

$$\mathcal{L}(Y,X)=\frac{1}{2}\sum_{i=1}^{n}m_i y_i^2-V(X)\overset{\text{def}}{=}K(Y)-V(X),\quad Y=(y_1,\ldots,y_n)$$

is called the Lagrangian function and the action can be written as

$$\int_{t_1}^{t_2}\mathcal{L}(\dot{X}(t),X(t))\,\mathrm{d}t$$

The quantity $K(\dot{X}(t))$ is called kinetic energy and motions satisfying [1] conserve energy as time $t$ varies, that is,

$$K(\dot{X}(t))+V(X(t))=E=\text{const.} \qquad [3]$$

Hence the action principle can be intuitively thought of as saying that motions proceed by keeping constant the energy, sum of the kinetic and potential energies, while trying to share as evenly as possible their (average over time) contribution to the energy.

In the special case in which $V$ is translation invariant, motions conserve linear momentum $Q\overset{\text{def}}{=}\sum_i m_i\dot{x}_i$; if $V$

is rotation invariant around the origin $O$, motions conserve angular momentum $\boldsymbol{M} \stackrel{\text{def}}{=} \sum_i m_i \boldsymbol{x}_i \wedge \dot{\boldsymbol{x}}_i$, where $\wedge$ denotes the vector product in $\mathbb{R}^d$, that is, it is the tensor $(\boldsymbol{a} \wedge \boldsymbol{b})_{ij} = a_i b_j - b_i a_j, i, j = 1, \ldots, d$: if the dimension $d = 3$ the $\boldsymbol{a} \wedge \boldsymbol{b}$ will be naturally regarded as a vector. More generally, to any continuous symmetry group of the Lagrangian correspond conserved quantities: this is formalized in the *Noether theorem*.

It is convenient to think that the scalar product in $\mathbb{R}^{dn}$ is defined in terms of the ordinary scalar product in $\mathbb{R}^d$, $\boldsymbol{a} \cdot \boldsymbol{b} = \sum_{j=1}^d a_j b_j$, by $(\boldsymbol{v}, \boldsymbol{w}) = \sum_{i=1}^n m_i \boldsymbol{v}_i \cdot \boldsymbol{w}_i$: so that kinetic energy and line element $\mathrm{d}s$ can be written as $K(\dot{\boldsymbol{X}}) = \frac{1}{2}(\dot{\boldsymbol{X}}, \dot{\boldsymbol{X}})$ and $\mathrm{d}s^2 = \sum_{i=1}^n m_i \, \mathrm{d}\boldsymbol{x}_i^2$, respectively. Therefore, the metric generated by the latter scalar product can be called *kinetic energy metric*.

The interest of the kinetic metric appears from the *Maupertuis' principle* (equivalent to [1]): the principle allows us to identify the trajectory traced in $\mathbb{R}^d$ by a motion that leads from $\boldsymbol{X}^1$ to $\boldsymbol{X}^2$ moving with energy $E$. Parametrizing such trajectories as $\tau \to \boldsymbol{X}(\tau)$ by a parameter $\tau$ varying in [0, 1] so that the line element is $\mathrm{d}s^2 = (\partial_\tau \boldsymbol{X}, \partial_\tau \boldsymbol{X}) \, \mathrm{d}\tau^2$, the principle states that the trajectory of a motion with energy $E$ which leads from $\boldsymbol{X}^1$ to $\boldsymbol{X}^2$ makes stationary, among the analytic curves $\boldsymbol{\xi} \in \mathcal{M}_{0,1}(\boldsymbol{X}^1, \boldsymbol{X}^2)$, the function

$$L(\boldsymbol{\xi}) = \int_{\boldsymbol{\xi}} \sqrt{E - V(\boldsymbol{\xi}(s))} \, \mathrm{d}s \qquad [4]$$

so that the possible trajectories traced by the solutions of [1] in $\mathbb{R}^{nd}$ and with energy $E$ can be identified with the geodesics of the metric $\mathrm{d}m^2 \stackrel{\text{def}}{=} (E - V(\boldsymbol{X})) \cdot \mathrm{d}s^2$.

For more details, the reader is referred to Landau and Lifshitz (1976) and Gallavotti (1983).

## Constraints

Often particles are subject to constraints which force the motion to take place on a surface $M \subset \mathbb{R}^{nd}$, i.e., $\boldsymbol{X}(t)$ is forced to be a point on the manifold $M$. A typical example is provided by rigid systems in which motions are subject to forces which keep the mutual distances of the particles constant: $|\boldsymbol{x}_i - \boldsymbol{x}_j| = \rho_{ij}$, with $\rho_{ij}$ time-independent positive quantities. In essentially all cases, the forces that imply constraints, called constraint reactions, are velocity dependent and, therefore, are not in the class of conservative forces considered here, cf. [1]. Hence, from a fundamental viewpoint admitting only conservative forces, constrained systems should be regarded as idealizations of systems subject to conservative forces which approximately imply the constraints.

In general, the $\ell$-dimensional manifold $M$ will not admit a global system of coordinates: however, it will be possible to describe points in the vicinity of any $\boldsymbol{X}^0 \in M$ by using $N = nd$ coordinates $\boldsymbol{q} = (q_1, \ldots, q_\ell, q_{\ell+1}, \ldots, q_N)$ varying in an open ball $B_{\boldsymbol{X}^0}$: $\boldsymbol{X} = \boldsymbol{X}(q_1, \ldots, q_\ell, q_{\ell+1}, \ldots, q_N)$.

The $q$-coordinates can be chosen well adapted to the surface $M$ and to the kinetic metric, i.e., so that the points of $M$ are identified by $q_{\ell+1} = \cdots = q_N = 0$ (which is the meaning of "adapted"); furthermore, infinitesimal displacements $(0, \ldots, 0, \mathrm{d}\varepsilon_{\ell+1}, \ldots, \mathrm{d}\varepsilon_N)$ out of a point $\boldsymbol{X}^0 \in M$ are orthogonal to $M$ (in the kinetic metric) and have a length independent of the position of $\boldsymbol{X}^0$ on $M$ (which is the meaning of "well adapted" to the kinetic metric).

Motions constrained on $M$ arise when the potential $V$ has the form

$$V(\boldsymbol{X}) = V_a(\boldsymbol{X}) + \lambda W(\boldsymbol{X}) \qquad [5]$$

where $W$ is a smooth function which reaches its minimum value, say equal to 0, precisely on the manifold $M$ while $V_a$ is another smooth potential. The factor $\lambda > 0$ is a parameter called the rigidity of the constraint.

A particularly interesting case arises when the level surfaces of $W$ also have the geometric property of being "parallel" to the surface $M$: in the precise sense that the matrix $\partial^2_{q_i q_j} W(\boldsymbol{X})$, $i, j > \ell$ is positive definite and $\boldsymbol{X}$-independent, for all $\boldsymbol{X} \in M$, in a system of coordinates well adapted to the kinetic metric.

A potential $W$ with the latter properties can be called an approximately ideal constraint reaction. In fact, it can be proved that, given an initial datum $\boldsymbol{X}^0 \in M$ with velocity $\dot{\boldsymbol{X}}^0$ tangent to $M$, i.e., given an initial datum whose coordinates in a local system of coordinates are $(\boldsymbol{q}_0, \boldsymbol{0})$ and $(\dot{\boldsymbol{q}}_0, \boldsymbol{0})$ with $\boldsymbol{q}_0 = (q_{01}, \ldots, q_{0\ell})$ and $\dot{\boldsymbol{q}}_0 = (\dot{q}_{01}, \ldots, \dot{q}_{0\ell})$, the motion generated by [1] with $V$ given by [5] is a motion $t \to \boldsymbol{X}_\lambda(t)$ which

1. as $\lambda \to \infty$ tends to a motion $t \to \boldsymbol{X}_\infty(t)$;
2. as long as $\boldsymbol{X}_\infty(t)$ stays in the vicinity of the initial data, say for $0 \le t \le t_1$, so that it can be described in the above local adapted coordinates, its coordinates have the form $t \to (\boldsymbol{q}(t), \boldsymbol{0}) = (q_1(t), \ldots, q_\ell(t), 0, \ldots, 0)$: that is, it is a motion developing on the constraint surface $M$; and
3. the curve $t \to \boldsymbol{X}_\infty(t)$, $t \in [0, t_1]$, as an element of the space $\mathcal{M}_{0,t_1}(\boldsymbol{X}^0, \boldsymbol{X}_\infty(t_1))$ of analytic curves on $M$ connecting $\boldsymbol{X}^0$ to $\boldsymbol{X}_\infty(t_1)$, renders the action

$$A(\boldsymbol{X}) = \int_0^{t_1} \big( K(\dot{\boldsymbol{X}}(t)) - V_a(\boldsymbol{X}(t)) \big) \mathrm{d}t \qquad [6]$$

stationary.

The latter property can be formulated "intrinsically," that is, referring only to $M$ as a surface, via the restriction of the metric $\mathrm{d}s^2$ to line elements $\mathrm{d}\boldsymbol{s} = (\mathrm{d}q_1, \ldots, \mathrm{d}q_\ell, 0, \ldots, 0)$ tangent to $M$ at the point $\boldsymbol{X} = (q_0, 0, \ldots, 0) \in M$; we write $\mathrm{d}s^2 = \sum_{i,j}^{1,\ell} g_{ij}(q) \times \mathrm{d}q_i\,\mathrm{d}q_j$. The $\ell \times \ell$ symmetric positive-definite matrix $g$ can be called the *metric* on $M$ induced by the kinetic energy. Then the action in [6] can be written as

$$\mathcal{A}(q) = \int_0^{t_1} \left( \frac{1}{2} \sum_{i,j}^{1,\ell} g_{ij}(q(t))\dot{q}_i(t)\dot{q}_j(t) - \overline{V}_a(q(t)) \right) \mathrm{d}t \qquad [7]$$

where $\overline{V}_a(q) \stackrel{\text{def}}{=} V_a(\boldsymbol{X}(q_1, \ldots, q_\ell, 0, \ldots, 0))$: the function

$$\mathcal{L}(\boldsymbol{\eta}, q) \stackrel{\text{def}}{=} \frac{1}{2} \sum_{i,j}^{1,\ell} g_{ij}(q)\eta_i\eta_j - \overline{V}_a(q) \equiv \frac{1}{2} g(q)\boldsymbol{\eta} \cdot \boldsymbol{\eta} - \overline{V}_a(q) \qquad [8]$$

is called the constrained Lagrangian of the system.

An important property is that the constrained motions conserve the energy defined as $E = \frac{1}{2}(g(q)\dot{q}, \dot{q}) + \overline{V}_a(q)$; see next section.

The constrained motion $\boldsymbol{X}_\infty(t)$ of energy $E$ satisfies the Maupertuis' principle in the sense that the curve on $M$ on which the motion develops renders

$$L(\boldsymbol{\xi}) = \int_{\boldsymbol{\xi}} \sqrt{E - V_a(\boldsymbol{\xi}(s))}\, \mathrm{d}s \qquad [9]$$

stationary among the (smooth) curves that develop on $M$ connecting two fixed values $\boldsymbol{X}_1$ and $\boldsymbol{X}_2$. In the particular case in which $\ell = n$ this is again Maupertuis' principle for unconstrained motions under the potential $V(\boldsymbol{X})$. In general, $\ell$ is called the number of degrees of freedom because a complete description of the initial data requires $2\ell$ coordinates $q(0), \dot{q}(0)$.

If $W$ is minimal on $M$ but the condition on $W$ of having level surfaces parallel to $M$ is not satisfied, i.e., if $W$ is not an approximate ideal constraint reaction, it still remains true that the limit motion $\boldsymbol{X}_\infty(t)$ takes place on $M$. However, in general, it will not satisfy the above variational principles. For this reason, motions arising as limits (as $\lambda \to \infty$) of motions developing under the potential [5] with $W$ having minimum on $M$ and level curves parallel (in the above sense) to $M$ are called ideally constrained motions or motions subject by ideal constraints to the surface $M$.

As an example, suppose that $W$ has the form $W(\boldsymbol{X}) = \sum_{i,j \in \mathcal{P}} w_{ij}(|\boldsymbol{x}_i - \boldsymbol{x}_j|)$ with $w_{ij}(|\boldsymbol{\xi}|) \geq 0$ an analytic function vanishing only when $|\boldsymbol{\xi}| = \rho_{ij}$ for $i$, $j$ in some set of pairs $\mathcal{P}$ and for some given distances $\rho_{ij}$ (e.g., $w_{ij}(\boldsymbol{\xi}) = (\boldsymbol{\xi}^2 - \rho_{ij}^2)^2\gamma, \gamma > 0$). Then $W$ can be shown to satisfy the mentioned conditions and therefore, the so constrained motions $\boldsymbol{X}_\infty(t)$ of the body satisfy the variational principles mentioned in connection with [7] and [9]: in other words, the above natural way of realizing a rather general rigidity constraint is ideal.

The modern viewpoint on the physical meaning of the constraint reactions is as follows: looking at motions in an inertial Cartesian system, it will appear that the system is subject to the applied forces with potential $V_a(\boldsymbol{X})$ and to constraint forces which are defined as the differences $\boldsymbol{R}_i = m_i\ddot{\boldsymbol{x}}_i + \boldsymbol{\partial}_{\boldsymbol{x}_i} V_a(\boldsymbol{X})$. The latter reflect the action of the forces with potential $\lambda W(\boldsymbol{X})$ in the limit of infinite rigidity ($\lambda \to \infty$).

In applications, sometimes the action of a constraint can be regarded as ideal: the motion will then verify the variational principles mentioned and $\boldsymbol{R}$ can be computed as the differences between the $m_i\ddot{\boldsymbol{x}}_i$ and the active forces $-\boldsymbol{\partial}_{\boldsymbol{x}_i} V_a(\boldsymbol{X})$. In dynamics problems it is, however, a very difficult and important matter, particularly in engineering, to judge whether a system of particles can be considered as subject to ideal constraints: this leads to important decisions in the construction of machines. It simplifies the calculations of the reactions and fatigue of the materials but a misjudgment can have serious consequences about stability and safety. For statics problems, the difficulty is of lower order: usually assuming that the constraint reaction is ideal leads to an overestimate of the requirements for stability of equilibria. Hence, employing the action principle to statics problems, where it constitutes the principle of *virtual work*, generally leads to economic problems rather than to safety issues. Its discovery even predates Newtonian mechanics.

We refer the reader to Arnol'd (1989) and Gallavotti (1983) for more details.

## Lagrange and Hamilton Forms of the Equations of Motion

The stationarity condition for the action $\mathcal{A}(q)$, cf. [7], [8], is formulated in terms of the Lagrangian $\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\xi})$, see [8], by

$$\frac{\mathrm{d}}{\mathrm{d}t} \partial_{\eta_i} \mathcal{L}(\dot{q}(t), q(t)) = \partial_{\xi_i} \mathcal{L}(\dot{q}(t), q(t)), \quad i = 1, \ldots, \ell \qquad [10]$$

which is a second-order differential equation called the Lagrangian equation of motion. It can be cast in "normal form": for this purpose, adopting the convention of "summation over repeated indices," introduce the "generalized momenta"

$$p_i \stackrel{\text{def}}{=} g(q)_{ij}\dot{q}_j, \quad i = 1, \ldots, \ell \qquad [11]$$

Since $g(q) > 0$, the motions $t \to q(t)$ and the corresponding velocities $t \to \dot{q}(t)$ can be described equivalently by $t \to (q(t), p(t))$: and the equations of motion [10] become the first-order equations

$$\dot{q}_i = \partial_{p_i} \mathcal{H}(p, q), \qquad \dot{p}_i = -\partial_{q_i} H(p, q) \qquad [12]$$

where the function $\mathcal{H}$, called the Hamiltonian of the system, is defined by

$$\mathcal{H}(p, q) \stackrel{\text{def}}{=} \tfrac{1}{2}(g(q)^{-1} p, p) + \overline{V}_a(q) \qquad [13]$$

Equations [12], regarded as equations of motion for phase space points $(p, q)$, are called Hamilton equations. In general, $q$ are local coordinates on $M$ and motions are specified by giving $q, \dot{q}$ or $p, q$.

Looking for a coordinate-free representation of motions consider the pairs $X$, $Y$ with $X \in M$ and $Y$ a vector $Y \in T_X$ tangent to $M$ at the point $X$. The collection of pairs $(Y, X)$ is denoted $T(M) = \cup_{X \in M} (T_X \times \{X\})$ and a motion $t \to (\dot{X}(t), X(t)) \in T(M)$ in local coordinates is represented by $(\dot{q}(t), q(t))$. The space $T(M)$ can be called the space of initial data for Lagrange's equations of motion: it has $2\ell$ dimensions (also known as the "tangent bundle" of $M$).

Likewise, the space of initial data for the Hamilton equations will be denoted $T^*(M)$ and it consists of pairs $X, P$ with $X \in M$ and $P = g(X)Y$ with $Y$ a vector tangent to $M$ at $X$. The space $T^*(M)$ is called the phase space of the system: it has $2\ell$ dimensions (and it is occasionally called the "cotangent bundle" of $M$).

Immediate consequence of [12] is

$$\frac{d}{dt} \mathcal{H}(p(t), q(t)) \equiv 0$$

and it means that $\mathcal{H}(p(t), q(t))$ is constant along the solutions of [12]. Noting that $\mathcal{H}(p, q) = (1/2)(g(q) \;\; \dot{q}, \dot{q}) + \overline{V}_a(q)$ is the sum of the kinetic and potential energies, it follows that the conservation of $\mathcal{H}$ along solutions means energy conservation in presence of ideal constraints.

Let $S_t$ be the flow generated on the phase space variables $(p, q)$ by the solutions of the equations of motion [12], that is, let $t \to S_t(p, q) \equiv (p(t), q(t))$ denote a solution of [12] with initial data $(p, q)$. Then a (measurable) set $\Delta$ in phase space evolves in time $t$ into a new set $S_t \Delta$ with the same volume: this is obvious because the Hamilton equations [12] have manifestly zero divergence ("Liouville's theorem").

The Hamilton equations also satisfy a variational principle, called the Hamilton action principle: that is, if $\mathcal{M}_{t_1, t_2}((p_1, q_1), (p_2, q_2); M)$ denotes the space of the analytic functions $\varphi : t \to (\pi(t), \kappa(t))$ which in the time interval $[t_1, t_2]$ lead from $(p_1, q_1)$ to $(p_2, q_2)$, then the condition that $\varphi_0(t) = (p(t), q(t))$ satisfies [12] can be equivalently formulated by requiring that the function

$$\mathcal{A}_{\mathcal{H}}(\varphi) \stackrel{\text{def}}{=} \int_{t_1}^{t_2} \Big( \pi(t) \cdot \dot{\kappa}(t) - \mathcal{H}(\pi(t), \kappa(t)) \Big) \, dt \qquad [14]$$

be stationary for $\varphi = \varphi_0$: in fact, eqns [12] are the stationarity conditions for the Hamilton action [14] on $\mathcal{M}_{t_0, t_1}((p_1, q_1), (p_2, q_2); M)$. And, since the derivatives of $\pi(t)$ do not appear in [14], stationarity is even achieved in the larger space $\mathcal{M}_{t_1, t_2}(q_1, q_2; M)$ of the motions $\varphi : t \to (\pi(t), \kappa(t))$ leading from $q_1$ to $q_2$ without any restriction on the initial and final momenta $p_1, p_2$ (which, therefore, cannot be prescribed *a priori* independently of $q_1, q_2$). If the prescribed data $p_1, q_1, p_2, q_2$ are not compatible with the equations of motion (e.g., $H(p_1, q_2) \neq H(p_2, q_2)$), then the action functional has no stationary trajectory in $\mathcal{M}_{t_1, t_2}((p_1, q_1), (p_2 q_2); M)$.

For more details, the reader is referred to Landau and Lifshitz (1976), Arnol'd (1989), and Gallavotti (1983).

## Canonical Transformations of Phase Space Coordinates

The Hamiltonian form, [13], of the equations of motion turns out to be quite useful in several problems. It is, therefore, important to remark that it is invariant under a special class of transformations of coordinates, called canonical transformations.

Consider a local change of coordinates on phase space, i.e., a smooth, smoothly invertible map $\mathcal{C}(\pi, \kappa) = (\pi', \kappa')$ between an open set $U$ in the phase space of a Hamiltonian system with $\ell$ degrees of freedom, into an open set $U'$ in a $2\ell$-dimensional space. The change of coordinates is said to be *canonical* if for any solution $t \to (\pi(t), \kappa(t))$ of equations like [12], for any Hamiltonian $\mathcal{H}(\pi, \kappa)$ defined on $U$, the $\mathcal{C}$–image $t \to (\pi'(t), \kappa'(t)) = \mathcal{C}(\pi(t), \kappa(t))$ is a solution of [12] with the "same" Hamiltonian, that is, with Hamiltonian $\mathcal{H}'(\pi', \kappa') \stackrel{\text{def}}{=} \mathcal{H}(\mathcal{C}^{-1}(\pi', \kappa'))$.

The condition that a transformation of coordinates is canonical is obtained by using the arbitrariness of the function $\mathcal{H}$ and is simply expressed as a necessary and sufficient property of the Jacobian $L$,

$$\begin{gathered} L = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \\ A_{ij} = \partial_{\pi_j} \pi'_i, \quad B_{ij} = \partial_{\kappa_j} \pi'_i, \\ C_{ij} = \partial_{\pi_j} \kappa'_i, \quad D_{ij} = \partial_{\kappa_j} \kappa'_i \end{gathered} \qquad [15]$$

where $i, j = 1, \ldots, \ell$. Let

$$E = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

denote the $2\ell \times 2\ell$ matrix formed by four $\ell \times \ell$ blocks, equal to the 0 matrix or, as indicated, to the $\pm$(identity matrix); then, if a superscript T denotes matrix transposition, the condition that the map be canonical is that

$$L^{-1} = EL^{\mathrm{T}}E^{\mathrm{T}} \text{ or } L^{-1} = \begin{pmatrix} D^{\mathrm{T}} & -B^{\mathrm{T}} \\ -C^{\mathrm{T}} & A^{\mathrm{T}} \end{pmatrix} \qquad [16]$$

which immediately implies that $\det L = \pm 1$. In fact, it is possible to show that [16] implies $\det L = 1$. Equation [16] is equivalent to the four relations $AD^{\mathrm{T}} - BC^{\mathrm{T}} = 1$, $-AB^{\mathrm{T}} + BA^{\mathrm{T}} = 0$, $CD^{\mathrm{T}} - DC^{\mathrm{T}} = 0$, and $-CB^{\mathrm{T}} + DA^{\mathrm{T}} = 1$. More explicitly, since the first and the fourth relations coincide, these can be expressed as

$$\{\pi'_i, \kappa'_j\} = \delta_{ij}, \ \{\pi'_i, \pi'_j\} = 0, \ \{\kappa'_i, \kappa'_j\} = 0 \qquad [17]$$

where, for any two functions $F(\boldsymbol{\pi}, \boldsymbol{\kappa})$, $G(\boldsymbol{\pi}, \boldsymbol{\kappa})$, the *Poisson bracket* is

$$\{F, G\}(\boldsymbol{\pi}, \boldsymbol{\kappa}) \stackrel{\text{def}}{=} \sum_{k=1}^{\ell} \big(\partial_{\pi_k} F(\boldsymbol{\pi}, \boldsymbol{\kappa}) \partial_{\kappa_k} G(\boldsymbol{\pi}, \boldsymbol{\kappa}) - \partial_{\kappa_k} F(\boldsymbol{\pi}, \boldsymbol{\kappa}) \, \partial_{\pi_k} G(\boldsymbol{\pi}, \boldsymbol{\kappa})\big) \qquad [18]$$

The latter satisfies *Jacobi's identity*: $\{\{F, G\}, Q\} + \{\{G, Q\}, F\} + \{\{Q, F\}, G\} = 0$, for any three functions $F, G, Q$ on the phase space. It is quite useful to remark that if $t \to (\boldsymbol{p}(t), \ \boldsymbol{q}(t)) = S_t(\boldsymbol{p}, \boldsymbol{q})$ is a solution to Hamilton equations with Hamiltonian $\mathcal{H}$ then, given any observable $F(\boldsymbol{p}, \boldsymbol{q})$, it "evolves" as $F(t) \stackrel{\text{def}}{=} F(\boldsymbol{p}(t), \boldsymbol{q}(t))$ satisfying

$$\partial_t F(\boldsymbol{p}(t), \ \boldsymbol{q}(t)) = \{\mathcal{H}, \ F\}(\boldsymbol{p}(t), \ \boldsymbol{q}(t))$$

Requiring the latter identity to hold for all observables $F$ is equivalent to requiring that the $t \to (\boldsymbol{p}(t), \boldsymbol{q}(t))$ be a solution of Hamilton's equations for $\mathcal{H}$.

Let $\mathcal{C} : U \longleftrightarrow U'$ be a smooth, smoothly invertible transformation between two open $2\ell$-dimensional sets: $\mathcal{C}(\boldsymbol{\pi}, \boldsymbol{\kappa}) = (\boldsymbol{\pi}', \boldsymbol{\kappa}')$. Suppose that there is a function $\Phi(\boldsymbol{\pi}', \boldsymbol{\kappa})$ defined on a suitable domain $W$ such that

$$\mathcal{C}(\boldsymbol{\pi}, \boldsymbol{\kappa}) = (\boldsymbol{\pi}', \boldsymbol{\kappa}') \ \Rightarrow \ \begin{cases} \boldsymbol{\pi} = \partial_{\boldsymbol{\kappa}} \Phi(\boldsymbol{\pi}', \boldsymbol{\kappa}) \\ \boldsymbol{\kappa}' = \partial_{\boldsymbol{\pi}'} \Phi(\boldsymbol{\pi}', \boldsymbol{\kappa}) \end{cases} \qquad [19]$$

then $\mathcal{C}$ is canonical. This is because [19] implies that if $\boldsymbol{\kappa}, \boldsymbol{\pi}'$ are varied and if $\boldsymbol{\pi}, \boldsymbol{\kappa}', \boldsymbol{\pi}', \boldsymbol{\kappa}$ are related by $\mathcal{C}(\boldsymbol{\pi}, \boldsymbol{\kappa}) = (\boldsymbol{\pi}', \boldsymbol{\kappa}')$, then $\boldsymbol{\pi} \cdot \mathrm{d}\boldsymbol{\kappa} + \boldsymbol{\kappa}' \cdot \mathrm{d}\boldsymbol{\pi}' = \mathrm{d}\Phi(\boldsymbol{\pi}', \boldsymbol{\kappa})$, which implies that

$$\boldsymbol{\pi} \cdot \mathrm{d}\boldsymbol{\kappa} - \mathcal{H}(\boldsymbol{\pi}, \boldsymbol{\kappa})\mathrm{d}t \equiv \boldsymbol{\pi}' \cdot \mathrm{d}\boldsymbol{\kappa}' - \mathcal{H}(\mathcal{C}^{-1}(\boldsymbol{\pi}', \boldsymbol{\kappa}'))\mathrm{d}t + \mathrm{d}\Phi(\boldsymbol{\pi}', \boldsymbol{\kappa}) - \mathrm{d}(\boldsymbol{\pi}' \cdot \boldsymbol{\kappa}') \qquad [20]$$

It means that the Hamiltonians $\mathcal{H}(\boldsymbol{p}, \boldsymbol{q})$ and $\mathcal{H}'(\boldsymbol{p}', \boldsymbol{q}')) \stackrel{\text{def}}{=} \mathcal{H}(\mathcal{C}^{-1}(\boldsymbol{p}', \boldsymbol{q}'))$ have Hamilton actions $\mathcal{A}_{\mathcal{H}}$ and $\mathcal{A}_{\mathcal{H}'}$ differing by a constant, if evaluated on corresponding motions $(\boldsymbol{p}(t), \boldsymbol{q}(t))$ and $(\boldsymbol{p}'(t), \boldsymbol{q}'(t)) = \mathcal{C}(\boldsymbol{p}(t), \boldsymbol{q}(t))$.

The constant depends only on the initial and final values $(\boldsymbol{p}(t_1), \boldsymbol{q}(t_1))$ and $(\boldsymbol{p}(t_2), \boldsymbol{q}(t_2))$ and, respectively, $(\boldsymbol{p}'(t_1), \boldsymbol{q}'(t_1))$ and $(\boldsymbol{p}'(t_2), \boldsymbol{q}'(t_2))$ so that if $(\boldsymbol{p}(t), \boldsymbol{q}(t))$ makes $\mathcal{A}_{\mathcal{H}}$ extreme, then $(\boldsymbol{p}'(t), \boldsymbol{q}'(t)) = \mathcal{C}(\boldsymbol{p}(t), \boldsymbol{q}(t))$ also makes $\mathcal{A}_{\mathcal{H}'}$ extreme.

Hence, if $t \to (\boldsymbol{p}(t), \boldsymbol{q}(t))$ solves the Hamilton equations with Hamiltonian $\mathcal{H}(\boldsymbol{p}, \boldsymbol{q})$ then the motion $t \to (\boldsymbol{p}'(t), \boldsymbol{q}'(t)) = \mathcal{C}(\boldsymbol{p}(t), \boldsymbol{q}(t))$ solves the Hamilton equations with Hamiltonian $\mathcal{H}'(\boldsymbol{p}', \boldsymbol{q}') = \mathcal{H}(\mathcal{C}^{-1}(\boldsymbol{p}', \boldsymbol{q}'))$ no matter which it is: therefore, the transformation is canonical. The function $\Phi$ is called its generating function.

Equation [19] provides a way to construct canonical maps. Suppose that a function $\Phi(\boldsymbol{\pi}', \boldsymbol{\kappa})$ is given and defined on some domain $W$; then setting

$$\begin{cases} \boldsymbol{\pi} = \partial_{\boldsymbol{\kappa}} \Phi(\boldsymbol{\pi}', \boldsymbol{\kappa}) \\ \boldsymbol{\kappa}' = \partial_{\boldsymbol{\pi}'} \Phi(\boldsymbol{\pi}', \boldsymbol{\kappa}) \end{cases}$$

and inverting the first equation in the form $\boldsymbol{\pi}' = \Xi(\boldsymbol{\pi}, \boldsymbol{\kappa})$ and substituting the value for $\boldsymbol{\pi}'$ thus obtained, in the second equation, a map $\mathcal{C}(\boldsymbol{\pi}, \boldsymbol{\kappa}) = (\boldsymbol{\pi}', \boldsymbol{\kappa}')$ is defined on some domain (where the mentioned operations can be performed) and if such domain is open and not empty then $\mathcal{C}$ is a canonical map.

For similar reasons, if $\Gamma(\boldsymbol{\kappa}, \boldsymbol{\kappa}')$ is a function defined on some domain then setting $\boldsymbol{\pi} = \partial_{\boldsymbol{\kappa}} \Gamma(\boldsymbol{\kappa}, \boldsymbol{\kappa}')$, $\boldsymbol{\pi}' = -\partial_{\boldsymbol{\kappa}'} \Gamma(\boldsymbol{\kappa}, \boldsymbol{\kappa}')$ and solving the first relation to express $\boldsymbol{\kappa}' = \boldsymbol{\Delta}(\boldsymbol{\pi}, \boldsymbol{\kappa})$ and substituting in the second relation a map $(\boldsymbol{\pi}', \boldsymbol{\kappa}') = \mathcal{C}(\boldsymbol{\pi}, \boldsymbol{\kappa})$ is defined on some domain (where the mentioned operations can be performed) and if such domain is open and not empty then $\mathcal{C}$ is a canonical map.

Likewise, canonical transformations can be constructed starting from *a priori* given functions $F(\boldsymbol{\pi}, \boldsymbol{\kappa}')$ or $G(\boldsymbol{\pi}, \boldsymbol{\pi}')$. And the most general canonical map can be generated locally (i.e., near a given point in phase space) by a single one of the above four ways, possibly composed with a few "trivial" canonical maps in which one pair of coordinates $(\pi_i, \kappa_i)$ is transformed into $(-\kappa_i, \pi_i)$. The necessity of also including the trivial maps can be traced to the existence of homogeneous canonical maps, that is, maps such that $\boldsymbol{\pi} \cdot \mathrm{d}\boldsymbol{\kappa} = \boldsymbol{\pi}' \cdot \mathrm{d}\boldsymbol{\kappa}'$ (e.g., the identity map, see below or [49] for nontrivial examples) which are action preserving hence canonical, but which evidently cannot be generated by a function $\Phi(\boldsymbol{\kappa}, \boldsymbol{\kappa}')$ although they can be generated by a function depending on $\boldsymbol{\pi}', \boldsymbol{\kappa}$.

Simple examples of homogeneous canonical maps are maps in which the coordinates $\boldsymbol{q}$ are changed into $\boldsymbol{q}' = \boldsymbol{R}(\boldsymbol{q})$ and, correspondingly, the $\boldsymbol{p}$'s are transformed as $\boldsymbol{p}' = (\partial_q \boldsymbol{R}(\boldsymbol{q}))^{-1\,\mathrm{T}}\boldsymbol{p}$, linearly: indeed, this map is generated by the function $F(\boldsymbol{p}', \boldsymbol{q}) \stackrel{\text{def}}{=} \boldsymbol{p}' \cdot \boldsymbol{R}(\boldsymbol{q})$.

For instance, consider the map "Cartesian–polar" coordinates $(q_1, q_2) \longleftrightarrow (\rho, \theta)$ with $(\rho, \theta)$ the polar coordinates of $\boldsymbol{q}$ (namely $\rho = \sqrt{q_1^2 + q_2^2}, \theta =$ arctan $(q_2/q_1)$) and let $\boldsymbol{n} \stackrel{\text{def}}{=} \boldsymbol{q}/|\boldsymbol{q}| = (n_1, n_2)$ and $\boldsymbol{t} = (-n_2, n_1)$. Setting $p_\rho \stackrel{\text{def}}{=} \boldsymbol{p}\cdot\boldsymbol{n}, p_\theta \stackrel{\text{def}}{=} \rho\boldsymbol{p}\cdot\boldsymbol{t}$, the map $(p_1, p_2, q_1, q_2) \longleftrightarrow (p_\rho, p_\theta, \rho, \theta)$ is homogeneous canonical (because $\boldsymbol{p}\cdot \mathrm{d}\boldsymbol{q} = \boldsymbol{p}\cdot\boldsymbol{n}\,\mathrm{d}\rho + \boldsymbol{p}\cdot\boldsymbol{t}\rho\,\mathrm{d}\theta = p_\rho\,\mathrm{d}\rho + p_\theta\,\mathrm{d}\theta$).

As a further example, any area-preserving map $(p, q) \longleftrightarrow (p', q')$ defined on an open region of the plane $\mathbb{R}^2$ is canonical: because in this case the matrices $A, B, C, D$ are just numbers, which satisfy $AD - BC = 1$ and, therefore, [16] holds.

For more details, the reader is referred to Landau and Lifshitz (1976) and Gallavotti (1983).

## Quadratures

The simplest mechanical systems are integrable by quadratures. For instance, the Hamiltonian on $\mathbb{R}^2$,

$$\mathcal{H}(p, q) = \frac{1}{2m}p^2 + V(q) \qquad [21]$$

generates a motion $t \to q(t)$ with initial data $q_0, \dot{q}_0$ such that $\mathcal{H}(p_0, q_0) = E$, i.e., $\frac{1}{2}m\dot{q}_0^2 + V(q_0) = E$, satisfying

$$\dot{q}(t) = \pm\sqrt{\frac{2}{m}(E - V(q(t)))}$$

If the equation $E = V(q)$ has only two solutions $q_-(E) < q_+(E)$ and $|\partial_q V(q_\pm(E))| > 0$, the motion is periodic with period

$$T(E) = 2\int_{q_-(E)}^{q_+(E)} \frac{\mathrm{d}x}{\sqrt{(2/m)(E - V(x))}} \qquad [22]$$

The special solution with initial data $q_0 = q_-(E), \dot{q}_0 = 0$ will be denoted $Q(t)$, and it is an analytic function (by the general regularity theorem on ordinary differential equations). For $0 \le t \le T/2$ or for $T/2 \le t \le T$ it is given, respectively, by

$$t = \int_{q_-(E)}^{Q(t)} \frac{\mathrm{d}x}{\sqrt{(2/m)(E - V(x))}} \qquad [23a]$$

or

$$t = \frac{T}{2} - \int_{q_+(E)}^{Q(t)} \frac{\mathrm{d}x}{\sqrt{(2/m)(E - V(x))}} \qquad [23b]$$

The most general solution with energy $E$ has the form $q(t) = Q(t_0 + t)$, where $t_0$ is defined by $q_0 = Q(t_0)$, $\dot{q}_0 = \dot{Q}(t_0)$, i.e., it is the time needed for the "standard solution" $Q(t)$ to reach the initial data for the new motion.

If the derivative of $V$ vanishes in one of the extremes or if at least one of the two solutions $q_\pm(E)$ does not exist, the motion is not periodic and it may be unbounded: nevertheless, it is still expressible via integrals of the type [22]. If the potential $V$ is periodic in $q$ and the variable $q$ is considered to be varying on a circle then essentially all solutions are periodic: exceptions can occur if the energy $E$ has a value such that $V(q) = E$ admits a solution where $V$ has zero derivative.

Typical examples are the harmonic oscillator, the pendulum, and the Kepler oscillator: whose Hamiltonians, if $m, \omega, g, h, G, k$ are positive constants, are, respectively,

$$\begin{aligned} &\frac{p^2}{2m} + \frac{1}{2}m\omega^2 q^2 \\ &\frac{p^2}{2m} + mg\left(1 - \cos\frac{q}{h}\right) \\ &\frac{p^2}{2m} - mk\frac{1}{|q|} + m\frac{G^2}{2q^2} \end{aligned} \qquad [24]$$

the Kepler oscillator Hamiltonian has a potential which is singular at $q = 0$ but if $G \ne 0$ the energy conservation forbids too close an approach to $q = 0$ and the singularity becomes irrelevant.

The integral in [23] is called a *quadrature* and the systems in [21] are therefore *integrable by quadratures*. Such systems, at least when the motion is periodic, are best described in new coordinates in which periodicity is more manifest. Namely when $V(q) = E$ has only two roots $q_\pm(E)$ and $\mp V'(q_\pm(E)) > 0$ the *energy–time coordinates* can be used by replacing $q, \dot{q}$ or $p, q$ by $E, \tau$, where $\tau$ is the time needed for the standard solution $t \to Q(t)$ to reach the given data, that is, $Q(\tau) = q, \dot{Q}(\tau) = \dot{q}$. In such coordinates, the motion is simply $(E, \tau) \to (E, \tau + t)$ and, of course, the variable $\tau$ has to be regarded as varying on a circle of radius $T/2\pi$. The $E, \tau$ variables are a kind of polar coordinates, as can be checked by drawing the curves of constant $E$, "energy levels," in the plane $p, q$ in the cases in [24]; see **Figure 1**.

In the harmonic oscillator case, all trajectories are periodic. In the pendulum case, all motions are periodic except the ones which separate the oscillatory motions (the closed curves in the second drawing) from the rotatory motions (the apparently open curves) which, in fact, are on closed curves as well if the $q$ coordinate, that is, the vertical

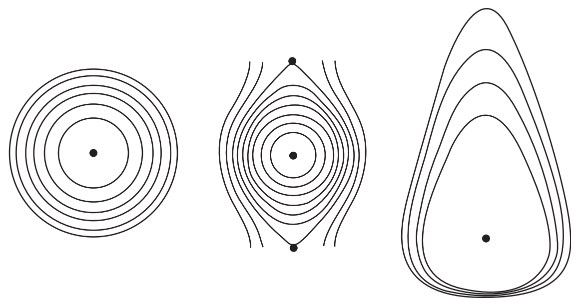

**Figure 1** The energy levels of the harmonic oscillator, the pendulum, and the Kepler motion.

coordinate in Figure 1, is regarded as "periodic" with period $2\pi h$. In the Kepler case, only the negative-energy trajectories are periodic and a few of them are drawn in Figure 1. The single dots represent the equilibrium points in phase space.

The region of phase space where motions are periodic is a set of points $(p, q)$ with the topological structure of $\cup_{u \in U}(\{u\} \times C_u)$, where $u$ is a coordinate varying in an open interval $U$ (e.g., the set of values of the energy), and $C_u$ is a closed curve whose points $(p, q)$ are identified by a coordinate (e.g., by the time necessary for an arbitrarily fixed datum with the same energy to evolve into $(p, q)$).

In the above cases, [24], if the "radial" coordinate is chosen to be the energy the set $U$ is the interval $(0, +\infty)$ for the harmonic oscillator, $(0, 2mg)$ or $(2mg, +\infty)$ for the pendulum, and $(-\frac{1}{2}mk^2/G^2, 0)$ in the Kepler case. The fixed datum for the reference motion can be taken, in all cases, to be of the form $(0, q_0)$ with the time coordinate $t_0$ given by [23].

It is remarkable that the energy–time coordinates are canonical coordinates: for instance, in the vicinity of $(p_0, q_0)$ and if $p_0 > 0$, this can be seen by setting

$$S(q, E) = \int_{q_0}^{q} \sqrt{2m(E - V(x))}\mathrm{d}x \qquad [25]$$

and checking that $p = \partial_q S(q, E)$, $t = \partial_E S(q, E)$ are identities if $(p, q)$ and $(E, t)$ are coordinates for the same point so that the criterion expressed by [20] applies.

It is convenient to standardize the coordinates by replacing the time variable by an angle $\alpha = (2\pi/T(E))t$; and instead of the energy any invertible function of it can be used.

It is natural to look for a coordinate $A = A(E)$ such that the map $(p, q) \longleftrightarrow (A, \alpha)$ is a canonical map: this is easily done as the function

$$\hat{S}(q, A) = \int_{q_0}^{q} \sqrt{2m(E(A) - V(x))}\,\mathrm{d}x \qquad [26]$$

generates (locally) the correspondence between $p = \sqrt{2m(E(A) - V(q))}$ and

$$\alpha = E'(A) \int_0^q \frac{\mathrm{d}x}{\sqrt{2m^{-1}(E(A) - V(x))}}$$

Therefore, by the criterion [20], if

$$E'(A) = \frac{2\pi}{T(E(A))}$$

i.e., if $A'(E) = T(E)/2\pi$, the coordinates $(A, \alpha)$ will be canonical coordinates. Hence, by [22], $A(E)$ can be taken as

$$A = \frac{1}{2\pi} 2 \int_{q_-(E)}^{q_+(E)} \sqrt{2m(E - V(q))}\mathrm{d}q \equiv \frac{1}{2\pi} \oint p\,\mathrm{d}q \qquad [27]$$

where the last integral is extended to the closed curve of energy $E$; see Figure 1. The *action–angle coordinates* $(A, \alpha)$ are defined in open regions of phase space covered by periodic motions: in action–angle coordinates such regions have the form $W = J \times \mathbb{T}$ of a product of an open interval $J$ and a one-dimensional "torus" $\mathbb{T} = [0, 2\pi]$ (i.e., a unit circle).

For details, the reader is again referred to Landau and Lifshitz (1976), Arnol'd (1989), and Gallavotti (1983).

## Quasiperiodicity and Integrability

A Hamiltonian is called *integrable* in an open region $W \subset T^*(M)$ of phase space if

1. there is an analytic and nonsingular (i.e., with nonzero Jacobian) change of coordinates $(\boldsymbol{p}, \boldsymbol{q}) \longleftrightarrow (\boldsymbol{I}, \boldsymbol{\varphi})$ mapping $W$ into a set of the form $\mathcal{I} \times \mathbb{T}^\ell$ with $\mathcal{I} \subset \mathbb{R}^\ell$ (open); and furthermore
2. the flow $t \to S_t(\boldsymbol{p}, \boldsymbol{q})$ on phase space is transformed into $(\boldsymbol{I}, \boldsymbol{\varphi}) \to (\boldsymbol{I}, \boldsymbol{\varphi} + \boldsymbol{\omega}(\boldsymbol{I})t)$ where $\boldsymbol{\omega}(\boldsymbol{I})$ is a smooth function on $\mathcal{I}$.

This means that, in suitable coordinates, which can be called "integrating coordinates," the system appears as a set of $\ell$ points with coordinates $\boldsymbol{\varphi} = (\varphi_1, \ldots, \varphi_\ell)$ moving on a unit circle at angular velocities $\boldsymbol{\omega}(\boldsymbol{I}) = (\omega_1(\boldsymbol{I}), \ldots, \omega_\ell(\boldsymbol{I}))$ depending on the actions of the initial data.

A system integrable in a region $W$ which, in integrating coordinates $\boldsymbol{I}, \boldsymbol{\varphi}$, has the form $\mathcal{I} \times \mathbb{T}^\ell$ is said to be *anisochronous* if $\det \partial_{\boldsymbol{I}} \boldsymbol{\omega}(\boldsymbol{I}) \neq 0$. It is said to be isochronous if $\boldsymbol{\omega}(\boldsymbol{I}) \equiv \boldsymbol{\omega}$ is independent of $\boldsymbol{I}$. The motions of integrable systems are called *quasiperiodic* with frequency spectrum $\boldsymbol{\omega}(\boldsymbol{I})$, or with *frequencies* $\boldsymbol{\omega}(\boldsymbol{I})/2\pi$, in the coordinates $(\boldsymbol{I}, \boldsymbol{\varphi})$.

Clearly, an integrable system admits $\ell$ independent constants of motion, the $\boldsymbol{I} = (I_1, \ldots, I_\ell)$, and, for each

choice of $\boldsymbol{I}$, the other coordinates vary on a "standard" $\ell$-dimensional torus $\mathbb{T}^\ell$: hence, it is possible to say that a phase space region of integrability is *foliated* into $\ell$-dimensional invariant tori $\mathcal{T}(\boldsymbol{I})$ parametrized by the values of the constants of motion $\boldsymbol{I} \in \mathcal{I}$.

If an integrable system is anisochronous then it is *canonically integrable*: that is, it is possible to define on $W$ a canonical change of coordinates $(\boldsymbol{p}, \boldsymbol{q}) = \mathcal{C}(\boldsymbol{A}, \boldsymbol{\alpha})$ mapping $W$ onto $J \times \mathbb{T}^\ell$ and such that $\mathcal{H}(\mathcal{C}(\boldsymbol{A}, \boldsymbol{\alpha})) = h(\boldsymbol{A})$ for a suitable $h$. Then, if $\boldsymbol{\omega}(\boldsymbol{A}) \stackrel{\text{def}}{=} \partial_{\boldsymbol{A}} h(\boldsymbol{A})$, the equations of motion become

$$\dot{\boldsymbol{A}} = \boldsymbol{0}, \qquad \dot{\boldsymbol{\alpha}} = \boldsymbol{\omega}(\boldsymbol{A}) \qquad [28]$$

Given a system $(\boldsymbol{I}, \boldsymbol{\varphi})$ of coordinates integrating an anisochronous system the construction of action–angle coordinates can be performed, in principle, via a classical procedure (under a few extra assumptions).

Let $\gamma_1, \ldots, \gamma_\ell$ be $\ell$ topologically independent circles on $\mathbb{T}^\ell$, for definiteness let $\gamma_i(\boldsymbol{I}) = \{\boldsymbol{\varphi} \,|\, \varphi_1 = \varphi_2 = \cdots = \varphi_{i-1} = \varphi_{i+1} = \cdots = 0,\ \varphi_i \in [0, 2\pi]\}$, and set

$$A_i(\boldsymbol{I}) = \frac{1}{2\pi} \oint_{\gamma_i(\boldsymbol{I})} \boldsymbol{p} \cdot \mathrm{d}\boldsymbol{q} \qquad [29]$$

If the map $\boldsymbol{I} \longleftrightarrow \boldsymbol{A}(\boldsymbol{I})$ is analytically invertible as $\boldsymbol{I} = \boldsymbol{I}(\boldsymbol{A})$, the function

$$S(\boldsymbol{A}, \boldsymbol{\varphi}) = (\lambda) \int_{\boldsymbol{0}}^{\boldsymbol{\varphi}} \boldsymbol{p} \cdot \mathrm{d}\boldsymbol{q} \qquad [30]$$

is well defined if the integral is over any path $\lambda$ joining the points $(p(\boldsymbol{I}(\boldsymbol{A}), \boldsymbol{0}), q(\boldsymbol{I}(\boldsymbol{A}), \boldsymbol{0}))$ and $(p(\boldsymbol{I}(\boldsymbol{A}), \boldsymbol{\varphi})), q(\boldsymbol{I}(\boldsymbol{A}), \boldsymbol{\varphi})$ and lying on the torus parametrized by $\boldsymbol{I}(\boldsymbol{A})$.

The key remark in the proof that [30] really defines a function of the only variables $\boldsymbol{A}, \boldsymbol{\varphi}$ is that anisochrony implies the vanishing of the Poisson brackets (cf. [18]): $\{I_i, I_j\} = 0$ (hence also $\{A_i, A_j\} \equiv \sum_{h,k} \partial_{I_k} A_i\, \partial_{I_h} A_j \{I_k, I_h\} = 0$). And the property $\{I_i, I_j\} = 0$ can be checked to be precisely the integrability condition for the differential form $\boldsymbol{p} \cdot \mathrm{d}\boldsymbol{q}$ restricted to the surface obtained by varying $\boldsymbol{q}$ while $\boldsymbol{p}$ is constrained so that $(\boldsymbol{p}, \boldsymbol{q})$ stays on the surface $\boldsymbol{I} =$ constant, i.e., on the invariant torus of the points with fixed $\boldsymbol{I}$.

The latter property is necessary and sufficient in order that the function $S(\boldsymbol{A}, \boldsymbol{\varphi})$ be well defined (i.e., be independent on the integration path $\lambda$) up to an additive quantity of the form $\sum_i 2\pi n_i A_i$ with $\boldsymbol{n} = (n_1, \ldots, n_\ell)$ integers.

Then the action–angle variables are defined by the canonical change of coordinates with $S(\boldsymbol{A}, \boldsymbol{\varphi})$ as generating function, i.e., by setting

$$\alpha_i = \partial_{A_i} S(\boldsymbol{A}, \boldsymbol{\varphi}), \qquad I_i = \partial_{\boldsymbol{\varphi}_i} S(\boldsymbol{A}, \boldsymbol{\varphi}) \qquad [31]$$

and, since the computation of $S(\boldsymbol{A}, \boldsymbol{\varphi})$ is "reduced to integrations" which can be regarded as a natural extension of the quadratures discussed in the one-dimensional cases, such systems are also called *integrable by quadratures*. The just-described construction is a version of the more general *Arnol'd–Liouville theorem*.

In practice, however, the actual evaluation of the integrals in [29], [30] can be difficult: its analysis in various cases (even as "elementary" as the pendulum) has in fact led to key progress in various domains, for example, in the theory of special functions and in group theory.

In general, any surface on phase space on which the restriction of the differential form $\boldsymbol{p} \cdot \mathrm{d}\boldsymbol{q}$ is locally integrable is called a *Lagrangian manifold*: hence the invariant tori of an anisochronous integrable system are Lagrangian manifolds.

If an integrable system is anisochronous, it cannot admit more than $\ell$ independent constants of motion; furthermore, it does not admit invariant tori of dimension $> \ell$. Hence $\ell$-dimensional invariant tori are called maximal.

Of course, invariant tori of dimension $< \ell$ can also exist: this happens when the variables $\boldsymbol{I}$ are such that the frequencies $\boldsymbol{\omega}(\boldsymbol{I})$ admit nontrivial rational relations; i.e., there is an integer components vector $\boldsymbol{\nu} \in \mathbb{Z}^\ell$, $\boldsymbol{\nu} = (\nu_1, \ldots, \nu_\ell) \neq 0$ such that

$$\boldsymbol{\omega}(\boldsymbol{I}) \cdot \boldsymbol{\nu} = \sum_i \omega_i(\boldsymbol{I}) \nu_i = 0 \qquad [32]$$

in this case, the invariant torus $\mathcal{T}(\boldsymbol{I})$ is called *resonant*. If the system is anisochronous then $\det \partial_{\boldsymbol{I}} \boldsymbol{\omega}(\boldsymbol{I}) \neq 0$ and, therefore, the resonant tori are associated with values of the constants of motion $\boldsymbol{I}$ which form a set of measure zero in the space $\mathcal{I}$ but which is not empty and dense.

Examples of isochronous systems are the systems of harmonic oscillators, i.e., systems with Hamiltonian

$$\sum_{i=1}^{\ell} \frac{1}{2m_i} p_i^2 + \frac{1}{2} \sum_{i,j}^{1,\ell} c_{ij} q_i q_j$$

where the matrix $v$ is a positive-definite matrix. This is an isochronous system with frequencies $\boldsymbol{\omega} = (\omega_1, \ldots, \omega_\ell)$ whose squares are the eigenvalues of the matrix $m_i^{-1/2} c_{ij} m_j^{-1/2}$. It is integrable in the region $W$ of the data $\boldsymbol{x} = (\boldsymbol{p}, \boldsymbol{q}) \in \mathbb{R}^{2\ell}$ such that, setting

$$A_\beta = \frac{1}{2\omega_\beta} \left( \left( \sum_{i=1}^{\ell} \frac{v_{\beta,i} p_i}{\sqrt{m_i}} \right)^2 + \omega_\beta^2 \left( \sum_{i=1}^{\ell} \frac{v_{\beta,i} q_i}{\sqrt{m_i^{-1}}} \right)^2 \right)$$

for all eigenvectors $\boldsymbol{v}_\beta$, $\beta = 1, \ldots, \ell$, of the above matrix, the vectors $\boldsymbol{A}$ have all components $>0$.

Even though this system is isochronous, it nevertheless admits a system of canonical action–angle coordinates in which the Hamiltonian takes the simplest form

$$h(\boldsymbol{A}) = \sum_{\beta=1}^{\ell} \omega_\beta A_\beta \equiv \boldsymbol{\omega} \cdot \boldsymbol{A} \qquad [33]$$

with

$$\alpha_\beta = -\arctan\left(\frac{\sum_{i=1}^{\ell} \frac{v_{\beta,i} p_i}{\sqrt{m_i}}}{\sum_{i=1}^{\ell} \sqrt{m_i}\omega_\beta v_{\beta,i} q_i}\right)$$

as conjugate angles.

An example of anisochronous system is the *free rotators* or *free wheels*: i.e., $\ell$ noninteracting points on a circle of radius $R$ or $\ell$ noninteracting homogeneous coaxial wheels of radius $R$. If $J_i = m_i R^2$ or, respectively, $J_i = (1/2) m_i R^2$ are the inertia moments and if the positions are determined by $\ell$ angles $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_\ell)$, the angular velocities are constants related to the angular momenta $\boldsymbol{A} = (A_1, \ldots, A_\ell)$ by $\omega_i = A_i / J_i$. The Hamiltonian and the spectrum are

$$h(\boldsymbol{A}) = \sum_{i=1}^{\ell} \frac{1}{2J_i} A_i^2, \qquad \boldsymbol{\omega}(\boldsymbol{A}) = \left(\frac{1}{J_i} A_i\right)_{i=1,\ldots,\ell} \qquad [34]$$

For further details see Landau and Lifshitz (1976), Gallavotti (1983), Arnol'd (1989), and Fassò (1998).

## Multidimensional Quadratures: Central Motion

Several important mechanical systems with more than one degree of freedom are integrable by canonical quadratures in vast regions of phase space. This is checked by showing that there is a foliation into invariant tori $\mathcal{T}(\boldsymbol{I})$ of dimension equal to the number of degrees of freedom ($\ell$) parametrized by $\ell$ constants of motion $\boldsymbol{I}$ in involution, i.e., such that $\{I_i, I_j\} = 0$. One then performs, if possible, the construction of the action–angle variables by the quadratures discussed in the previous section.

The above procedure is well illustrated by the theory of the planar motion of a unit mass attracted by a coplanar center of force: the Lagrangian is, in polar coordinates $(\rho, \theta)$,

$$\mathcal{L} = \frac{m}{2}(\dot\rho^2 + \rho^2 \dot\theta^2) - V(\rho)$$

The planarity of the motion is not a strong restriction as central motion always takes place on a plane.

Hence, the equations of motion are

$$\frac{\mathrm{d}}{\mathrm{d}t} m\rho^2\dot\theta = 0$$

i.e., $m\rho^2\dot\theta = G$ is a constant of motion (it is the angular momentum), and

$$\begin{aligned} \ddot\rho &= -\partial_\rho V(\rho) + \partial_\rho \frac{m}{2}\rho^2\dot\theta^2 \\ &= -\partial_\rho V(\rho) + \frac{G^2}{m\rho^3} \\ &\stackrel{\text{def}}{=} -\partial_\rho V_G(\rho) \end{aligned}$$

Then the energy conservation yields a second constant of motion $E$,

$$\begin{aligned} \frac{m}{2}\dot\rho^2 + \frac{1}{2}\frac{G^2}{m\rho^2} + V(\rho) &= E \\ = \frac{1}{2m}p_\rho^2 + \frac{1}{2m}\frac{p_\theta^2}{\rho^2} + V(\rho) & \end{aligned} \qquad [35]$$

The right-hand side (rhs) is the Hamiltonian for the system, derived from $\mathcal{L}$, if $p_\rho$, $p_\theta$ denote conjugate momenta of $\rho$, $\theta$: $p_\rho = m\dot\rho$ and $p_\theta = m\rho^2\dot\theta$ (note that $p_\theta = G$).

Suppose $\rho^2 V(\rho) \xrightarrow[\rho\to 0]{} 0$: then the singularity at the origin cannot be reached by any motion starting with $\rho > 0$ if $G > 0$. Assume also that the function

$$V_G(\rho) \stackrel{\text{def}}{=} \frac{1}{2}\frac{G^2}{m\rho^2} + V(\rho)$$

has only one minimum $E_0(G)$, no maximum and no horizontal inflection, and tends to a limit $E_\infty(G) \le \infty$ when $\rho \to \infty$. Then the system is integrable in the domain $W = \{(\boldsymbol{p}, \boldsymbol{q}) \mid E_0(G) < E < E_\infty(G), G \neq 0\}$.

This is checked by introducing a "standard" periodic solution $t \to R(t)$ of $m\ddot\rho = -\partial_\rho V_G(\rho)$ with energy $E_0(G) < E < E_\infty(G)$ and initial data $\rho = \rho_{E,-}(G)$, $\dot\rho = 0$ at time $t = 0$, where $\rho_{E,\pm}(G)$ are the two solutions of $V_G(\rho) = E$, see the section "Quadratures": this is a periodic analytic function of $t$ with period

$$T(E,G) = 2\int_{\rho_{E,-}(G)}^{\rho_{E,+}(G)} \frac{\mathrm{d}x}{\sqrt{(2/m)(E - V_G(x))}}$$

The function $R(t)$ is given, for $0 \le t \le \frac{1}{2}T(E,G)$ or for $\frac{1}{2}T(E,G) \le t \le T(E,G)$, by the quadratures

$$t = \int_{\rho_{E,-}(G)}^{R(t)} \frac{\mathrm{d}x}{\sqrt{(2/m)(E - V_G(x))}} \qquad [36a]$$

or

$$t = \frac{T(E,G)}{2} - \int_{\rho_{E,+}(G)}^{R(t)} \frac{\mathrm{d}x}{\sqrt{(2/m)(E - V_G(x))}} \qquad [36b]$$

respectively. The analytic regularity of $R(t)$ follows from the general existence, uniqueness, and regularity theorems applied to the differential equation for $\ddot{\rho}$.

Given an initial datum $\dot{\rho}_0, \rho_0, \dot{\theta}_0, \theta_0$ with energy $E$ and angular momentum $G$, define $t_0$ to be the time such that $R(t_0) = \rho_0, \dot{R}(t_0) = \dot{\rho}_0$: then $\rho(t) \equiv R(t + t_0)$ and $\theta(t)$ can be computed as

$$\theta(t) = \theta_0 + \int_0^t \frac{G}{mR(t' + t_0)^2} \mathrm{d}t'$$

a second quadrature. Therefore, we can use as coordinates for the motion $E, G, t_0$, which determine $\dot{\rho}_0, \rho_0, \dot{\theta}_0$ and a fourth coordinate that determines $\theta_0$ which could be $\theta_0$ itself but which is conveniently determined, via the second quadrature, as follows.

The function $Gm^{-1}R(t)^{-2}$ is periodic with period $T(E, G)$; hence it can be expressed in a Fourier series

$$\chi_0(E, G) + \sum_{k \neq 0} \chi_k(E, G) \exp\left(\frac{2\pi}{T(E, G)} \mathrm{i}tk\right)$$

the quadrature for $\theta(t)$ can be performed by integrating the series terms. Setting

$$\bar{\theta}(t_0) \stackrel{\text{def}}{=} \frac{T(E, G)}{2\pi} \sum_{k \neq 0} \frac{\chi_k(E, G)}{k} \exp\left(\frac{2\pi}{T(E, G)} \mathrm{i}t_0 k\right)$$

and $\varphi_1(0) = \theta_0 - \bar{\theta}(t_0)$, the expression

$$\theta(t) = \theta_0 + \int_0^t \frac{G}{mR(t' + t_0)^2} \mathrm{d}t'$$

becomes

$$\varphi_1(t) = \varphi_1(0) + \chi_0(E, G)\, t \qquad [37]$$

Hence the system is integrable and the spectrum is $\boldsymbol{\omega}(E, G) = (\omega_0(E, G), \omega_1(E, G)) \equiv (\omega_0, \omega_1)$ with

$$\omega_0 \stackrel{\text{def}}{=} \frac{2\pi}{T(E, G)} \quad \text{and} \quad \omega_1 \stackrel{\text{def}}{=} \chi_0(E, G)$$

while $\boldsymbol{I} = (E, G)$ are constants of motion and the angles $\boldsymbol{\varphi} = (\varphi_0, \varphi_1)$ can be taken as

$$\varphi_0 \stackrel{\text{def}}{=} \omega_0 t_0, \qquad \varphi_1 \stackrel{\text{def}}{=} \theta_0 - \bar{\theta}(t_0)$$

At $E$, $G$ fixed, the motion takes place on a two-dimensional torus $\mathcal{T}(E, G)$ with $\varphi_0, \varphi_1$ as angles.

In the anisochronous cases, i.e., when $\det \partial_{E,G} \boldsymbol{\omega}(E, G) \neq 0$, canonical action–angle variables conjugated to $(p_\rho, \rho, p_\theta, \theta)$ can be constructed via [29], [30] by using two cycles $\gamma_1, \gamma_2$ on the torus $\mathcal{T}(E, G)$. It is convenient to choose

1. $\gamma_1$ as the cycle consisting of the points $\rho = x, \theta = 0$ whose first half (where $p_\rho \geq 0$) consists in the set $\rho_{E,-}(G) \leq x \leq \rho_{E,+}(G), p_\rho = \sqrt{2m(E - V_G(x))}$ and $\mathrm{d}\theta = 0$; and
2. $\gamma_2$ as the cycle $\rho = \text{const}, \theta \in [0, 2\pi]$ on which $\mathrm{d}\rho = 0$ and $p_\theta = G$ obtaining

$$A_1 = \frac{2}{2\pi} \int_{\rho_{E,-}(G)}^{\rho_{E,+}(G)} \sqrt{2m(E - V_G(x))} \mathrm{d}x, \qquad A_2 = G \qquad [38]$$

According to the general theory (cf. the previous section) a generating function for the canonical change of coordinates from $(p_\rho, \rho, p_\theta, \theta)$ to action–angle variables is (if, to fix ideas, $p_\rho > 0$)

$$S(A_1, A_2, \rho, \theta) = G\theta + \int_{\rho_{E,-}}^{\rho} \sqrt{2m(E - V_G(x))} \mathrm{d}x \qquad [39]$$

In terms of the above $\omega_0, \chi_0$ the Jacobian matrix $\partial(E, G)/\partial(A_1, A_2)$ is computed from [38], [39] to be $\begin{pmatrix} \omega_0 & \chi_0 \\ 0 & 1 \end{pmatrix}$. It follows that $\partial_E S = t, \partial_G S = \theta - \bar{\theta}(t) - \chi_0{}^t$ so that, see [31],

$$\alpha_1 \stackrel{\text{def}}{=} \partial_{A_1} S = \omega_0 t, \qquad \alpha_2 \stackrel{\text{def}}{=} \partial_{A_2} S = \theta - \bar{\theta}(t) \qquad [40]$$

and $(A_1, \alpha_1), (A_2, \alpha_2)$ are the action–angle pairs.

For more details, see Landau and Lifshitz (1976) and Gallavotti (1983).

## Newtonian Potential and Kepler's Laws

The anisochrony property, that is, $\det \partial(\omega_0, \chi_0)/\partial(A_1, A_2) \neq 0$ or, equivalently, $\det \partial(\omega_0, \chi_0)/\partial(E, G) \neq 0$, is not satisfied in the important cases of the harmonic potential and the Newtonian potential. Anisochrony being only a sufficient condition for canonical integrability it is still possible (and true) that, nevertheless, in both cases the canonical transformation generated by [39] integrates the system. This is expected since the two potentials are limiting cases of anisochronous ones (e.g., $|\boldsymbol{q}|^{2+\varepsilon}$ and $|\boldsymbol{q}|^{-1-\varepsilon}$ with $\varepsilon \to 0$).

The Newtonian potential

$$\mathcal{H}(\boldsymbol{p}, \boldsymbol{q}) = \frac{1}{2m} \boldsymbol{p}^2 - \frac{km}{|\boldsymbol{q}|}$$

is integrable in the region $G \neq 0, E_0(G) = -k^2 m^3 / 2G^2 < E < 0, |G| < \sqrt{k^2 m^3 / (-2E)}$. Proceeding as in the last section, one finds integrating coordinates and that the integrable motions develop on ellipses with one focus on the center of attraction $S$ so that motions are periodic, hence not anisochronous: nevertheless, the construction of the canonical coordinates via [29]–[31] (hence [39]) works and leads to canonical coordinates $(L', \lambda', G', \gamma')$. To obtain action–angle variables with a simple

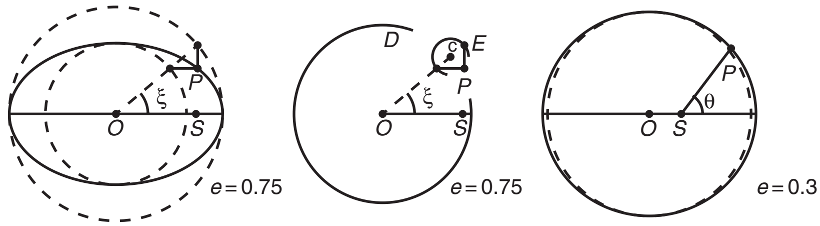

**Figure 2** Eccentric and true anomalies of $P$, which moves on a small circle $E$ centered at a point $c$ moving on the circle $D$ located half-way between the two concentric circles containing the Keplerian ellipse: the anomaly of $c$ with respect to the axis $OS$ is $\xi$. The circle $D$ is *eccentric* with respect to $S$ and therefore $\xi$ is, even today, called eccentric anomaly, whereas the circle $D$ is, in ancient terminology, the *deferent* circle (eccentric circles were introduced in astronomy by Ptolemy). The small circle $E$ on which the point $P$ moves is, in ancient terminology, an *epicycle*. The deferent and the epicyclical motions are synchronous (i.e., they have the same period); Kepler discovered that his key *a priori* hypothesis of inverse proportionality between angular velocity on the deferent and distance between $P$ and $S$ (i.e., $\rho\dot{\xi} = \text{constant}$) implied both synchrony and elliptical shape of the orbit, with focus in $S$. The latter law is equivalent to $\rho^2\dot{\theta} = \text{constant}$ (because of the identity $a\dot{\xi} = \rho\dot{\theta}$). Small eccentricity ellipses can hardly be distinguished from circles.

interpretation, it is convenient to perform on the variables $(L', \lambda', G', \gamma')$ (constructed by following the procedure just indicated) a further trivial canonical transformation by setting $L = L' + G'$, $G = G'$, $\lambda = \lambda'$, $\gamma = \gamma' - \lambda'$; then

1. $\lambda$ (average anomaly) is the time necessary for the point $P$ to move from the pericenter to its actual position, in units of the period, times $2\pi$;
2. $L$ (action) is essentially the energy $E = -k^2m^3/2L^2$;
3. $G$ (angular momentum);
4. $\gamma$ (axis longitude), is the angle between a fixed axis and the major axis of the ellipse oriented from the center of the ellipse $O$ to the center of attraction $S$.

The eccentricity of the ellipse is $e$ such that $G = \pm L\sqrt{1-e^2}$. The ellipse equation is $\rho = a(1 - e\cos\xi)$, where $\xi$ is the eccentric anomaly (see Figure 2), $a = L^2/km^2$ is the major semiaxis, and $\rho$ is the distance to the center of attraction S.

Finally, the relations between eccentric anomaly $\xi$, average anomaly $\lambda$, true anomaly $\theta$ (the latter is the polar angle), and SP distance $\rho$ are given by the Kepler equations

$$\begin{aligned} &\lambda = \xi - e\sin\xi \\ &(1 - e\cos\xi)(1 + e\cos\theta) = 1 - e^2 \\ &\lambda = (1-e^2)^{3/2}\int_0^\theta \frac{\mathrm{d}\theta'}{(1 + e\cos\theta')^2} \\ &\frac{\rho}{a} = \frac{1-e^2}{1+e\cos\theta} \end{aligned} \qquad [41]$$

and the relation between true anomaly and average anomaly can be inverted in the form

$$\begin{aligned} \xi &= \lambda + g_\lambda \\ \theta &= \lambda + f_\lambda \;\Rightarrow\; \frac{\rho}{a} = \frac{1-e^2}{1 + e\cos(\lambda + f_\lambda)} \end{aligned} \qquad [42]$$

where $g_\lambda = g(e\sin\lambda, e\cos\lambda)$, $f_\lambda = f(e\sin\lambda, e\cos\lambda)$, and $g(x,y), f(x,y)$ are suitable functions analytic for $|x|, |y| < 1$. Furthermore, $g(x,y) = x(1 + y + \cdots)$, $f(x,y) = 2x(1 + \frac{5}{4}y + \cdots)$ and the ellipses denote terms of degree 2 or higher in $x, y$, containing only even powers of $x$.

For more details, the reader is referred to Landau and Lifshitz (1976) and Gallavotti (1983).

## Rigid Body

Another fundamental integrable system is the rigid body in the absence of gravity and with a fixed point O. It can be naturally described in terms of the Euler angles $\theta_0, \varphi_0, \psi_0$ (see Figure 3) and their derivatives $\dot{\theta}_0$, $\dot{\varphi}_0$, $\dot{\psi}_0$.

Let $I_1, I_2, I_3$ be the three *principal inertia moments* of the body along the three principal axes with unit vectors $\boldsymbol{i}_1, \boldsymbol{i}_2, \boldsymbol{i}_3$. The inertia moments and the principal axes are the eigenvalues and the associated unit eigenvectors of the $3\times 3$ inertia matrix $\mathcal{I}$, which is defined by $\mathcal{I}_{hk} = \sum_{i=1}^n m_i(\boldsymbol{x}_i)_h(\boldsymbol{x}_i)_k$, where $h, k = 1, 2, 3$ and $\boldsymbol{x}_i$ is the position of the $i$th particle in a reference frame with origin at O and in which

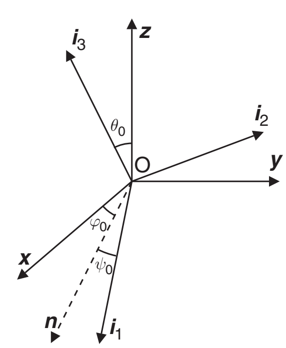

**Figure 3** The *Euler angles* of the comoving frame $\boldsymbol{i}_1, \boldsymbol{i}_2, \boldsymbol{i}_3$ with respect to a fixed frame $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}$. The direction $\boldsymbol{n}$ is the "node line, intersection between the planes $\boldsymbol{x}, \boldsymbol{y}$ and $\boldsymbol{i}_1, \boldsymbol{i}_2$.

all particles are at rest: this *comoving frame* exists as a consequence of the rigidity constraint. The principal axes form a coordinate system which is comoving as well: that is, in the frame $(O; \boldsymbol{i}_1, \boldsymbol{i}_2, \boldsymbol{i}_3)$ as well, the particles are at rest.

The Lagrangian is simply the kinetic energy: we imagine the rigidity constraint to be ideal (e.g., as realized by internal central forces in the limit of infinite rigidity, as mentioned in the section "Lagrange and Hamilton forms of equations of motion"). The *angular velocity* of the rigid motion is defined by

$$\boldsymbol{\omega} = \dot{\theta}_0 \boldsymbol{n} + \dot{\varphi}_0 \boldsymbol{z} + \dot{\psi}_0 \boldsymbol{i}_3 \qquad [43]$$

expressing that a generic infinitesimal motion must consist of a variation of the three Euler angles and, therefore, it has to be a rotation of speeds $\dot{\theta}_0, \dot{\varphi}_0, \dot{\psi}_0$ around the axes $\boldsymbol{n}, \boldsymbol{z}, \boldsymbol{i}_3$ as shown in Figure 3.

Let $(\omega_1, \omega_2, \omega_3)$ be the components of $\boldsymbol{\omega}$ along the principal axes $\boldsymbol{i}_1, \boldsymbol{i}_2, \boldsymbol{i}_3$: for brevity, the latter axes will often be called $\mathbf{1}, \mathbf{2}, \mathbf{3}$. Then the angular momentum $\boldsymbol{M}$, with respect to the pivot point $O$, and the kinetic energy $K$ can be checked to be

$$\begin{aligned} \boldsymbol{M} &= I_1\omega_1 \boldsymbol{i}_1 + I_2\omega_2 \boldsymbol{i}_2 + I_3\omega_3 \boldsymbol{i}_3 \\ K &= \frac{1}{2}(I_1\omega_1^2 + I_2\omega_2^2 + I_2\omega_3^2) \end{aligned} \qquad [44]$$

and are constants of motion. From Figure 3 it follows that $\omega_1 = \dot{\theta}_0 \cos\psi_0 + \dot{\varphi}_0 \sin\theta_0 \sin\psi_0$, $\omega_2 = -\dot{\theta}_0 \sin\psi_0 + \dot{\varphi}_0 \sin\theta_0 \cos\psi_0$ and $\omega_3 = \dot{\varphi}_0 \cos\theta_0 + \dot{\psi}_0$, so that the Lagrangian, uninspiring at first, is

$$\begin{aligned} \mathcal{L} \stackrel{\text{def}}{=} & \frac{1}{2} I_1 (\dot{\theta}_0 \cos\psi_0 + \dot{\varphi}_0 \sin\theta_0 \sin\psi_0)^2 \\ & + \frac{1}{2} I_2 (-\dot{\theta}_0 \sin\psi_0 + \dot{\varphi}_0 \sin\theta_0 \cos\psi_0)^2 \\ & + \frac{1}{2} I_3 (\dot{\varphi}_0 \cos\theta_0 + \dot{\psi}_0)^2 \end{aligned} \qquad [45]$$

Angular momentum conservation does not imply that the components $\omega_j$ are constants because $\boldsymbol{i}_1, \boldsymbol{i}_2, \boldsymbol{i}_3$ also change with time according to

$$\frac{\mathrm{d}}{\mathrm{d}t} \boldsymbol{i}_j = \boldsymbol{\omega} \wedge \boldsymbol{i}_j, \quad j = 1, 2, 3$$

Hence, $\dot{\boldsymbol{M}} = \mathbf{0}$ becomes, by the first of [44] and denoting $I\boldsymbol{\omega} = (I_1\omega_1, I_2\omega_2, I_3\omega_3)$, the *Euler equations* $I\dot{\boldsymbol{\omega}} + \boldsymbol{\omega} \wedge I\boldsymbol{\omega} = \mathbf{0}$, or

$$\begin{aligned} I_1\dot{\omega}_1 &= (I_2 - I_3)\omega_2\omega_3 \\ I_2\dot{\omega}_2 &= (I_3 - I_1)\omega_3\omega_1 \\ I_3\dot{\omega}_3 &= (I_1 - I_2)\omega_1\omega_2 \end{aligned} \qquad [46]$$

which can be considered together with the conserved quantities [44].

Since angular momentum is conserved, it is convenient to introduce the *laboratory frame* $(O; \boldsymbol{x}_0, \boldsymbol{y}_0, \boldsymbol{z}_0)$ with fixed axes $\boldsymbol{x}_0, \boldsymbol{y}_0, \boldsymbol{z}_0$ and (see Figure 4):

1. $(O; \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$, the *momentum frame* with fixed axes, but with $\boldsymbol{z}$-axis oriented as $\boldsymbol{M}$, and $\boldsymbol{x}$-axis coinciding with the node (i.e., the intersection) of the $\boldsymbol{x}_0$–$\boldsymbol{y}_0$ plane and the $\boldsymbol{x}$–$\boldsymbol{y}$ plane (orthogonal to $\boldsymbol{M}$). Therefore, $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}$ is determined by the two Euler angles $\zeta, \gamma$ of $(O; \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ in $(O; \boldsymbol{x}_0, \boldsymbol{y}_0, \boldsymbol{z}_0)$;
2. $(O; \mathbf{1}, \mathbf{2}, \mathbf{3})$, the comoving frame, that is, the frame fixed with the body, and with unit vectors $\boldsymbol{i}_1, \boldsymbol{i}_2, \boldsymbol{i}_3$ parallel to the principal axes of the body. The frame is determined by three Euler angles $\theta_0, \varphi_0, \psi_0$;
3. the Euler angles of $(O; \mathbf{1}, \mathbf{2}, \mathbf{3})$ with respect to $(O; \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$, which are denoted $\theta, \varphi, \psi$;
4. $G$, the total angular momentum: $G^2 = \sum_j I_j^2 \omega_j^2$;
5. $M_3$, the angular momentum along the $z_0$ axis; $M_3 = G\cos\zeta$; and
6. $L$, the projection of $\boldsymbol{M}$ on the axis $\mathbf{3}$, $L = G\cos\theta$.

The quantities $G, M_3, L, \varphi, \gamma, \psi$ determine $\theta_0, \varphi_0, \psi_0$ and $\dot{\theta}_0, \dot{\varphi}_0, \dot{\psi}_0$, or the $p_{\theta_0}, p_{\varphi_0}, p_{\psi_0}$ variables conjugated to $\theta_0, \varphi_0, \psi_0$ as shown by the following comment.

Considering Figure 4, the angles $\zeta, \gamma$ determine location, in the fixed frame $(O; \boldsymbol{x}_0, \boldsymbol{y}_0, \boldsymbol{z}_0)$ of the direction of $\boldsymbol{M}$ and the node line $\boldsymbol{m}$, which are, respectively, the $\boldsymbol{z}$-axis and the $\boldsymbol{x}$-axis of the fixed frame associated with the angular momentum; the angles $\theta, \varphi, \psi$ then determine the position of the comoving frame with respect to the fixed frame $(O; \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$, hence its position with respect to $(O; \boldsymbol{x}_0, \boldsymbol{y}_0, \boldsymbol{z}_0)$, that is, $(\theta_0, \varphi_0, \psi_0)$. From this and $G$, it is possible to determine $\boldsymbol{\omega}$ because

$$\begin{aligned} \cos\theta = \frac{I_3\omega_3}{G}, \qquad \tan\psi = \frac{I_2\omega_2}{I_1\omega_1} \\ \omega_2^2 = I_2^{-2}(G^2 - I_1^2\omega_1^2 - I_3^2\omega_3^2) \end{aligned} \qquad [47]$$

and, from [43], $\dot{\theta}_0, \dot{\varphi}_0, \dot{\psi}_0$ are determined.

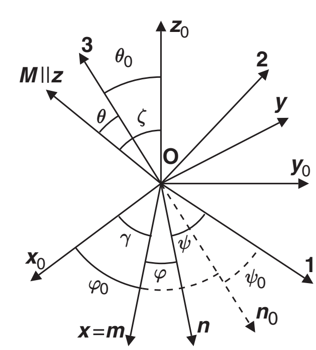

**Figure 4** The laboratory frame, the angular momentum frame, and the comoving frame (and the Deprit angles).

The Lagrangian [45] gives immediately (after expressing $\boldsymbol{\omega}$, i.e., $\boldsymbol{n}, \boldsymbol{z}, \boldsymbol{i}_3$, in terms of the Euler angles $\theta_0, \varphi_0, \psi_0$) an expression for the variables $p_{\theta_0}, p_{\varphi_0}, p_{\psi_0}$ conjugated to $\theta_0, \varphi_0, \psi_0$:

$$p_{\theta_0} = \boldsymbol{M}\cdot\boldsymbol{n}_0, \quad p_{\varphi_0} = \boldsymbol{M}\cdot\boldsymbol{z}_0, \quad p_{\psi_0} = \boldsymbol{M}\cdot\boldsymbol{i}_3 \qquad [48]$$

and, in principle, we could proceed to compute the Hamiltonian.

However, the computation can be avoided because of the very remarkable property (Deprit), which can be checked with some patience, making use of [48] and of elementary spherical trigonometry identities,

$$\begin{aligned} &M_3\,\mathrm{d}\gamma + G\,\mathrm{d}\varphi + L\,\mathrm{d}\psi \\ &\quad = p_{\varphi_0}\,\mathrm{d}\varphi_0 + p_{\psi_0}\,\mathrm{d}\psi_0 + p_{\theta_0}\,\mathrm{d}\theta_0 \end{aligned} \qquad [49]$$

which means that the map $((M_3,\gamma),(L,\psi),(G,\varphi)) \longleftrightarrow ((p_{\theta_0},\theta_0),(p_{\varphi_0},\varphi_0),(p_{\psi_0},\psi_0))$ is a canonical map. And in the new coordinates, the kinetic energy, hence the Hamiltonian, takes the form

$$K = \frac{1}{2}\left[\frac{L^2}{I_3} + (G^2 - L^2)\left(\frac{\sin^2\psi}{I_1} + \frac{\cos^2\psi}{I_2}\right)\right] \qquad [50]$$

This again shows that $G, M_3$ are constants of motion, and the $L, \psi$ variables are determined by a quadrature, because the Hamilton equation for $\psi$ combined with the energy conservation yields

$$\dot\psi = \pm\left(\frac{1}{I_3} - \frac{\sin^2\psi}{I_1} - \frac{\cos^2\psi}{I_2}\right) \times \sqrt{\frac{2E - G^2\left(\frac{\sin^2\psi}{I_1} + \frac{\cos^2\psi}{I_2}\right)}{\frac{1}{I_3} - \frac{\sin^2\psi}{I_1} - \frac{\cos^2\psi}{I_2}}} \qquad [51]$$

In the integrability region, this motion is periodic with some period $T_L(E,G)$. Once $\psi(t)$ is determined, the Hamilton equation for $\varphi$ leads to the further quadrature

$$\dot\varphi = \left(\frac{\sin^2\psi(t)}{I_1} + \frac{\cos^2\psi(t)}{I_2}\right)G \qquad [52]$$

which determines a second periodic motion with period $T_G(E,G)$. The $\gamma, M_3$ are constants and, therefore, the motion takes place on three-dimensional invariant tori $\mathcal{T}_{E,G,M_3}$ in phase space, each of which is "always" foliated into two-dimensional invariant tori parametrized by the angle $\gamma$ which is constant (by [50], because $K$ is $M_3$-independent): the latter are in turn foliated by one-dimensional invariant tori, that is, by periodic orbits, with $E, G$ such that the value of $T_L(E,G)/T_G(E,G)$ is rational.

Note that if $I_1 = I_2 = I$, the above analysis is extremely simplified. Furthermore, if gravity $g$ acts on the system the Hamiltonian will simply change by the addition of a potential $-mgz$ if $z$ is the height of the center of mass. Then (see **Figure 4**), if the center of mass of the body is on the axis $\boldsymbol{i}_3$ and $z = h\cos\theta_0$, and $h$ is the distance of the center of mass from $O$, since $\cos\theta_0 = \cos\theta\cos\zeta - \sin\theta\sin\zeta\cos\varphi$, the Hamiltonian will become $\mathcal{H} = K - mgh\cos\theta_0$ or

$$\mathcal{H} = \frac{G^2}{2I_3} + \frac{G^2 - L^2}{2I} - mgh\left(\frac{M_3 L}{G^2} - \left(1 - \frac{M_3^2}{G^2}\right)^{1/2} \times \left(1 - \frac{L^2}{G^2}\right)^{1/2}\cos\varphi\right) \qquad [53]$$

so that, again, the system is integrable by quadratures (with the roles of $\psi$ and $\varphi$ "interchanged" with respect to the previous case) in suitable regions of phase space. This is called the *Lagrange's gyroscope*.

A less elementary integrable case is when the inertia moments are related as $I_1 = I_2 = 2I_3$ and the center of mass is in the $\boldsymbol{i}_1$–$\boldsymbol{i}_2$ plane (rather than on the $\boldsymbol{i}_3$-axis) and only gravity acts, besides the constraint force on the pivot point $O$; this is called *Kowalevskaia's gyroscope*.

For more details, see Gallavotti (1983).

## Other Quadratures

An interesting classical integrable motion is that of a point mass attracted by two equal-mass centers of gravitational attraction, or a point ideally constrained to move on the surface of a general ellipsoid.

New integrable systems have been discovered quite recently and have generated a wealth of new developments ranging from group theory (as integrable systems are closely related to symmetries) to partial differential equations.

It is convenient to extend the notion of integrability by stating that a system is integrable in a region $W$ of phase space if

1. there is a change of coordinates $(\boldsymbol{p},\boldsymbol{q}) \in W \longleftrightarrow \{\boldsymbol{A},\boldsymbol{\alpha},\boldsymbol{Y},\boldsymbol{y}\} \in (U \times \mathbb{T}^\ell) \times (V \times \mathbb{R}^m)$ where $U \subset \mathbb{R}^\ell$, $V \subset \mathbb{R}^m$, with $\ell + m \geq 1$, are open sets; and
2. the $\boldsymbol{A}, \boldsymbol{Y}$ are constants of motion while the other coordinates vary "linearly":

$$(\boldsymbol{\alpha},\boldsymbol{y}) \rightarrow (\boldsymbol{\alpha} + \boldsymbol{\omega}(\boldsymbol{A},\boldsymbol{Y})t,\ \boldsymbol{y} + \boldsymbol{v}(\boldsymbol{A},\boldsymbol{Y})t) \qquad [54]$$

where $\boldsymbol{\omega}(\boldsymbol{A},\boldsymbol{Y}), \boldsymbol{v}(\boldsymbol{A},\boldsymbol{Y})$ are smooth functions.

In the new sense, the systems studied in the previous sections are integrable in much wider regions (essentially on the entire phase space with the exception of a set of data which lie on lower-dimensional surfaces

forming sets of zero volume). The notion is convenient also because it allows us to say that even the systems of free particles are integrable.

Two very remarkable systems integrable in the new sense are the Hamiltonian systems, respectively called *Toda lattice* (KRUSKAL, ZABUSKY), and *Calogero lattice* (CALOGERO, MOSER); if $(p_i, q_i) \in \mathbb{R}^2$, they are

$$\begin{aligned} \mathcal{H}_T(\boldsymbol{p},\boldsymbol{q}) &= \frac{1}{2m}\sum_{i=1}^{n} p_i^2 + \sum_{i=1}^{n-1} g\,\mathrm{e}^{-\kappa(q_{i+1}-q_i)} \\ \mathcal{H}_C(\boldsymbol{p},\boldsymbol{q}) &= \frac{1}{2m}\sum_{i=1}^{n} p_i^2 + \sum_{i<j}^{n} \frac{g}{(q_i-q_j)^2} \\ &\quad + \frac{1}{2}\sum_{i=1}^{n} m\omega^2 q_i^2 \end{aligned} \qquad [55]$$

where $m > 0$ and $\kappa, \omega, g \geq 0$. They describe the motion of $n$ interacting particles on a line.

The integration method for the above systems is again to find first the constants of motion and later to look for quadratures, when appropriate. The constants of motion can be found with the method of the *Lax pairs*. One shows that there is a pair of self-adjoint $n \times n$ matrices $M(\boldsymbol{p},\boldsymbol{q}), N(\boldsymbol{p},\boldsymbol{q})$ such that the equations of motion become

$$\frac{\mathrm{d}}{\mathrm{d}t} M(\boldsymbol{p},\boldsymbol{q}) = \mathrm{i}[M(\boldsymbol{p},\boldsymbol{q}), N(\boldsymbol{p},\boldsymbol{q})], \quad \mathrm{i} = \sqrt{-1} \qquad [56]$$

which imply that $M(t) = U(t)M(0)U(t)^{-1}$, with $U(t)$ a unitary matrix. When the equations can be written in the above form, it is clear that the $n$ eigenvalues of the matrix $M(0) = M(\boldsymbol{p}_0, \boldsymbol{q}_0)$ are constants of motion. When appropriate (e.g., in the Calogero lattice case with $\omega > 0$), it is possible to proceed to find canonical action–angle coordinates: a task that is quite difficult due to the arbitrariness of $n$, but which is possible.

The Lax pairs for the Calogero lattice (with $\omega = 0$, $g = m = 1$) are

$$\begin{aligned} M_{hh} &= p_h, \qquad N_{hh} = 0 \\ M_{hk} &= \frac{\mathrm{i}}{(q_h - q_k)}, \qquad N_{hk} = \frac{1}{(q_h - q_k)^2}\, h \neq k \end{aligned} \qquad [57]$$

while for the Toda lattice (with $m = g = \frac{1}{2}\kappa = 1$) the nonzero matrix elements of $M$, $N$ are

$$\begin{aligned} M_{hh} &= p_h, \qquad M_{h,h+1} = M_{h+1,h} = \mathrm{e}^{-(q_h - q_{h+1})} \\ N_{h,h+1} &= -N_{h+1,h} = \mathrm{i}\,\mathrm{e}^{-(q_h - q_{h+1})} \end{aligned} \qquad [58]$$

which are checked by first trying the case $n = 2$.

Another integrable system (SUTHERLAND) is

$$\mathcal{H}_S(\boldsymbol{p},\boldsymbol{q}) = \frac{1}{2m}\sum_{i=k}^{n} p_k^2 + \sum_{h<k}^{n} \frac{g}{\sinh^2(q_h - q_k)} \qquad [59]$$

whose Lax pair is related to that of the Calogero lattice.

By taking suitable limits as $n \to \infty$ and as the other parameters tend to 0 or $\infty$ at suitable rates, integrability of a few differential equations, among which the *Korteweg–deVries equation* or the nonlinear *Schrödinger equation*, can be derived.

As mentioned in the introductory section, symmetry properties under continuous groups imply existence of constants of motion. Hence, it is natural to think that integrability of a mechanical system reflects enough symmetry to imply the existence of as many constants of motion, independent and in involution, as the number of degrees of freedom, $n$.

This is in fact always true, and in some respects it is a tautological statement in the anisochronous cases. Integrability in a region $W$ implies existence of canonical action–angle coordinates $(\boldsymbol{A}, \boldsymbol{\alpha})$ (see the section "Quasiperiodicity and integrability") and the Hamiltonian depends solely on the $A$'s: therefore, its restriction to $W$ is invariant with respect to the action of the continuous commutative group $\mathcal{T}^n$ of the translations of the angle variables. The actions can be seen as constants of motion whose existence follows from Noether's theorem, at least in the anisochronous cases in which the Hamiltonian formulation is equivalent to a Lagrangian one.

What is nontrivial is to recognize, prior to realizing integrability, that a system admits this kind of symmetry: in most of the interesting cases, the systems either do not exhibit obvious symmetries or they exhibit symmetries apparently unrelated to the group $\mathcal{T}^n$, which nevertheless imply existence of sufficiently many independent constants of motion as required for integrability. Hence, nontrivial integrable systems possess a "hidden" symmetry under $\mathcal{T}^n$: the rigid body is an example.

However, very often the symmetries of a Hamiltonian $H$ which imply integrability also imply partial isochrony, that is, they imply that the number of independent frequencies is smaller than $n$ (see the section "Quasiperiodicity and integrability"). Even in such cases, often a map exists from the original coordinates $(\boldsymbol{p}, \boldsymbol{q})$ to the integrating variables $(\boldsymbol{A}, \boldsymbol{\alpha})$ in which $\boldsymbol{A}$ are constants of motion and the $\boldsymbol{\alpha}$ are uniformly rotating angles (some of which are also constant) with spectrum $\boldsymbol{\omega}(\boldsymbol{A})$, which is the gradient $\partial_{\boldsymbol{A}} h(\boldsymbol{A})$ for some function $h(\boldsymbol{A})$ depending only on a few of the $\boldsymbol{A}$ coordinates. However, the map might fail to be canonical. The system is then said to be bi-Hamiltonian: in the sense that one can represent motions in two systems of canonical coordinates, not related by a canonical transformation, and by two Hamiltonian functions $H$ and $H' \equiv h$ which generate the same motions in the respective

coordinates (the latter changes of variables are sometimes called "canonical with respect to the pair $H, H'$" while the transformations considered in the section "Canonical transformations of phase space coordination" are called completely canonical).

For more details, we refer the reader to Calogero and Degasperis (1982).

## Generic Nonintegrability

It is natural to try to prove that a system "close" to an integrable one has motions with properties very close to quasiperiodic. This is indeed the case, but in a rather subtle way. That there is a problem is easily seen in the case of a perturbation of an anisochronous integrable system.

Assume that a system is integrable in a region $W$ of phase space which, in the integrating action–angle variables $(\boldsymbol{A}, \boldsymbol{\alpha})$, has the standard form $U \times \mathbb{T}^\ell$ with a Hamiltonian $h(\boldsymbol{A})$ with gradient $\boldsymbol{\omega}(\boldsymbol{A}) = \partial_{\boldsymbol{A}} h(\boldsymbol{A})$. If the forces are perturbed by a potential which is smooth then the new system will be described, in the same coordinates, by a Hamiltonian like

$$\mathcal{H}_\varepsilon(\boldsymbol{A}, \boldsymbol{\alpha}) = h(\boldsymbol{A}) + \varepsilon f(\boldsymbol{A}, \boldsymbol{\alpha}) \qquad [60]$$

with $h, f$ analytic in the variables $\boldsymbol{A}, \boldsymbol{\alpha}$.

If the system really behaved like the unperturbed one, it ought to have $\ell$ constants of motion of the form $F_\varepsilon(\boldsymbol{A}, \boldsymbol{\alpha})$ analytic in $\varepsilon$ near $\varepsilon = 0$ and uniform, that is, single valued (which is the same as periodic) in the variables $\boldsymbol{\alpha}$. However, the following theorem (POINCARÉ) shows that this is a somewhat unlikely possibility.

**Theorem 1** *If the matrix* $\partial^2_{\boldsymbol{AA}} h(\boldsymbol{A})$ *has rank* $\geq 2$, *the Hamiltonian* [60] *"generically"* (an intuitive notion precised below) *cannot be integrated by a canonical transformation* $\mathcal{C}_\varepsilon(\boldsymbol{A}, \boldsymbol{\alpha})$ *which*

(i) *reduces to the identity as* $\varepsilon \to 0$; *and*
(ii) *is analytic in* $\varepsilon$ *near* $\varepsilon = 0$ *and in* $(\boldsymbol{A}, \boldsymbol{\alpha}) \in U' \times \mathbb{T}^\ell$, *with* $U' \subset U$ *open.*

*Furthermore, no uniform constants of motion* $F_\varepsilon(\boldsymbol{A}, \boldsymbol{\alpha})$, *defined for* $\varepsilon$ *near 0 and* $(\boldsymbol{A}, \boldsymbol{\alpha})$ *in an open domain* $U' \times \mathbb{T}^\ell$, *exist other than the functions of* $\mathcal{H}_\varepsilon$ *itself.*

Integrability in the sense (i), (ii) can be called analytic integrability and it is the strongest (and most naive) sense that can be given to the attribute.

The first part of the theorem, that is, (i), (ii), holds simply because, if integrability was assumed, a generating function of the integrating map would have the form $\boldsymbol{A}' \cdot \boldsymbol{\alpha} + \Phi_\varepsilon(\boldsymbol{A}', \boldsymbol{\alpha})$ with $\Phi$ admitting a power series expansion in $\varepsilon$ as $\Phi_\varepsilon = \varepsilon \Phi^1 + \varepsilon^2 \Phi^2 + \cdots$. Hence, $\Phi^1$ would have to satisfy

$$\boldsymbol{\omega}(\boldsymbol{A}') \cdot \partial_{\boldsymbol{\alpha}} \Phi^1(\boldsymbol{A}', \boldsymbol{\alpha}) + f(\boldsymbol{A}', \boldsymbol{\alpha}) = \overline{f}(\boldsymbol{A}') \qquad [61]$$

where $\overline{f}(\boldsymbol{A}')$ depends only on $\boldsymbol{A}'$ (hence integrating both sides with respect to $\boldsymbol{\alpha}$, it appears that $\overline{f}(\boldsymbol{A}')$ must coincide with the average of $f(\boldsymbol{A}', \boldsymbol{\alpha})$ over $\boldsymbol{\alpha}$).

This implies that the Fourier transform $f_{\boldsymbol{\nu}}(\boldsymbol{A})$, $\boldsymbol{\nu} \in \mathbb{Z}^\ell$, should satisfy

$$f_{\boldsymbol{\nu}}(\boldsymbol{A}') = 0 \qquad \text{if } \boldsymbol{\omega}(\boldsymbol{A}') \cdot \boldsymbol{\nu} = 0, \quad \boldsymbol{\nu} \neq \boldsymbol{0} \qquad [62]$$

which is equivalent to the existence of $\widetilde{f}_{\boldsymbol{\nu}}(\boldsymbol{A}')$ such that $f_{\boldsymbol{\nu}}(\boldsymbol{A}) = \boldsymbol{\omega}(\boldsymbol{A}') \cdot \boldsymbol{\nu} \widetilde{f}_{\boldsymbol{\nu}}(\boldsymbol{A})$ for $\boldsymbol{\nu} \neq \boldsymbol{0}$. But since there is no relation between $\boldsymbol{\omega}(\boldsymbol{A})$ and $f(\boldsymbol{A}, \boldsymbol{\alpha})$, this property "generically" will not hold in the sense that as close as wished to an $f$ which satisfies the property [62] there will be another $f$ which does not satisfy it essentially no matter how "closeness" is defined, (e.g., with respect to the metric $||f - g|| = \sum_{\boldsymbol{\nu}} |f_{\boldsymbol{\nu}}(\boldsymbol{A}) - g_{\boldsymbol{\nu}}(\boldsymbol{A})||$). This is so because the rank of $\partial^2_{\boldsymbol{AA}} h(\boldsymbol{A})$ is higher than 1 and $\boldsymbol{\omega}(\boldsymbol{A})$ varies at least on a two-dimensional surface, so that $\boldsymbol{\omega} \cdot \boldsymbol{\nu} = 0$ becomes certainly possible for some $\boldsymbol{\nu} \neq \boldsymbol{0}$ while $f_{\boldsymbol{\nu}}(\boldsymbol{A})$ in general will not vanish, so that $\Phi^1$, hence $\Phi_\varepsilon$, does not exist.

This means that close to a function $f$ there is a function $f'$ which violates [62] for some $\boldsymbol{\nu}$. Of course, this depends on what is meant by "close": however, here essentially any topology introduced on the space of the functions $f$ will make the statement correct. For instance, if the distance between two functions is defined by $\sum_{\boldsymbol{\nu}} \sup_{\boldsymbol{A} \in U} |f_{\boldsymbol{\nu}}(\boldsymbol{A}) - g_{\boldsymbol{\nu}}(\boldsymbol{A})|$ or by $\sup_{\boldsymbol{A}, \boldsymbol{\alpha}} |f(\boldsymbol{A}, \boldsymbol{\alpha}) - g(\boldsymbol{A}, \boldsymbol{\alpha})|$.

The idea behind the last statement of the theorem is in essence the same: consider, for simplicity, the anisochronous case in which the matrix $\partial^2_{\boldsymbol{AA}} h(\boldsymbol{A})$ has maximal rank $\ell$, that is, the determinant $\det \partial^2_{\boldsymbol{AA}} h(\boldsymbol{A})$ does not vanish. Anisochrony implies that $\boldsymbol{\omega}(\boldsymbol{A}) \cdot \boldsymbol{\nu} \neq 0$ for all $\boldsymbol{\nu} \neq \boldsymbol{0}$ and $\boldsymbol{A}$ on a dense set, and this property will be used repeatedly in the following analysis.

Let $B(\varepsilon, \boldsymbol{A}, \boldsymbol{\alpha})$ be a "uniform" constant of motion, meaning that it is single valued and analytic in the non-simply-connected region $U \times \mathbb{T}^\ell$ and, for $\varepsilon$ small,

$$B(\varepsilon, \boldsymbol{A}, \boldsymbol{\alpha}) = B_0(\boldsymbol{A}, \boldsymbol{\alpha}) + \varepsilon B_1(\boldsymbol{A}, \boldsymbol{\alpha}) + \varepsilon^2 B_2(\boldsymbol{A}, \boldsymbol{\alpha}) + \cdots \qquad [63]$$

The condition that $B$ is a constant of motion can be written order by order in its expansion in $\varepsilon$: the first two orders are

$$\begin{aligned} &\boldsymbol{\omega}(\boldsymbol{A}) \cdot \partial_{\boldsymbol{\alpha}} B_0(\boldsymbol{A}, \boldsymbol{\alpha}) = 0 \\ &\partial_{\boldsymbol{A}} f(\boldsymbol{A}, \boldsymbol{\alpha}) \cdot \partial_{\boldsymbol{\alpha}} B_0(\boldsymbol{A}, \boldsymbol{\alpha}) - \partial_{\boldsymbol{\alpha}} f(\boldsymbol{A}, \boldsymbol{\alpha}) \cdot \partial_{\boldsymbol{A}} B_0(\boldsymbol{A}, \boldsymbol{\alpha}) \\ &\quad + \boldsymbol{\omega}(\boldsymbol{A}) \cdot \partial_{\boldsymbol{\alpha}} B_1(\boldsymbol{A}, \boldsymbol{\alpha}) = 0 \end{aligned} \qquad [64]$$

Then the above two relations and anisochrony imply (1) that $B_0$ must be a function of $\boldsymbol{A}$ only and (2) that $\boldsymbol{\omega}(\boldsymbol{A})\cdot\boldsymbol{\nu}$ and $\partial_{\boldsymbol{A}}B_0(\boldsymbol{A})\cdot\boldsymbol{\nu}$ vanish simultaneously for all $\boldsymbol{\nu}$. Hence, the gradient of $B_0$ must be proportional to $\boldsymbol{\omega}(\boldsymbol{A})$, that is, to the gradient of $h(\boldsymbol{A}):\boldsymbol{\partial}_{\boldsymbol{A}}B_0(\boldsymbol{A})=\lambda(\boldsymbol{A})\boldsymbol{\partial}_{\boldsymbol{A}}h(\boldsymbol{A})$. Therefore, generically (because of the anisochrony) it must be that $B_0$ depends on $\boldsymbol{A}$ through $h(\boldsymbol{A}):B_0(\boldsymbol{A})=F(h(\boldsymbol{A}))$ for some $F$.

Looking again, with the new information, at the second of [64] it follows that at fixed $\boldsymbol{A}$ the $\boldsymbol{\alpha}$-derivative in the direction $\boldsymbol{\omega}(\boldsymbol{A})$ of $B_1$ equals $F'(h(\boldsymbol{A}))$ times the $\boldsymbol{\alpha}$-derivative of $f$, that is, $B_1(\boldsymbol{A},\boldsymbol{\alpha})=f(\boldsymbol{A},\boldsymbol{\alpha})F'(h(\boldsymbol{A}))+C_1(\boldsymbol{A})$.

Summarizing: the constant of motion $B$ has been written as $B(\boldsymbol{A},\boldsymbol{\alpha})=F(h(\boldsymbol{A}))+\varepsilon F'(h(\boldsymbol{A}))f(\boldsymbol{A},\boldsymbol{\alpha})+\varepsilon C_1(\boldsymbol{A})+\varepsilon^2B_2+\cdots$ which is equivalent to $B(\boldsymbol{A},\boldsymbol{\alpha})=F(\mathcal{H}_\varepsilon)+\varepsilon(B_0'+\varepsilon B_1'+\cdots)$ and therefore $B_0'+\varepsilon B_1'+\cdots$ is another analytic constant of motion. Repeating the argument also $B_0'+\varepsilon B_1'+\cdots$ must have the form $F_1(\mathcal{H}_\varepsilon)+\varepsilon(B_0''+\varepsilon B_1''+\cdots)$; conclusion

$$B=F(\mathcal{H}_\varepsilon)+\varepsilon F_1(\mathcal{H}_\varepsilon)+\varepsilon^2F_2(\mathcal{H}_\varepsilon)+\cdots+\varepsilon^nF_n(\mathcal{H}_\varepsilon)+O(\varepsilon^{n+1}) \qquad [65]$$

By analyticity, $B=F_\varepsilon(\mathcal{H}_\varepsilon(\boldsymbol{A},\boldsymbol{\alpha}))$ for some $F_\varepsilon$: hence generically all constants of motion are trivial.

Therefore, a system close to integrable cannot behave as it would naively be expected. The problem, however, was not manifest until Poincaré's proof of the above results: because in most applications the function $f$ has only finitely many Fourier components, or at least is replaced by an approximation with this property, so that at least [62] and even a few of the higher-order constraints like [64] become possible in open regions of action space. In fact, it may happen that the values of $\boldsymbol{A}$ of interest are restricted so that $\boldsymbol{\omega}(\boldsymbol{A})\cdot\boldsymbol{\nu}=0$ only for "large" values of $\boldsymbol{\nu}$ for which $f_{\boldsymbol{\nu}}=0$. Nevertheless, the property that $f_{\boldsymbol{\nu}}(\boldsymbol{A})=(\boldsymbol{\omega}(\boldsymbol{A})\cdot\boldsymbol{\nu})\widetilde{f}_{\boldsymbol{\nu}}(\boldsymbol{A})$ (or the analogous higher-order conditions, e.g., [64]), which we have seen to be necessary for analytic integrability of the perturbed system, can be checked to fail in important problems, if no approximation is made on $f$. Hence a conceptual problem arises.

For more details see Poincaré (1987).

## Perturbing Functions

To check, in a given problem, the nonexistence of nontrivial constants of motion along the lines indicated in the previous section, it is necessary to express the potential, usually given in Cartesian coordinates as $\varepsilon V(\boldsymbol{x})$, in terms of the action–angle variables of the unperturbed, integrable, system.

In particular, the problem arises when trying to check nonexistence of nontrivial constants of motion when the anisochrony assumption (cf. the previous section) is not satisfied. Usually it becomes satisfied "to second order" (or higher): but to show this, a more detailed information on the structure of the perturbing function expressed in action–angle variables is needed. For instance, this is often necessary even when the perturbation is approximated by a trigonometric polynomial, as it is essentially always the case in celestial mechanics.

Finding explicit expressions for the action–angle variables is in itself a rather nontrivial task which leads to many problems of intrinsic interest even in seemingly simple cases. For instance, in the case of the planar gravitational central motion, the Kepler equation $\lambda=\xi-\varepsilon\sin\xi$ (see the first of [41]) must be solved expressing $\xi$ in terms of $\lambda$ (see the first of [42]). It is obvious that for small $\varepsilon$, the variable $\xi$ can be expressed as an analytic function of $\varepsilon$: nevertheless, the actual construction of this expression leads to several problems. For small $\varepsilon$, an interesting algorithm is the following.

Let $h(\lambda)=\xi-\lambda$, so that the equation to solve (i.e., the first of [41]) is

$$h(\lambda)=\varepsilon\sin(\lambda+h(\lambda))\equiv-\varepsilon\frac{\partial c}{\partial\lambda}(\lambda+h(\lambda)) \qquad [66]$$

where $c(\lambda)=\cos\lambda$; the function $\lambda\to h(\lambda)$ should be periodic in $\lambda$, with period $2\pi$, and analytic in $\varepsilon,\lambda$ for $\varepsilon$ small and $\lambda$ real. If $h(\lambda)=\varepsilon h^{(1)}+\varepsilon^2h^{(2)}+\cdots$, the Fourier transform of $h^{(k)}(\lambda)$ satisfies the recursion relation

$$h_\nu^{(k)}=-\sum_{p=1}^{\infty}\frac{1}{p!}\sum_{\substack{k_1+\cdots+k_p=k-1\\ \nu_0+\nu_1+\cdots+\nu_p=\nu}}(\mathrm{i}\nu_0)c_{\nu_0}(\mathrm{i}\nu_0)^p\times\prod h_{\nu_j}^{(k_j)},\quad k>1 \qquad [67]$$

with $c_\nu$ the Fourier transform of the cosine ($c_{\pm1}=\frac{1}{2}$, $c_\nu=0$ if $\nu\neq\pm1$), and (of course) $h_\nu^{(1)}=-\mathrm{i}\nu c_\nu$. Equation [67] is obtained by expanding the RHS of [66] in powers of $h$ and then taking the Fourier transform of both sides retaining only terms of order $k$ in $\varepsilon$.

Iterating the above relation, imagine drawing all trees $\theta$ with $k$ "branches," or "lines," distinguished by a label taking $k$ values, and $k$ nodes and attach to each node $v$ a harmonic label $\nu_v=\pm1$ as in Figure 5. The trees will be assumed to start with a root line $vr$ linking a point $r$ and the "first node" $v$ (see **Figure 5**)

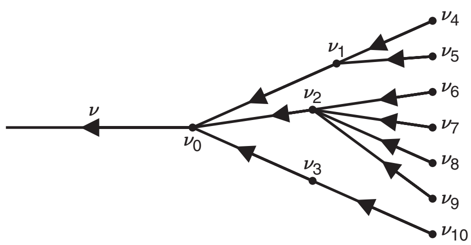

**Figure 5** An example of a tree graph and its labels. It contains only one simple node (3). Harmonics are indicated next to their nodes. Labels distinguishing lines are not marked.

and then bifurcate arbitrarily (such trees are sometimes called "rooted trees").

Imagine the tree oriented from the endpoints towards the root $r$ (not to be considered a node) and given a node $v$ call $v'$ the node immediately following it. If $v$ is the first node before the root $r$, let $v' = r$ and $\nu_{v'} = 1$. For each such decorated tree define its numerical value

$$\mathrm{Val}(\theta) = \frac{-\mathrm{i}}{k!} \prod_{\text{lines } l=v'v} (\nu_{v'}\nu_v) \prod_{\text{nodes}} c_{\nu_v} \qquad [68]$$

and define a current $\nu(l)$ on a line $l = v'v$ to be the sum of the harmonics of the nodes preceding $v'$: $\nu(l) = \sum_{w\le v} \nu_v$. Call $\nu(\theta)$ the current flowing in the root branch and call order of $\theta$ the number of nodes (or branches). Then

$$h_\nu^{(k)} = \sum_{\substack{\theta,\nu(\theta)=\nu \\ \mathrm{order}(\theta)=k}} \mathrm{Val}(\theta) \qquad [69]$$

provided trees are considered identical if they can be overlapped (labels included) after suitably scaling the lengths of their branches and pivoting them around the nodes out of which they emerge (the root is always imagined to be fixed at the origin).

If the trees are stripped of the harmonic labels, their number is finite and it can be estimated to be $\le k!4^k$ (because the labels which distinguish the lines can be attached to an unlabeled tree in many ways). The harmonic labels (i.e., $\nu_v = \pm 1$) can be laid down in $2^k$ ways, and the value of each tree can be bounded by $(1/k!)2^{-k}$ (because $c_{\pm1} = \frac{1}{2}$).

Hence $\sum_\nu |h_\nu^{(k)}| \le 4^k$, which gives a (rough) estimate of the radius of convergence of the expansion of $h$ in powers of $\varepsilon$: namely 0.25 (easily improvable to 0.3678 if $4^k k!$ is replaced by $k^{k-1}$ using Cayley's formula for the enumeration of rooted trees). A simple expression for $h^{(k)}(\psi)$ (Lagrange) is

$$h^{(k)}(\psi) = \frac{1}{k!}\partial_\psi^{k-1} \sin^k \psi$$

(also readable from the tree representation): the actual radius of convergence, first determined by Laplace, of the series for $h$ can also be determined from the latter expression for $h$ (Rouché) or directly from the tree representation: it is $\sim 0.6627$.

One can find better estimates or at least more efficient methods for evaluating the sums in [69]: in fact, in performing the sum in [69] important cancellations occur. For instance, the harmonic labels can be subject to the further strong constraint that no line carries zero current because the sum of the values of the trees of fixed order and with at least one line carrying zero current vanishes.

The above expansion can also be simplified by *partial resummations*. For the purpose of an example, let the nodes with one entering and one exiting line (see Figure 5) be called as "simple" nodes. Then all tree graphs which, on any line between two nonsimple nodes, contain any number of simple nodes can be eliminated. This is done by replacing, in evaluating the (remaining) tree values, the factors $\nu_{v'}\nu_v$ in [68] by $\nu_{v'}\nu_v/(1-\varepsilon\cos\psi)$: then the value of $\theta$ (denoted $\mathrm{Val}(\theta)_\psi$) for a tree becomes a function of $\psi$ and $\varepsilon$ and [69] is replaced by

$$h(\psi) = \sum_{k=1}^{\infty} \sum_{\substack{\theta,\,\nu(\theta)=\nu \\ \mathrm{order}(\theta)=k}}^{*} \varepsilon^k \mathrm{e}^{\mathrm{i}\nu\psi} \mathrm{Val}(\theta)_\psi \qquad [70]$$

where the $*$ means that the trees are subject to the further restriction of not containing any simple node. It should be noted that the above graphical representation of the solution of the Kepler equation is strongly reminiscent of the representations of quantities in terms of graphs that occur often in quantum field theory. Here the trees correspond to *Feynman graphs*, the factors associated with the nodes are the *couplings*, the factors associated with the lines are the *propagators*, and the resummations are analogous to the *self-energy resummations*, while the cancellations mentioned above can be related to the class of identities called *Ward identities*. Not only the analogy can be shown not to be superficial, but it also turns out to be very helpful in key mechanical problems: see Appendix 1.

The existence of a vast number of identities relating the tree values is shown already by the *simple* form of the Lagrange series and by the even more remarkable resummation (Levi-Civita) leading to

$$h(\psi) = \sum_{k=1}^{\infty} \frac{(\varepsilon\sin\psi)^k}{k!} \left(\frac{1}{1-\varepsilon\cos\psi}\partial_\psi\right)^k \psi \qquad [71]$$

It is even possible to further collect the series terms to express it as a series with much better convergence properties; for instance, its terms can be reorganized and collected (resummed) so that $h$ is expressed as a power series in the parameter

$$\eta = \frac{\varepsilon\, e^{\sqrt{1-\varepsilon^2}}}{1+\sqrt{1-\varepsilon^2}} \qquad [72]$$

with radius of convergence 1, which corresponds to $\varepsilon = 1$ (via a simple argument by Levi-Civita). The analyticity domain for the Lagrange series is $|\eta| < 1$. This also determines the value of Laplace radius, which is the point closest to the origin of the complex curve $|\eta(\varepsilon)| = 1$: it is imaginary so that it is the root of the equation

$$\varepsilon e^{\sqrt{1+\varepsilon^2}}/(1+\sqrt{1+\varepsilon^2}) = 1$$

The analysis provides an example, in a simple case of great interest in applications, of the kind of computations actually necessary to represent the perturbing function in terms of action–angle variables. The property that the function $c(\lambda)$ in [66] is the cosine has been used only to limit the range of the label $\nu$ to be $\pm 1$; hence the same method, with similar results, can be applied to study the inversion of the relation between the average anomaly $\lambda$ and the true anomaly $\theta$ and to efficiently obtain, for instance, the properties of $f$, $g$ in [42].

For more details, the reader is referred to Levi-Civita (1956).

## Lindstedt and Birkhoff Series: Divergences

Nonexistence of constants of motion, rather than being the end of the attempts to study motions close to integrable ones by perturbation methods, marks the beginning of renewed efforts to understand their nature.

Let $(\boldsymbol{A}, \boldsymbol{\alpha}) \in U \times \mathbb{T}^\ell$ be action–angle variables defined in the integrability region for an analytic Hamiltonian and let $h(\boldsymbol{A})$ be its value in the action–angle coordinates. Suppose that $h(\boldsymbol{A}_0)$ is anisochronous and let $f(\boldsymbol{A}, \boldsymbol{\alpha})$ be an analytic perturbing function. Consider, for $\varepsilon$ small, the Hamiltonian $\mathcal{H}_\varepsilon(\boldsymbol{A}, \boldsymbol{\alpha}) = \mathcal{H}_0(\boldsymbol{A}) + \varepsilon f(\boldsymbol{A}, \boldsymbol{\alpha})$.

Let $\boldsymbol{\omega}_0 = \boldsymbol{\omega}(\boldsymbol{A}_0) \equiv \boldsymbol{\partial}_A \mathcal{H}_0(\boldsymbol{A})$ be the frequency spectrum (see the section "Quasiperiodicity and integrability") of one of the invariant tori of the unperturbed system corresponding to an action $\boldsymbol{A}_0$. Short of integrability, the question to ask at this point is whether the perturbed system admits an analytic invariant torus on which the motion is quasiperiodic and

1. has the same spectrum $\boldsymbol{\omega}_0$,
2. depends analytically on $\varepsilon$ at least for $\varepsilon$ small,
3. reduces to the "unperturbed torus" $\{\boldsymbol{A}_0\} \times \mathbb{T}^\ell$ as $\varepsilon \to 0$.

More concretely, the question is:

> Are there functions $\boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{h}_\varepsilon(\boldsymbol{\psi})$ analytic in $\boldsymbol{\psi} \in \mathbb{T}^\ell$ and in $\varepsilon$ near 0, vanishing as $\varepsilon \to 0$ and such that the torus with parametric equations
>
> $$\boldsymbol{A} = \boldsymbol{A}_0 + \boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), \ \boldsymbol{\alpha} = \boldsymbol{\psi} + \boldsymbol{h}_\varepsilon(\boldsymbol{\psi}), \quad \boldsymbol{\psi} \in \mathbb{T}^\ell \quad [73]$$
>
> is invariant and, if $\boldsymbol{\omega}_0 \stackrel{\text{def}}{=} \boldsymbol{\omega}(\boldsymbol{A}_0)$, the motion on it is simply $\boldsymbol{\psi} \to \boldsymbol{\psi} + \boldsymbol{\omega}_0 t$, i.e., it is quasiperiodic with spectrum $\boldsymbol{\omega}_0$?

In this context, Poincaré's theorem (in the section "Generic nonintegrability") had followed another key result, earlier developed in particular cases and completed by him, which provides a partial answer to the question.

Suppose that $\boldsymbol{\omega}_0 = \boldsymbol{\omega}(\boldsymbol{A}_0) \in \mathbb{R}^\ell$ satisfies a Diophantine property, namely suppose that there exist constants $C, \tau > 0$ such that

$$|\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}| \geq \frac{1}{C|\boldsymbol{\nu}|^\tau}, \quad \text{for all } \boldsymbol{0} \neq \boldsymbol{\nu} \in \mathbb{Z}^\ell \qquad [74]$$

which, for each $\tau > \ell - 1$ fixed, is a property enjoyed by all $\boldsymbol{\omega} \in \mathbb{R}^\ell$ but for a set of zero measure. Then the motions on the unperturbed torus run over trajectories that fill the torus densely because of the "irrationality" of $\boldsymbol{\omega}_0$ implied by [74]. Writing Hamilton's equations,

$$\dot{\boldsymbol{\alpha}} = \partial_A \mathcal{H}_0(\boldsymbol{A}) + \varepsilon \boldsymbol{\partial}_A f(\boldsymbol{A}, \boldsymbol{\alpha}), \quad \dot{\boldsymbol{A}} = -\varepsilon \boldsymbol{\partial}_\alpha f(\boldsymbol{A}, \boldsymbol{\alpha})$$

with $\boldsymbol{A}, \boldsymbol{\alpha}$ given by [73] with $\boldsymbol{\psi}$ replaced by $\boldsymbol{\psi} + \boldsymbol{\omega} t$, and using the density of the unperturbed trajectories implied by [74], the condition that [73] are equations for an invariant torus on which the motion is $\boldsymbol{\psi} \to \boldsymbol{\psi} + \boldsymbol{\omega}_0 t$ are

$$\begin{aligned} \boldsymbol{\omega}_0 + (\boldsymbol{\omega}_0 \cdot \boldsymbol{\partial}_\psi)\boldsymbol{h}_\varepsilon(\boldsymbol{\psi}) &= \boldsymbol{\partial}_A \mathcal{H}_0(\boldsymbol{A}_0 + \boldsymbol{H}_\varepsilon(\boldsymbol{\psi})) \\ &\quad + \varepsilon \boldsymbol{\partial}_A f(\boldsymbol{A}_0 + \boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{\psi} + \boldsymbol{h}_\varepsilon(\boldsymbol{\psi}))(\boldsymbol{\omega}_0 \cdot \boldsymbol{\partial}_\psi)\boldsymbol{H}_\varepsilon(\boldsymbol{\psi}) \\ &= -\varepsilon \boldsymbol{\partial}_\alpha f(\boldsymbol{A}_0 + \boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{\psi} + \boldsymbol{h}_\varepsilon(\boldsymbol{\psi})) \end{aligned} \qquad [75]$$

The theorem referred to above (Poincaré) is that

**Theorem 2** *If the unperturbed system is anisochronous and $\boldsymbol{\omega}_0 = \boldsymbol{\omega}(\boldsymbol{A}_0)$ satisfies [74] for some $C, \tau > 0$ there exist two well defined power series $\boldsymbol{h}_\varepsilon(\boldsymbol{\psi}) = \sum_{k=1}^\infty \varepsilon^k \boldsymbol{h}^{(k)}(\boldsymbol{\psi})$ and $\boldsymbol{H}_\varepsilon(\boldsymbol{\psi}) = \sum_{k=1}^\infty \varepsilon^k \boldsymbol{H}^{(k)}(\boldsymbol{\psi})$ which*

*solve [75] to all orders in $\varepsilon$. The series for $\boldsymbol{H}_\varepsilon$ is uniquely determined, and such is also the series for $\boldsymbol{h}_\varepsilon$ up to the addition of an arbitrary constant at each order, so that it is unique if $\boldsymbol{h}_\varepsilon$ is required, as henceforth done with no loss of generality, to have zero average over $\boldsymbol{\psi}$.*

The algorithm for the construction is illustrated in a simple case in the next section (see eqns [83], [84]). Convergence of the above series, called *Lindstedt series*, even for small $\varepsilon$ has been a problem for rather a long time. Poincaré proved the existence of the formal solution; but his other result, discussed in the section "Generic nonintegrability," casts doubts on convergence although it does not exclude it, as was immediately stressed by several authors (including Poincaré himself). The result in that section shows the impossibility of solving [75] for all $\boldsymbol{\omega}_0$'s near a given spectrum, analytically and uniformly, but it does not exclude the possibility of solving it for a single $\boldsymbol{\omega}_0$.

The theorem admits several extensions or analogs: an interesting one is to the case of isochronous unperturbed systems:

> Given the Hamiltonian $\mathcal{H}_\varepsilon(\boldsymbol{A},\boldsymbol{\alpha}) = \boldsymbol{\omega}_0 \cdot \boldsymbol{A} + \varepsilon f(\boldsymbol{A},\boldsymbol{\alpha})$, with $\boldsymbol{\omega}_0$ satisfying [74] and $f$ analytic, there exist power series $\mathcal{C}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha}')$, $u_\varepsilon(\boldsymbol{A}')$ such that $\mathcal{H}_\varepsilon(\mathcal{C}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha}')) = \boldsymbol{\omega}_0 \cdot \boldsymbol{A}' + u_\varepsilon(\boldsymbol{A}')$ holds as an equality between formal power series (i.e., order by order in $\varepsilon$) and at the same time the $\mathcal{C}_\varepsilon$, regarded as a map, satisfies order by order the condition (i.e., (4.3)) that it is a canonical map.

This means that there is a generating function $\boldsymbol{A}' \cdot \boldsymbol{\alpha} + \boldsymbol{\Phi}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha})$ also defined by a formal power series $\boldsymbol{\Phi}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha}) = \sum_{k=1}^{\infty} \varepsilon^k \boldsymbol{\Phi}^{(k)}(\boldsymbol{A}',\boldsymbol{\alpha})$, that is, such that if $\mathcal{C}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha}') = (\boldsymbol{A},\boldsymbol{\alpha})$ then it is true, order by order in powers of $\varepsilon$, that $\boldsymbol{A} = \boldsymbol{A}' + \boldsymbol{\partial}_{\boldsymbol{\alpha}} \boldsymbol{\Phi}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha})$ and $\boldsymbol{\alpha}' = \boldsymbol{\alpha} + \boldsymbol{\partial}_{\boldsymbol{A}'} \boldsymbol{\Phi}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha})$. The series for $\boldsymbol{\Phi}_\varepsilon, u_\varepsilon$ are called Birkhoff series.

In this isochronous case, if Birkhoff series were convergent for small $\varepsilon$ and $(\boldsymbol{A}',\boldsymbol{\alpha})$ in a region of the form $U \times \mathbb{T}^\ell$, with $U \subset \mathbb{R}^\ell$ open and bounded, it would follow that, for small $\varepsilon, \mathcal{H}_\varepsilon$ would be integrable in a large region of phase space (i.e., where the generating function can be used to build a canonical map: this would essentially be $U \times \mathbb{T}^\ell$ deprived of a small layer of points near the boundary of $U$). However, convergence for small $\varepsilon$ is false (in general), as shown by the simple two-dimensional example

$$\mathcal{H}_\varepsilon(\boldsymbol{A},\boldsymbol{\alpha}) = \boldsymbol{\omega}_0 \cdot \boldsymbol{A} + \varepsilon\,(A_2 + f(\boldsymbol{\alpha})) \qquad (\boldsymbol{A},\boldsymbol{\alpha}) \in \mathbb{R}^2 \times \mathbb{T}^2 \qquad [76]$$

with $f(\boldsymbol{\alpha})$ an arbitrary analytic function with all Fourier coefficients $f_{\boldsymbol{\nu}}$ positive for $\boldsymbol{\nu} \neq 0$ and $f_{\mathbf{o}} = 0$. In the latter case, the solution is

$$u_\varepsilon(\boldsymbol{A}') = \varepsilon A_2$$

$$\boldsymbol{\Phi}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha}) = \sum_{k=1}^{\infty} \varepsilon^k \sum_{0 \neq \boldsymbol{\nu} \in \mathbb{Z}^2} f_{\boldsymbol{\nu}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{\alpha}\cdot\boldsymbol{\nu}} \frac{(\mathrm{i}\,\nu_2)^k}{(\mathrm{i}(\omega_{01}\nu_1 + \omega_{02}\nu_2))^{k+1}} \qquad [77]$$

The series does not converge: in fact, its convergence would imply integrability and, consequently, bounded trajectories in phase space: however, the equations of motion for [76] can be easily solved explicitly and in any open region near given initial data there are other data which have unbounded trajectories if $\omega_{01}/(\omega_{02} + \varepsilon)$ is rational.

Nevertheless, even in this elementary case a formal sum of the series yields

$$u(\boldsymbol{A}') = \varepsilon A_2'$$

$$\boldsymbol{\Phi}_\varepsilon(\boldsymbol{A}',\boldsymbol{\alpha}) = \varepsilon \sum_{0 \neq \boldsymbol{\nu} \in \mathbb{Z}^2} \frac{f_{\boldsymbol{\nu}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{\alpha}\cdot\boldsymbol{\nu}}}{\mathrm{i}(\omega_{01}\nu_1 + (\omega_{20} + \varepsilon)\nu_2)} \qquad [78]$$

and the series in [78] (no longer a power series in $\varepsilon$) is really convergent if $\boldsymbol{\omega} = (\omega_{01}, \omega_{02} + \varepsilon)$ is a Diophantine vector (by [74], because analyticity implies exponential decay of $|f_{\boldsymbol{\nu}}|$). Remarkably, for such values of $\varepsilon$ the Hamiltonian $\mathcal{H}_\varepsilon$ is integrable and it is integrated by the canonical map generated by [78], in spite of the fact that [78] is obtained, from [77], via the nonrigorous sum rule

$$\sum_{k=0}^{\infty} z^k = \frac{1}{1-z} \quad \text{for } z \neq 1 \qquad [79]$$

(applied to cases with $|z| \geq 1$, which are certainly realized for a dense set of $\varepsilon$'s even if $\boldsymbol{\omega}$ is Diophantine because the $z$'s have values $z = \nu_2/\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}$). In other words, the integration of the equations is elementary and once performed it becomes apparent that, if $\boldsymbol{\omega}$ is diophantine, the solutions can be rigorously found from [78]. Note that, for instance, this means that relations like $\sum_{k=0}^{\infty} 2^k = -1$ are really used to obtain [78] from [77].

Another extension of Lindstedt series arises in a perturbation of an anisochronous system when asking the question as to what happens to the unperturbed invariant tori $\mathcal{T}_{\boldsymbol{\omega}_0}$ on which the spectrum is resonant, that is, $\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu} = 0$ for some $\boldsymbol{\nu} \neq 0$, $\boldsymbol{\nu} \in \mathbb{Z}^\ell$. The result is that even in such a case there is a formal power series solution showing that at least a few of the (infinitely many) invariant tori into which $\mathcal{T}_{\boldsymbol{\omega}_0}$ is in turn foliated in the unperturbed case can be formally continued at $\varepsilon \neq 0$ (see the section "Resonances and their stability").

For more details, we refer the reader to Poincaré (1987).

## Quasiperiodicity and KAM Stability

To discuss more advanced results, it is convenient to restrict attention to a special (nontrivial) paradigmatic case

$$\mathcal{H}_\varepsilon(A,\boldsymbol{\alpha}) = \tfrac{1}{2}A^2 + \varepsilon f(\boldsymbol{\alpha}) \qquad [80]$$

In this simple case (called *Thirring model*: representing $\ell$ particles on a circle interacting via a potential $\varepsilon f(\boldsymbol{\alpha})$) the equations for the maximal tori [75] reduce to equations for the only functions $\boldsymbol{h}_\varepsilon$:

$$(\boldsymbol{\omega}\cdot\boldsymbol{\partial}_{\boldsymbol{\psi}})^2\boldsymbol{h}_\varepsilon(\boldsymbol{\psi}) = -\varepsilon\boldsymbol{\partial}_{\boldsymbol{\alpha}}f(\boldsymbol{\psi}+\boldsymbol{h}_\varepsilon(\boldsymbol{\psi})), \quad \boldsymbol{\psi}\in\mathbb{T}^\ell \qquad [81]$$

as the second of [75] simply becomes the definition of $\boldsymbol{H}_\varepsilon$ because the RHS does not involve $\boldsymbol{H}_\varepsilon$.

The real problem is therefore whether the formal series considered in the last section converge at least for small $\varepsilon$: and the example [76] on the Birkhoff series shows that sometimes sum rules might be needed in order to give a meaning to the series. In fact, whenever a problem (of physical interest) admits a formal power series solution which is not convergent, or which is such that it is not known whether it is convergent, then one should look for sum rules for it.

The modern theory of perturbations starts with the proof of the convergence for $\varepsilon$ small enough of the Lindstedt series (Kolmogorov). The general "KAM" result is:

**Theorem 3** (KAM) *Consider the Hamiltonian* $\mathcal{H}_\varepsilon(\boldsymbol{A},\boldsymbol{\alpha}) = h(\boldsymbol{A}) + \varepsilon f(\boldsymbol{A},\boldsymbol{\alpha})$, *defined in* $U = V\times\mathbb{T}^\ell$ *with* $V\subset\mathbb{R}^\ell$ *open and bounded and with* $f(\boldsymbol{A},\boldsymbol{\alpha})$, $h(\boldsymbol{A})$ *analytic in the closure* $\overline{V}\times\mathbb{T}^\ell$ *where* $h(\boldsymbol{A})$ *is also anisochronous; let* $\boldsymbol{\omega}_0 \stackrel{\text{def}}{=} \boldsymbol{\omega}(\boldsymbol{A}_0) = \partial_{\boldsymbol{A}}h(\boldsymbol{A}_0)$ *and assume that* $\boldsymbol{\omega}_0$ *satisfies* [74]. *Then*

- (i) *there is* $\varepsilon_{C,\tau} > 0$ *such that the Lindstedt series converges for* $|\varepsilon| < \varepsilon_{C,\tau}$;
- (ii) *its sum yields two function* $\boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{h}_\varepsilon(\boldsymbol{\psi})$ *on* $\mathbb{T}^\ell$ *which parametrize an invariant torus* $\mathcal{T}_{C,\tau}(\boldsymbol{A}_0,\varepsilon)$;
- (iii) *on* $\mathcal{T}_{C,\tau}(\boldsymbol{A}_0,\varepsilon)$ *the motion is* $\boldsymbol{\psi}\to\boldsymbol{\psi}+\boldsymbol{\omega}_0 t$, *see* [73]; *and*
- (iv) *the set of data in* $U$ *which belong to invariant tori* $\mathcal{T}_{C,\tau}(\boldsymbol{A}_0,\varepsilon)$ *with* $\boldsymbol{\omega}(\boldsymbol{A}_0)$ *satisfying* [74] *with prefixed* $C,\tau$ *has complement with volume* $<$const $C^{-a}$ *for a suitable* $a>0$ *and with area also* $<$const $C^{-a}$ *on each nontrivial surface of constant energy* $\mathcal{H}_\varepsilon = E$.

In other words, for small $\varepsilon$ the spectra of most unperturbed quasiperiodic motions can still be found as spectra of perturbed quasiperiodic motions developing on tori which are close to the corresponding unperturbed ones (i.e., with the same spectrum).

This is a stability result: for instance, in systems with two degrees of freedom the invariant tori of dimension two which lie on a given three-dimensional energy surface, will separate the points on the energy surface into the set which is "inside" the torus and the set which is "outside." Hence, an initial datum starting (say) inside cannot reach the outside. Likewise, a point starting between two tori has to stay in between forever. Further, if the two tori are close, this means that motion will stay very localized in action space, with a trajectory accessing only points close to the tori and coming close to all such points, within a distance of the order of the distance between the confining tori. The case of three or more degrees of freedom is quite different (see sections "Diffusion in phase space" and "The three-body problem").

In the simple case of the rotators system [80] the equations for the parametric representation of the tori are given by [81]. The latter bear some analogy with the easier problem in [66]: but [81] are $\ell$ equations instead of one and they are differential equations rather than ordinary equations. Furthermore, the function $f(\boldsymbol{\alpha})$ which plays here the role of $c(\lambda)$ in [66] has Fourier coefficient $f_{\boldsymbol{\nu}}$ with no restrictions on $\boldsymbol{\nu}$, while the Fourier coefficients $c_\nu$ for $c$ in [66] do not vanish only for $\nu = \pm 1$.

The above differences are, to some extent, "minor" and the power series solution to [81] can be constructed by the same algorithm as used in the case of [66]: namely one forms trees as in Figure 5 with the harmonic labels $\nu_v\in\mathbb{Z}$ replaced by $\boldsymbol{\nu}_v\in\mathbb{Z}^\ell$ (still to be thought of as possible harmonic indices in the Fourier expansion of the perturbing function $f$). All other labels affixed to the trees in the section "Generic nonintegrability" will be the same. In particular, the current flowing on a branch $l = v'v$ will be defined as the sum of the harmonics of the nodes $w\le v$ preceding $v$:

$$\boldsymbol{\nu}(l) \stackrel{\text{def}}{=} \sum_{w\le v}\boldsymbol{\nu}_w \qquad [82]$$

and we call $\boldsymbol{\nu}(\theta)$ the current flowing in the root branch.

Here the value $\mathrm{Val}(\theta)$ of a tree has to be defined differently because the equation to be solved ([81]) contains the differential operator $(\boldsymbol{\omega}_0\cdot\boldsymbol{\partial}_{\boldsymbol{\psi}})^2$ which, when Fourier transformed, becomes multiplication of the Fourier component with harmonic $\boldsymbol{\nu}$ by $(\mathrm{i}\boldsymbol{\omega}\cdot\boldsymbol{\nu})^2$.

The variation due to the presence of the operator $(\boldsymbol{\omega}_0\cdot\boldsymbol{\partial}_{\boldsymbol{\psi}})^2$ and the necessity of its inversion in the evaluation of $\boldsymbol{u}\cdot\boldsymbol{h}^{(k)}_{\boldsymbol{\nu}}$, that is, of the component of $\boldsymbol{h}^{(k)}_{\boldsymbol{\nu}}$ along an arbitrary unit vector $\boldsymbol{u}$, is nevertheless quite simple: the value of a tree graph $\theta$ of order $k$

(i.e., with $k$ nodes and $k$ branches) has to be defined by (cf. [68])

$$\mathrm{Val}(\theta) \stackrel{\text{def}}{=} \frac{-\mathrm{i}(-1)^k}{k!}\left(\prod_{\text{lines } l=v'v} \frac{\boldsymbol{\nu}_{v'}\cdot\boldsymbol{\nu}_v}{(\boldsymbol{\omega}_0\cdot\boldsymbol{\nu}(l))^2}\right) \times \left(\prod_{\text{nodes } v} f_{\boldsymbol{\nu}_v}\right) \qquad [83]$$

where the $\boldsymbol{\nu}_{v'}$ appearing in the factor relative to the root line $rv$ from the first node $v$ to the root $r$ (see Figure 5) is interpreted as a unit vector $\boldsymbol{u}$ (it was interpreted as 1 in the one-dimensional case [66]). Equation [83] makes sense only for trees in which no line carries zero current. Then the component along $\boldsymbol{u}$ (the harmonic label attached to the root of a tree) of $\boldsymbol{h}^{(k)}$ is given (see also [69]) by

$$\boldsymbol{u}\cdot\boldsymbol{h}_{\boldsymbol{\nu}}^{(k)} = \sum_{\substack{\theta,\boldsymbol{\nu}(\theta)=\boldsymbol{\nu}\\ \mathrm{order}(\theta)=k}}^{*} \mathrm{Val}(\theta) \qquad [84]$$

where the $*$ means that the sum is only over trees in which a nonzero current $\boldsymbol{\nu}(l)$ flows on the lines $l\in\theta$. The quantity $\boldsymbol{u}\cdot\boldsymbol{h}_{\mathbf{0}}^{(k)}$ will be defined to be $\mathbf{0}$ (see the previous section).

In the case of [66] zero-current lines could appear: but the contributions from tree graphs containing at least one zero current line would cancel. In the present case, the statement that the above algorithm actually gives $\boldsymbol{h}_{\boldsymbol{\nu}}^{(k)}$ by simply ignoring trees with lines with zero current is nontrivial. It was Poincaré's contribution to the theory of Lindstedt series to show that even in the general case (cf. [75]) the equations for the invariant tori can be solved by a formal power series. Equation [84] is proved by induction on $k$ after checking it for the first few orders.

The algorithm just described leading to [83] can be extended to the case of the general Hamiltonian considered in the KAM theorem.

The convergence proof is more delicate than the (elementary) one for eqn [66]. In fact, the values of trees of order $k$ can give large contributions to $\boldsymbol{h}_{\boldsymbol{\nu}}^{(k)}$: because the "new" factors $(\boldsymbol{\omega}_0\cdot\boldsymbol{\nu}(l))^2$, although not zero, can be quite small and their small size can overwhelm the smallness of the factors $f_{\boldsymbol{\nu}}$ and $\varepsilon$. In fact, even if $f$ is a trigonometric polynomial (so that $f_{\boldsymbol{\nu}}$ vanishes identically for $|\boldsymbol{\nu}|$ large enough) the currents flowing in the branches can be very large, of the order of the number $k$ of nodes in the tree; see [82].

This is called the *small-divisors problem*. The key to its solution goes back to a related work (Siegel) which shows that

**Theorem 4** *Consider the contribution to the sum in [82] from graphs $\theta$ in which no pairs of lines which lie on the same path to the root carry the same current and, furthermore, the node harmonics are bounded by $|\boldsymbol{\nu}|\le N$ for some $N$. Then the number of lines $\ell$ in $\theta$ with divisor $\boldsymbol{\omega}_0\cdot\boldsymbol{\nu}_\ell$ satisfying $2^{-n} < C|\boldsymbol{\omega}_0\cdot\boldsymbol{\nu}_\ell| \le 2^{-n+1}$ does not exceed $4Nk2^{-n/\tau}$.*

Hence, setting

$$F \stackrel{\text{def}}{=} C^2\max_{|\boldsymbol{\nu}|\le N}|f_{\boldsymbol{\nu}}|$$

the corresponding $\mathrm{Val}(\theta)$ can be bounded by

$$\frac{1}{k!}F^kN^{2k}\prod_{n=0}^{\infty}2^{2n(4Nk2^{-n/\tau})} \stackrel{\text{def}}{=} \frac{1}{k!}B^k \qquad B = FN^2 2\sum_n 8n2^{-n/\tau} \qquad [85]$$

since the product is convergent. In the case in which $f$ is a trigonometric polynomial of degree $N$, the above restricted contributions to $\boldsymbol{u}\cdot\boldsymbol{h}_{\boldsymbol{\nu}}^{(k)}$ would generate a convergent series for $\varepsilon$ small enough. In fact, the number of trees is bounded (as in the section "Perturbing functions") by $k!4^k(2N+1)^{\ell k}$ so that the series $\sum_{\boldsymbol{\nu}}|\varepsilon|^k|\boldsymbol{u}\cdot\boldsymbol{h}_{\boldsymbol{\nu}}^{(k)}|$ would converge for small $\varepsilon$ (i.e., $|\varepsilon| < (B\cdot 4(2N+1)^\ell)^{-1}$).

Given this comment, the analysis of the "remaining contributions" becomes the real problem, and it requires new ideas because among the excluded trees there are some simple $k$th order trees whose value alone, if considered separately from the other contributions, would generate a factorially divergent power series in $\varepsilon$.

However, the contributions of all large-valued trees of order $k$ can be shown to cancel: although not exactly (unlike the case of the elementary problem in the section "Perturbing functions," where the cancellation is not necessary for the proof, in spite of its exact occurrence), but enough so that in spite of the existence of exceedingly large values of individual tree graphs their total sum can still be bounded by a constant to the power $k$ so that the power series actually converges for $\varepsilon$ small enough. The idea is discussed in Appendix 1.

For more details, the reader is referred to Poincaré (1987), Kolmogorov (1954), Moser (1962), and Arnol'd (1989).

## Resonances and their Stability

A quasiperiodic motion with $r$ rationally independent frequencies is called resonant if $r$ is strictly less than the number of degrees of freedom, $\ell$. The difference $s=\ell-r$ is the degree of the resonance.

Of particular interest are the cases of a perturbation of an integrable system in which resonant motions take place.

A typical example is the $n$-body problem which studies the mutual perturbations of the motions of $n-1$ particles gravitating around a more massive particle. If the particle masses can be considered to be negligible, the system will consist of $n-1$ central Keplerian motions: it will therefore have $\ell = 3(n-1)$ degrees of freedom. In general, only one frequency per body occurs in the absence of the perturbations (the period of the Keplerian orbit). Hence, $r \leq n-1$ and $s \geq 2(n-1)$ (or in the planar case $s \geq (n-1)$) with equality holding when the periods are rationally independent.

Another example is the rigid body with a fixed point perturbed by a conservative force: in this case, the unperturbed system has three degrees of freedom but, in general, only two frequencies (see the discussion following [52]).

Furthermore, in the above examples there is the possibility that the independent frequencies assume, for special initial data, values which are rationally related, giving rise to resonances of even higher order (i.e., with smaller values of $r$).

In an integrable anisochronous system, resonant motions will be dense in phase space because the frequencies $\boldsymbol{\omega}(\boldsymbol{A})$ will vary as much as the actions and therefore resonances of any order (i.e., any $r < \ell$) will be dense in phase space: in particular, the periodic motions (i.e., the highest-order resonances) will be dense.

Resonances, in integrable systems, can arise in *a priori* stable integrable systems and in *a priori* unstable systems: the former are systems whose Hamiltonian admits canonical action–angle coordinates $(\boldsymbol{A}, \boldsymbol{\alpha}) \in U \times \mathbb{T}^\ell$ with $U \subset \mathbb{R}^\ell$ open, while the latter are systems whose Hamiltonian has, in suitable local canonical coordinates, the form

$$\mathcal{H}_0(\boldsymbol{A}) + \sum_{i=1}^{s_1} \frac{1}{2}(p_i^2 - \lambda_i^2 q_i^2) + \sum_{j=1}^{s_2} \frac{1}{2}(\pi_j^2 + \mu_j^2 \kappa_j^2), \quad \lambda_i, \mu_j > 0 \qquad [86]$$

where $(\boldsymbol{A}, \boldsymbol{\alpha}) \in U \times \mathbb{T}^r$, $U \in \mathbb{R}^r$, $(\boldsymbol{p}, \boldsymbol{q}) \in V \subset \mathbb{R}^{2s_1}$, $(\boldsymbol{\pi}, \boldsymbol{\kappa}) \in V' \subset \mathbb{R}^{2s_2}$ with $V, V'$ neighborhoods of the origin and $\ell = r + s_1 + s_2$, $s_i \geq 0$, $s_1 + s_2 > 0$ and $\pm\sqrt{\lambda_j}$, $\pm\sqrt{\mu_j}$ are called Lyapunov coefficients of the resonance. The perturbations considered are supposed to have the form $\varepsilon f(\boldsymbol{A}, \boldsymbol{\alpha}, \boldsymbol{p}, \boldsymbol{q}, \boldsymbol{\pi}, \boldsymbol{\kappa})$. The denomination of *a priori* stable or unstable refers to the properties of the "*a priori* given unperturbed Hamiltonian." The label "*a priori* unstable" is certainly appropriate if $s_1 > 0$: here also $s_1 = 0$ is allowed for notational convenience implying that the Lyapunov coefficients in *a priori* unstable cases are all of order 1 (whether real $\lambda_j$ or imaginary $\mathrm{i}\sqrt{\mu_j}$). In other words, the *a priori* stable case, $s_1 = s_2 = 0$ in [86], is the only excluded case. Of course, the stability properties of the motions when a perturbation acts will depend on the perturbation in both cases.

The *a priori* stable systems usually have a great variety of resonances (e.g., in the anisochronous case, resonances of any dimension are dense). The *a priori* unstable systems have (among possible other resonances) some very special $r$-dimensional resonances occurring when the unstable coordinates $(\boldsymbol{p}, \boldsymbol{q})$ and $(\boldsymbol{\pi}, \boldsymbol{\kappa})$ are zero and the frequencies of the $r$ action–angle coordinates are rationally independent.

In the first case (*a priori* stable), the general question is whether the resonant motions, which form invariant tori of dimension $r$ arranged into families that fill $\ell$-dimensional invariant tori, continue to exist, in presence of small enough perturbations $\varepsilon f(\boldsymbol{A}, \boldsymbol{\alpha})$, on slightly deformed invariant tori. Similar questions can be asked in the *a priori* unstable cases. To examine the matter more closely consider the formulation of the simplest problems.

*A priori* stable resonances: more precisely, suppose $\mathcal{H}_0 = \frac{1}{2}\boldsymbol{A}^2$ and let $\{\boldsymbol{A}_0\} \times \mathbb{T}^\ell$ be the unperturbed invariant torus $\mathcal{T}_{\boldsymbol{A}_0}$ with spectrum $\boldsymbol{\omega}_0 = \boldsymbol{\omega}(\boldsymbol{A}_0) = \partial_{\boldsymbol{A}}\mathcal{H}_0(\boldsymbol{A}_0)$ with only $r$ rationally independent components. For simplicity, suppose that $\boldsymbol{\omega}_0 = (\omega_1, \ldots, \omega_r, 0, \ldots, 0) \stackrel{\text{def}}{=} (\boldsymbol{\omega}, \boldsymbol{0})$ with $\boldsymbol{\omega} \in \mathbb{R}^r$. The more general case in which $\boldsymbol{\omega}$ has only $r$ rationally independent components can be reduced to the special case above by a canonical linear change of coordinates at the price of changing the $\mathcal{H}_0$ to a new one, still quadratic in the actions but containing mixed products $A_i B_j$: the proofs of the results that are discussed here would not be really affected by such more general form of $\mathcal{H}$.

It is convenient to distinguish between the "fast" angles $\alpha_1, \ldots, \alpha_r$ and the "resonant" angles $\alpha_{r+1}, \ldots, \alpha_\ell$ (also called "slow" or "secular") and call $\boldsymbol{\alpha} = (\boldsymbol{\alpha}', \boldsymbol{\beta})$ with $\boldsymbol{\alpha}' \in \mathbb{T}^r$ and $\boldsymbol{\beta} \in \mathbb{T}^s$. Likewise, we distinguish the fast actions $\boldsymbol{A}' = (A_1, \ldots, A_r)$ and the resonant ones $A_{r+1}, \ldots, A_\ell$ and set $\boldsymbol{A} = (\boldsymbol{A}', \boldsymbol{B})$ with $\boldsymbol{A}' \in \mathbb{R}^r$ and $\boldsymbol{B} \in \mathbb{R}^s$.

Therefore, the torus $\mathcal{T}_{\boldsymbol{A}_0}, \boldsymbol{A}_0 = (\boldsymbol{A}'_0, \boldsymbol{B}_0)$, is in turn a continuum of invariant tori $\mathcal{T}_{\boldsymbol{A}_0, \boldsymbol{\beta}}$ with trivial parametric equations: $\boldsymbol{\beta}$ fixed, $\boldsymbol{\alpha}' = \boldsymbol{\psi}, \boldsymbol{\psi} \in \mathbb{T}^r$, and $\boldsymbol{A}' = \boldsymbol{A}'_0, \boldsymbol{B} = \boldsymbol{B}_0$. On each of them the motion is: $\boldsymbol{A}', \boldsymbol{B}, \boldsymbol{\beta}$ constant and $\boldsymbol{\alpha}' \to \boldsymbol{\alpha}' + \boldsymbol{\omega} t$, with rationally independent $\boldsymbol{\omega} \in \mathbb{R}^r$.

Then the natural question is whether there exist functions $\boldsymbol{h}_\varepsilon, \boldsymbol{k}_\varepsilon, \boldsymbol{H}_\varepsilon, \boldsymbol{K}_\varepsilon$ smooth in $\varepsilon$ near $\varepsilon = 0$ and in $\boldsymbol{\psi} \in \mathbb{T}^r$, vanishing for $\varepsilon = 0$, and such that the torus $\mathcal{T}_{\boldsymbol{A}_0, \boldsymbol{\beta}_0, \varepsilon}$ with parametric equations

$$\begin{aligned} \boldsymbol{A}' &= \boldsymbol{A}'_0 + \boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), & \boldsymbol{\alpha}' &= \boldsymbol{\psi} + \boldsymbol{h}_\varepsilon(\boldsymbol{\psi}), \\ \boldsymbol{B} &= \boldsymbol{B}_0 + \boldsymbol{K}_\varepsilon(\boldsymbol{\psi}), & \boldsymbol{\beta} &= \boldsymbol{\beta}_0 + \boldsymbol{k}_\varepsilon(\boldsymbol{\psi}) \end{aligned} \qquad \boldsymbol{\psi} \in \mathbb{T}^r \qquad [87]$$

is invariant for the motions with Hamiltonian

$$\mathcal{H}_\varepsilon(\boldsymbol{A},\boldsymbol{\alpha}) = \tfrac{1}{2}\boldsymbol{A}'^2 + \tfrac{1}{2}\boldsymbol{B}^2 + \varepsilon f(\boldsymbol{\alpha}', \boldsymbol{\beta})$$

and the motions on it are $\boldsymbol{\psi} \to \boldsymbol{\psi} + \boldsymbol{\omega} t$. The above property, when satisfied, is summarized by saying that the unperturbed resonant motions $\boldsymbol{A} = (\boldsymbol{A}'_0, \boldsymbol{B}_0)$, $\boldsymbol{\alpha} = (\boldsymbol{\alpha}'_0 + \boldsymbol{\omega}' t, \boldsymbol{\beta}_0)$ can be continued in presence of perturbation $\varepsilon f$, for small $\varepsilon$, to quasiperiodic motions with the same spectrum and on a slightly deformed torus $\mathcal{T}_{\boldsymbol{A}'_0,\boldsymbol{\beta}_0,\varepsilon}$.

*A priori* unstable resonances: here the question is whether the special invariant tori continue to exist in presence of small enough perturbations, of course slightly deformed. This means asking whether, given $\boldsymbol{A}_0$ such that $\boldsymbol{\omega}(\boldsymbol{A}_0) = \partial_{\boldsymbol{A}}\mathcal{H}_0(\boldsymbol{A}_0)$ has rationally independent components, there are functions $(\boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{h}_\varepsilon(\boldsymbol{\psi})), (\boldsymbol{P}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{Q}_\varepsilon(\boldsymbol{\psi}))$ and $(\boldsymbol{\Pi}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{K}_\varepsilon(\boldsymbol{\psi}))$ smooth in $\varepsilon$ near $\varepsilon = 0$, vanishing for $\varepsilon = 0$, analytic in $\boldsymbol{\psi} \in \mathbb{T}^r$ and such that the $r$-dimensional surface

$$\begin{aligned} \boldsymbol{A} &= \boldsymbol{A}_0 + \boldsymbol{H}_\varepsilon(\boldsymbol{\psi}), & \boldsymbol{\alpha} &= \boldsymbol{\psi} + \boldsymbol{h}_\varepsilon(\boldsymbol{\psi}) \\ \boldsymbol{p} &= \boldsymbol{P}_\varepsilon(\boldsymbol{\psi}), & \boldsymbol{q} &= \boldsymbol{Q}_\varepsilon(\boldsymbol{\psi}) \qquad \boldsymbol{\psi} \in \mathbb{T}^r \\ \boldsymbol{\pi} &= \boldsymbol{\Pi}_\varepsilon(\boldsymbol{\psi}), & \boldsymbol{\kappa} &= \boldsymbol{K}_\varepsilon(\boldsymbol{\psi}) \end{aligned} \qquad [88]$$

is an invariant torus $\mathcal{T}_{\boldsymbol{A}_0,\varepsilon}$ on which the motion is $\boldsymbol{\psi} \to \boldsymbol{\psi} + \boldsymbol{\omega}(\boldsymbol{A}_0)t$. Again, the above property is summarized by saying that the unperturbed special resonant motions can be continued in presence of perturbation $\varepsilon f$ for small $\varepsilon$ to quasiperiodic motions with the same spectrum and on a slightly deformed torus $\mathcal{T}_{\boldsymbol{A}_0,\varepsilon}$.

Some answers to the above questions are presented in the following section. For more details, the reader is referred to Gallavotti *et al.* (2004).

## Resonances and Lindstedt Series

We discuss eqns [87] in the paradigmatic case in which the Hamiltonian $\mathcal{H}_0(\boldsymbol{A})$ is $\frac{1}{2}\boldsymbol{A}^2$ (cf. [80]). It will be $\boldsymbol{\omega}(\boldsymbol{A}') \equiv \boldsymbol{A}'$ so that $\boldsymbol{A}_0 = \boldsymbol{\omega}$, $\boldsymbol{B}_0 = \boldsymbol{0}$ and the perturbation $f(\boldsymbol{\alpha})$ can be considered as a function of $\boldsymbol{\alpha} = (\boldsymbol{\alpha}', \boldsymbol{\beta})$: let $\overline{f}(\boldsymbol{\beta})$ be defined as its average over $\boldsymbol{\alpha}'$. The determination of the invariant torus of dimension $r$ which can be continued in the sense discussed in the last section is easily understood in this case.

A resonant invariant torus which, among the tori $\mathcal{T}_{\boldsymbol{A}_0,\boldsymbol{\beta}}$, has parametric equations that can be continued as a formal power series in $\varepsilon$ is the torus $\mathcal{T}_{\boldsymbol{A}_0,\boldsymbol{\beta}_0}$ with $\boldsymbol{\beta}_0$ a stationarity point for $\overline{f}(\boldsymbol{\beta})$, that is, an equilibrium point for the average perturbation: $\partial_{\boldsymbol{\beta}}\overline{f}(\boldsymbol{\beta}_0) = 0$. In fact, the following theorem holds:

**Theorem 5** *If $\boldsymbol{\omega} \in \mathbb{R}^r$ satisfies a Diophantine property and if $\boldsymbol{\beta}_0$ is a nondegenerate stationarity point for the "fast angle average" $\overline{f}(\boldsymbol{\beta})$* (i.e., *such that* $\det \partial^2_{\boldsymbol{\beta}\boldsymbol{\beta}}\overline{f}(\boldsymbol{\beta}_0) \neq 0$), *then the following equations for the functions $\boldsymbol{h}_\varepsilon, \boldsymbol{k}_\varepsilon$,*

$$\begin{aligned} (\boldsymbol{\omega} \cdot \partial_{\boldsymbol{\psi}})^2 \boldsymbol{h}_\varepsilon(\boldsymbol{\psi}) &= -\varepsilon \partial_{\boldsymbol{\alpha}'} f(\boldsymbol{\psi} + \boldsymbol{h}_\varepsilon(\boldsymbol{\psi}), \boldsymbol{\beta}_0 + \boldsymbol{k}_\varepsilon(\boldsymbol{\psi})) \\ (\boldsymbol{\omega} \cdot \partial_{\boldsymbol{\psi}})^2 \boldsymbol{k}_\varepsilon(\boldsymbol{\psi}) &= -\varepsilon \partial_{\boldsymbol{\beta}} f(\boldsymbol{\psi} + \boldsymbol{h}_\varepsilon(\boldsymbol{\psi}) + \boldsymbol{k}_\varepsilon(\boldsymbol{\psi})) \end{aligned} \qquad [89]$$

*can be formally solved in powers of $\varepsilon$.*

Given the simplicity of the Hamiltonian [80] that we are considering, it is not necessary to discuss the functions $\boldsymbol{H}_\varepsilon, \boldsymbol{K}_\varepsilon$ because the equations that they should obey reduce to their definitions as in the section "Quasiperiodicity and KAM stability," and for the same reason.

In other words, also the resonant tori admit a Lindstedt series representation. It is however very unlikely that the series are, in general, convergent.

Physically, this new aspect is due to the fact that the linearization of the motion near the torus $\mathcal{T}_{\boldsymbol{A}_0,\boldsymbol{\beta}_0}$ introduces oscillatory motions around $\mathcal{T}_{\boldsymbol{A}'_0,\boldsymbol{\beta}_0}$ with frequencies proportional to the square roots of the positive eigenvalues of the matrix $\varepsilon\partial^2_{\boldsymbol{\beta}\boldsymbol{\beta}}\overline{f}(\boldsymbol{\beta}_0)$: therefore, it is naively expected that it has to be necessary that a Diophantine property be required on the vector $(\boldsymbol{\omega}, \sqrt{\varepsilon\mu_1}, \ldots)$, where $\varepsilon\mu_j$ are the positive eigenvalues. Hence, some values of $\varepsilon$, namely those for which $(\boldsymbol{\omega}, \sqrt{\varepsilon\mu_1}, \ldots)$ is not a Diophantine vector or is too close to a non-Diophantine vector, should be excluded or at least should be expected to generate difficulties. Note that the problem arises irrespective of the assumptions about the nondegenerate matrix $\partial^2_{\boldsymbol{\beta}\boldsymbol{\beta}}\overline{f}(\boldsymbol{\beta}_0)$ (since $\varepsilon$ can have either sign), and no matter how small $|\varepsilon|$ is supposed to be. But we can expect that if the matrix $\partial^2_{\boldsymbol{\beta}\boldsymbol{\beta}}\overline{f}(\boldsymbol{\beta}_0)$ is (say) positive definite (i.e., $\boldsymbol{\beta}_0$ is a minimum point for $\overline{f}(\boldsymbol{\beta})$) then the problem should be easier for $\varepsilon < 0$ and vice versa, if $\boldsymbol{\beta}_0$ is a maximum, it should be easier for $\varepsilon > 0$ (i.e., in the cases in which the eigenvalues of $\varepsilon\partial^2_{\boldsymbol{\beta}\boldsymbol{\beta}}\overline{f}(\boldsymbol{\beta}_0)$ are negative and their roots do not have the interpretation of frequencies).

Technically, the sums of the formal series can be given (so far) a meaning only via summation rules involving divergent series: typically, one has to identify in the formal expressions (denumerably many) geometric series which, although divergent, can be given a meaning by applying the rule [79]. Since the rule can only be applied if $z \neq 1$, this leads to conditions on the parameter $\varepsilon$, in order to exclude that the various $z$ that have to be considered are very close to 1. Hence, this stability result turns out to be rather different from the KAM result for the maximal tori. Namely the series can be given a

meaning via summation rules provided $f$ and $\boldsymbol{\beta}_0$ satisfy certain additional conditions and provided certain values of $\varepsilon$ are excluded. An example of a theorem is the following:

**Theorem 6** *Given the Hamiltonian [80] and a resonant torus $\mathcal{T}_{A_0',\boldsymbol{\beta}_0}$ with $\boldsymbol{\omega}=A_0' \in \mathbb{R}^r$ satisfying a Diophantine property let $\boldsymbol{\beta}_0$ be a nondegenerate maximum point for the average potential $\overline{f}(\boldsymbol{\beta}) \stackrel{\text{def}}{=} (2\pi)^{-r}\int_{\mathbb{T}^r} f(\boldsymbol{\alpha}',\boldsymbol{\beta})d^r\boldsymbol{\alpha}'$. Consider the Lindstedt series solution for eqns [89] of the perturbed resonant torus with spectrum $(\boldsymbol{\omega},0)$. It is possible to express the single nth-order term of the series as a sum of many terms and then rearrange the series thus obtained so that the resummed series converges for $\varepsilon$ in a domain $\mathcal{E}$ which contains a segment $[0,\varepsilon_0]$ and also a subset of $[-\varepsilon_0,0]$ which, although with open dense complement, is so large that it has 0 as a Lebesgue density point. Furthermore, the resummed series for $\boldsymbol{h}_\varepsilon,\boldsymbol{k}_\varepsilon$ define an invariant r-dimensional analytic torus with spectrum $\boldsymbol{\omega}$.*

More generally, if $\boldsymbol{\beta}_0$ is only a nondegenerate stationarity point for $\overline{f}(\boldsymbol{\beta})$, the domain of definition of the resummed series is a set $\mathcal{E} \subset [-\varepsilon_0,\varepsilon_0]$ which on both sides of the origin has an open dense complement although it has 0 as a Lebesgue density point.

Theorem 6 can be naturally extended to the general case in which the Hamiltonian is the most general perturbation of an anisochronous integrable system $\mathcal{H}_\varepsilon(\boldsymbol{A},\boldsymbol{\alpha})=h(\boldsymbol{A})+\varepsilon f(\boldsymbol{A},\boldsymbol{\alpha})$ if $\partial^2_{\boldsymbol{AA}}h$ is a nonsingular matrix and the resonance arises from a spectrum $\boldsymbol{\omega}(A_0)$ which has $r$ independent components (while the remaining are not necessarily zero).

We see that the convergence is a delicate problem for the Lindstedt series for nearly integrable resonant motions. They might even be divergent (mathematically, a proof of divergence is an open problem but it is a very reasonable conjecture in view of the above physical interpretation); nevertheless, Theorem 6 shows that sum rules can be given that sometimes (i.e., for $\varepsilon$ in a large set near $\varepsilon=0$) yield a true solution to the problem.

This is reminiscent of the phenomenon met in discussing perturbations of isochronous systems in [76], but it is a much more complex situation. It leaves many open problems: foremost among them is the question of uniqueness. The sum rules of divergent series always contain some arbitrary choices, which lead to doubts about the uniqueness of the functions parametrizing the invariant tori constructed in this way. It might even be that the convergence set $\mathcal{E}$ may depend upon the arbitrary choices, and that considering several of them no $\varepsilon$ with $|\varepsilon|<\varepsilon_0$ is left out.

The case of *a priori* unstable systems has also been widely studied. In this case too resonances with Diophantine $r$-dimensional spectrum $\boldsymbol{\omega}$ are considered. However, in the case $s_2=0$ (called *a priori* unstable hyperbolic resonance) the Lindstedt series can be shown to be convergent, while in the case $s_1=0$ (called *a priori* unstable elliptic resonance) or in the mixed cases $s_1,s_2>0$ extra conditions are needed. They involve $\boldsymbol{\omega}$ and $\boldsymbol{\mu}=(\mu_1,\ldots,\mu_{s_2})$ (cf. [86]) and properties of the perturbations as well. It is also possible to study a slightly different problem: namely to look for conditions on $\boldsymbol{\omega},\boldsymbol{\mu},f$ which imply that, for small $\varepsilon$, invariant tori with spectrum $\varepsilon$-dependent but close, in a suitable sense, to $\boldsymbol{\omega}$ exist.

The literature is vast, but it seems fair to say that, given the above comments, particularly those concerning uniqueness and analyticity, the situation is still quite unsatisfactory. We refer the reader to Gallavotti *et al.* (2004) for more details.

## Diffusion in Phase Space

The KAM theorem implies that a perturbation of an analytic anisochronous integrable system, i.e., with an analytic Hamiltonian $\mathcal{H}_\varepsilon(\boldsymbol{A},\boldsymbol{\alpha})=\mathcal{H}_0(\boldsymbol{A})+\varepsilon f(\boldsymbol{A},\boldsymbol{\alpha})$ and nondegenerate Hessian matrix $\partial^2_{\boldsymbol{AA}}h(\boldsymbol{A})$, generates large families of maximal invariant tori. Such tori lie on the energy surfaces but do not have codimension 1 on them, i.e., they do not split the $(2\ell-1)$–dimensional energy surfaces into disconnected regions except, of course, in the case of systems with two degrees of freedom (see the section "Quasiperiodicity and KAM stability").

Therefore, there might exist trajectories with initial data close to $\boldsymbol{A}^{\mathrm{i}}$ in action space which reach phase space points close to $\boldsymbol{A}^{\mathrm{f}} \neq \boldsymbol{A}^{\mathrm{i}}$ in action space for $\varepsilon \neq 0$, *no matter how small*. Such *diffusion* phenomenon would occur in spite of the fact that the corresponding trajectory has to move in a space in which very close to each $\{\boldsymbol{A}\}\times\mathbb{T}^\ell$ there is an invariant surface on which points move keeping $\boldsymbol{A}$ constant within $O(\varepsilon)$, which for $\varepsilon$ small can be $\ll|\boldsymbol{A}^{\mathrm{f}}-\boldsymbol{A}^{\mathrm{i}}|$.

In *a priori* unstable systems (cf. the section "Resonances and their stability") with $s_1=1$, $s_2=0$, it is not difficult to see that the corresponding phenomenon can actually occur: the paradigmatic example (Arnol'd) is the *a priori* unstable system

$$\mathcal{H}_\varepsilon = \frac{A_1^2}{2}+A_2+\frac{p^2}{2}+g(\cos q-1) + \varepsilon(\cos\alpha_1+\sin\alpha_2)(\cos q-1) \qquad [90]$$

This is a system describing a motion of a "pendulum" ($(p, q)$ coordinates) interacting with a "rotating wheel" ($(A_1, \alpha_1)$ coordinates) and a "clock" ($(A_2, \alpha_2)$ coordinates) *a priori* unstable near the points $p = 0$, $q = 0$, $2\pi$ ($s_1 = 1$, $s_2 = 0$, $\lambda_1 = \sqrt{g}$, cf. [86]). It can be proved that on the energy surface of energy $E$ and for each $\varepsilon \neq 0$ small enough (no matter how small) there are initial data with action coordinates close to $\boldsymbol{A}^{\mathrm{i}} = (A_1^{\mathrm{i}}, A_2^{\mathrm{i}})$ with $(1/2)A_1^{\mathrm{i}2} + A_2^{\mathrm{i}}$ close to $E$ eventually evolving to a datum $\boldsymbol{A}' = (A_1', A_2')$ with $A_1'$ at a distance from $A_1^{\mathrm{f}}$ smaller than an arbitrarily prefixed distance (of course with energy $E$). Furthermore, during the whole process the pendulum energy stays close to zero within $o(\varepsilon)$ (i.e., the pendulum swings following closely the unperturbed separatrices).

In other words, [90] describes a machine (the pendulum) which, working approximately in a cycle, extracts energy from a reservoir (the clock) to transfer it to a mechanical device (the wheel). The statement that diffusion is possible means that the machine can work as soon as $\varepsilon \neq 0$, if the initial actions and the initial phases (i.e., $\alpha_1, \alpha_2, p, q$) are suitably tuned (as functions of $\varepsilon$).

The peculiarity of the system [90] is that the fixed points $P_\pm$ of the unperturbed pendulum (i.e., the equilibria $p = 0, q = 0, 2\pi$) *remain* unstable equilibria even when $\varepsilon \neq 0$ and this is an important simplifying feature.

It is a peculiarity that permits bypassing the obstacle, arising in the analysis of more general cases, represented by the resonance surfaces consisting of the $\boldsymbol{A}$'s with $A_1\nu_1 + \nu_2 = 0$: the latter correspond to harmonics $(\nu_1, \nu_2)$ present in the perturbing function, i.e., the harmonics which would lead to division by zero in an attempt to construct (as necessary in studying [90] by Arnol'd's method) the parametric equations of the perturbed invariant tori with action close to such $\boldsymbol{A}$'s. In the case of [90] the problem arises only on the resonance marked in **Figure 6** by a heavy line, i.e., $A_1 = 0$, corresponding to $\cos\alpha_1$ in [90].

If $\varepsilon = 0$, the points $P_-$ with $p = 0$, $q = 0$ and the point $P_+$ with $p = 0, q = 2\pi$ are both unstable equilibria (and they are, of course, the same point, if $q$ is an angular variable). The unstable manifold (it is a curve) of $P_+$ coincides with the stable manifold of $P_-$ and vice versa. So that the unperturbed system admits nontrivial motions leading from $P_+$ to $P_-$ and from $P_-$ to $P_+$, both in a bi-infinite time interval $(-\infty, \infty)$: the $p, q$ variables describe a pendulum and $P_\pm$ are its unstable equilibria which are connected by the separatrices (which constitute the zero-energy surfaces for the pendulum).

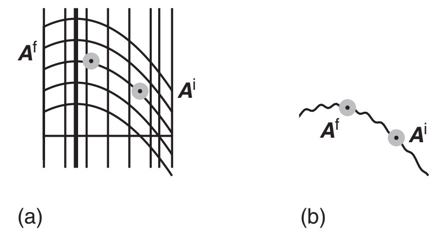

**Figure 6** (a) The $\varepsilon = 0$ geometry: the "partial energy" lines are parabolas, $(1/2)A_1^2 + A_2 = \text{const}$. The vertical lines are the resonances $A_1 = \text{rational}$ (i.e., $\nu_1 A_1 + \nu_2 = 0$). The disks are neighborhoods of the points $\boldsymbol{A}^{\mathrm{i}}$ and $\boldsymbol{A}^{\mathrm{f}}$ (the dots at their centers). (b) $\varepsilon \neq 0$; an artist's rendering of a trajectory in $\boldsymbol{A}$ space, driven by the pendulum swings to accelerate the wheel from $A_1^i$ to $A_1^f$ at the expenses of the clock energy, sneaking through invariant tori not represented and (approximately) located "away" from the intersections between resonances and partial energy lines (a dense set, however). The pendulum coordinates are not shown: its energy stays close to zero, within a power of $\varepsilon$. Hence the pendulum swings, staying close to the separatrix. The oscillations symbolize the wiggly behavior of the partial energy $(1/2)A_1^2 + A_2$ in the process of sneaking between invariant tori which, because of their invariance, would be impossible without the pendulum. The energy $(1/2)A_1^2$ of the wheel increases slightly at each pendulum swing: accurate estimates yield an increase of the wheel speed $A_1$ of the order of $\varepsilon/(\log \varepsilon^{-1})$ at each swing of the pendulum implying a transition time of the order of $g^{-1/2}\varepsilon^{-1} \log \varepsilon^{-1}$.

The latter property remains true for more general *a priori* unstable Hamiltonians

$$\mathcal{H}_\varepsilon = \mathcal{H}_0(\boldsymbol{A}) + \mathcal{H}_{\mathrm{u}}(p, q) + \varepsilon f(\boldsymbol{A}, \boldsymbol{\alpha}, p, q) \quad \text{in } (U \times \mathbb{T}^\ell) \times (\mathbb{R}^2) \qquad [91]$$

where $\mathcal{H}_{\mathrm{u}}$ is a one-dimensional Hamiltonian which has two unstable equilibrium points $P_+$ and $P_-$ linearly repulsive in one direction and linearly attractive in another which are connected by two heteroclinic trajectories which, as time tends to $\pm\infty$, approach $P_-$ and $P_+$ and vice versa.

Actually, the points need not be different but, if coinciding, the trajectories linking them must be nontrivial: in the case [90] the variable $q$ can be considered an angle and then $P_+$ and $P_-$ would coincide (but are connected by nontrivial trajectories, i.e., by trajectories that also visit points different from $P_\pm$). Such trajectories are called heteroclinic if $P_+ \neq P_-$ and homoclinic if $P_+ = P_-$.

In the general case, besides the homoclinicity (or heteroclinicity) condition, certain weak genericity conditions, automatically satisfied in the example [90], have to be imposed in order to show that, given $\boldsymbol{A}^{\mathrm{i}}$ and $\boldsymbol{A}^{\mathrm{f}}$ with the same unperturbed energy $E$, one can find, for all $\varepsilon$ small enough but not equal to zero, initial data ($\varepsilon$-dependent) with actions arbitrarily close to $\boldsymbol{A}^{\mathrm{i}}$ which evolve to data with actions arbitrarily close to $\boldsymbol{A}^{\mathrm{f}}$. This is a phenomenon

called the *Arnol'd diffusion*. Simple sufficient conditions for a transition from near $\boldsymbol{A}^{\mathrm{i}}$ to near $\boldsymbol{A}^{\mathrm{f}}$ are expressed by the following result:

**Theorem 7** *Given the Hamiltonian [91] with $\mathcal{H}_{\mathrm{u}}$ admitting two hyperbolic fixed points $P_{\pm}$ with heteroclinic connections, $t \to (p_a(t), q_a(t))$, $a = 1, 2$, suppose that:*

(i) *On the unperturbed energy surface of energy $E = \mathcal{H}(\boldsymbol{A}^{\mathrm{i}}) + \mathcal{H}_{\mathrm{u}}(P_{\pm})$ there is a regular curve $\gamma : s \to \boldsymbol{A}(s)$ joining $\boldsymbol{A}^{\mathrm{i}}$ to $\boldsymbol{A}^{\mathrm{f}}$ such that the unperturbed tori $\{\boldsymbol{A}(s)\} \times \mathbb{T}^{\ell}$ can be continued at $\varepsilon \neq 0$ into invariant tori $\mathcal{T}_{\boldsymbol{A}(s),\varepsilon}$ for a set of values of $s$ which fills the curve $\gamma$ leaving only gaps of size of order $o(\varepsilon)$.*

(ii) *The $\ell \times \ell$ matrix $D_{ij}$ of the second derivatives of the integral of $f$ over the heteroclinic motions is not degenerate, that is,*

$$|\det D| = \left| \det \left( \int_{-\infty}^{\infty} \mathrm{d}t \; \partial_{\alpha_i \alpha_j} f(\boldsymbol{A}, \boldsymbol{\alpha} + \boldsymbol{\omega}(\boldsymbol{A})t, p_a(t), q_a(t)) \right) \right| > c > 0 \qquad [92]$$

*for all $\boldsymbol{A}$'s on the curve $\gamma$ and all $\boldsymbol{\alpha} \in \mathbb{T}^2$.*

*Given arbitrary $\rho > 0$, for $\varepsilon \neq 0$ small enough there are initial data with action and energy closer than $\rho$ to $\boldsymbol{A}^{\mathrm{i}}$ and $E$, respectively, which after a long enough time acquire an action closer than $\rho$ to $\boldsymbol{A}^{\mathrm{f}}$ (keeping the initial energy).*

The above two conditions can be shown to hold generically for many pairs $\boldsymbol{A}^{\mathrm{i}} \neq \boldsymbol{A}^{\mathrm{f}}$ (and many choices of the curves $\gamma$ connecting them) if the number of degrees of freedom is $\geq 3$. Thus, the result, obtained by a simple extension of the argument originally outlined by Arnol'd to discuss the paradigmatic example [90], proves the existence of diffusion in *a priori* unstable systems. The integral in [92] is called *Melnikov integral*.

The real difficulty is to estimate the time needed for the transition: it is a time that obviously has to diverge as $\varepsilon \to 0$. Assuming $g$ fixed (i.e., $\varepsilon$ independent) a naive approach easily leads to estimates which can even be worse than $O(\exp(a\varepsilon^{-b}))$ with some $a, b > 0$. It has finally been shown that in such cases the minimum time can be, for rather general perturbations $\varepsilon f(\boldsymbol{\alpha}, q)$, estimated above by $O(\varepsilon^{-1} \log \varepsilon^{-1})$, which is the best that can be hoped for under generic assumptions.

The reader is referred to Arnol'd (1989) and Chierchia and Valdinoci (2000) for more details.

## Long-Time Stability of Quasiperiodic Motions

A more difficult problem is whether the same phenomenon of migration in action space occurs in *a priori* stable systems. The root of the difficulty is a remarkable stability property of quasiperiodic motions. Consider Hamiltonians $\mathcal{H}_{\varepsilon}(\boldsymbol{A}, \boldsymbol{\alpha}) = h(\boldsymbol{A}) + \varepsilon f(\boldsymbol{A}, \boldsymbol{\alpha})$ with $\mathcal{H}_0(\boldsymbol{A}) = h(\boldsymbol{A})$ strictly convex, analytic, and anisochronous on the closure $\overline{U}$ of an open bounded region $U \subset \mathbb{R}^{\ell}$, and a perturbation $\varepsilon f(\boldsymbol{A}, \boldsymbol{\alpha})$ analytic in $\overline{U} \times \mathbb{T}^{\ell}$.

Then *a priori* bounds are available on how long it can possibly take to migrate from an action close to $\boldsymbol{A}_1$ to one close to $\boldsymbol{A}_2$: and the bound is of "exponential type" as $\varepsilon \to 0$ (i.e., it admits a lower bound which behaves as the exponential of an inverse power of $\varepsilon$). The simplest theorem is (Nekhorossev):

**Theorem 7** *There are constants $0 < a, b, d, g, \tau$ such that any initial datum $(\boldsymbol{A}, \boldsymbol{\alpha})$ evolves so that $\boldsymbol{A}$ will not change by more than $a\varepsilon^g$ before a long time bounded below by $\tau \exp(b\varepsilon^{-d})$.*

Thus, this puts an exponential bound, i.e., a bound exponential in an inverse power of $\varepsilon$, to the diffusion time: before a time $\tau \exp(b\varepsilon^{-d})$ actions can only change by $O(\varepsilon^g)$ so that their variation cannot be large no matter how small $\varepsilon \neq 0$ is chosen. This places a (long) lower bound to the time of diffusion in *a priori* stable systems.

The proof of the theorem provides, actually, an interesting and detailed picture of the variations in actions showing that some actions may vary more slowly than others.

The theorem is constructive, i.e., all constants $0 < a, b, d, \tau$ can be explicitly chosen and depend on $\ell, \mathcal{H}_0, f$ although some of them can be fixed to depend only on $\ell$ and on the minimum curvature of the convex graph of $\mathcal{H}_0$. Its proof can be adapted to cover many cases which do not fall in the class of systems with strictly convex unperturbed Hamiltonian, and even to cases with a resonant unperturbed Hamiltonian.

However, in important problems (e.g., in the three-body problems met in celestial mechanics) there is empirical evidence that diffusion takes place at a fast pace (i.e., not exponentially slow in the above sense) while the above results would forbid a rapid migration in phase space if they applied: however, in such problems the assumptions of the theorem are not satisfied, because the unperturbed system is strongly resonant (as in the celestial mechanics problems, where the number of independent frequencies is a fraction of the number

of degrees of freedom and $h(\boldsymbol{A})$ is far from strictly convex), leaving wide open the possibility of observing rapid diffusion.

Further, changing the assumptions can dramatically change the results. For instance, rapid diffusion can sometimes be proved even though it might be feared that it should require exponentially long times: an example that has been proposed is the case of a three-timescales system, with Hamiltonian

$$\omega_1 A_1 + \omega_2 A_2 + \frac{p^2}{2} + g(1+\cos q) + \varepsilon f(\alpha_1, \alpha_2, p, q) \qquad [93]$$

with $\boldsymbol{\omega}_\varepsilon \stackrel{\text{def}}{=} (\omega_1, \omega_2)$, where $\omega_1 = \varepsilon^{-1/2}\overline{\omega}$, $\omega_2 = \varepsilon^{1/2}\widetilde{\omega}$ and $\overline{\omega}, \widetilde{\omega} > 0$ constants. The three scales are $\omega_1^{-1}$, $\sqrt{g^{-1}}$, $\omega_2^{-1}$. In this case, there are many (although by no means all) pairs $\boldsymbol{A}_1, \boldsymbol{A}_2$ which can be connected within a time that can be estimated to be of order $O(\varepsilon^{-1}\log\varepsilon^{-1})$.

This is a rapid-diffusion case in an *a priori* unstable system in which condition [92] is not satisfied: because the $\varepsilon$-dependence of $\boldsymbol{\omega}(\boldsymbol{A})$ implies that the lower bound $c$ in [92] must depend on $\varepsilon$ (and be exponentially small with an inverse power of $\varepsilon$ as $\varepsilon \to 0$).

The unperturbed system in [93] is nonresonant in the $\mathcal{H}_0$ part for $\varepsilon > 0$ outside a set of zero measure (i.e., where the vector $\boldsymbol{\omega}_\varepsilon$ satisfies a suitable Diophantine property) and, furthermore, it is *a priori* unstable: cases met in applications can be *a priori* stable and resonant (and often not anisochronous) in the $\mathcal{H}_0$ part. In such a system, not only the speed of diffusion is not understood but proposals to prove its existence, if present (as expected), have so far not given really satisfactory results.

For more details, the reader in referred to Nekhorossev (1977).

## The Three-Body Problem

Mechanics and the three-body problem can be almost identified with each other, in the sense that the motion of three gravitating masses has long been a key astronomical problem and at the same time the source of inspiration for many techniques: foremost among them the theory of perturbations.

As an introduction, consider a special case. Let three masses $m_S = m_0$, $m_J = m_1$, $m_M = m_2$ interact via gravity, that is, with interaction potential $-km_i m_j |\boldsymbol{x}_i - \boldsymbol{x}_j|^{-1}$: the simplest problem arises when the third body has a neglegible mass compared to the two others and the latter are supposed to be on a circular orbit; furthermore, the mass $m_J$ is $\varepsilon m_S$ with $\varepsilon$ small and the mass $m_M$ moves in the plane of the circular orbit. This will be called the "circular restricted three-body problem."

In a reference system with center $S$ and rotating at the angular speed of $J$ around $S$ inertial forces (centrifugal and Coriolis) act. Supposing that the body $J$ is located on the axis with unit vector $\boldsymbol{i}$ at distance $R$ from the origin $S$, the acceleration of the point $M$ is

$$\ddot{\varrho} = \boldsymbol{F} + \omega_0^2\left(\varrho - \frac{\varepsilon R}{1+\varepsilon}\boldsymbol{i}\right) - 2\boldsymbol{\omega}_0 \wedge \dot{\varrho}$$

if $\boldsymbol{F}$ is the force of attraction and $\boldsymbol{\omega}_0 \wedge \dot{\varrho} \equiv \omega_0 \dot{\varrho}^\perp$ where $\boldsymbol{\omega}_0$ is a vector with $|\boldsymbol{\omega}_0| = \omega_0$ and perpendicular to the orbital plane and $\varrho^\perp \stackrel{\text{def}}{=} (-\rho_2, \rho_1)$ if $\varrho = (\rho_1, \rho_2)$. Here, taking into account that the origin $S$ rotates around the fixed center of mass, $\omega_0^2(\varrho - \varepsilon R/(1+\varepsilon)\boldsymbol{i})$ is the centrifugal force while $-2\boldsymbol{\omega}_0 \wedge \dot{\varrho}$ is the Coriolis force. The equations of motion can therefore be derived from a Lagrangian

$$\mathcal{L} = \frac{1}{2}\dot{\varrho}^2 - W + \omega_0 \varrho^\perp \cdot \dot{\varrho} + \frac{1}{2}\omega_0^2 \varrho^2 - \omega_0^2 \frac{\varepsilon R}{1+\varepsilon}\varrho \cdot \boldsymbol{i} \qquad [94]$$

with

$$\omega_0^2 R^3 = km_S(1+\varepsilon) \stackrel{\text{def}}{=} g_0$$
$$W = -\frac{km_S}{|\varrho|} - \frac{km_S\varepsilon}{|\varrho - R\boldsymbol{i}|}$$

where $k$ is the gravitational constant, $R$ the distance between $S$ and $J$, and finally the last three terms in [94] come from the Coriolis force (the first) and from the centripetal force (the other two, taking into account that the origin $S$ rotates around the fixed center of mass).

Setting $g = g_0/(1+\varepsilon) \equiv km_S$, the Hamiltonian of the system is

$$\mathcal{H} = \frac{1}{2}(\boldsymbol{p} - \omega_0 \varrho^\perp)^2 - \frac{g}{|\varrho|} - \frac{1}{2}\omega_0^2\varrho^2 - \varepsilon\frac{g}{R}\left(\left|\frac{\varrho}{R} - \boldsymbol{i}\right|^{-1} - \frac{\varrho}{R}\cdot\boldsymbol{i}\right) \qquad [95]$$

The first part can be expressed immediately in the action–angle coordinates for the two-body problem (cf. the section "Newtonian potential and Kepler's laws"). Calling such coordinates $(L_0, \lambda_0, G_0, \gamma_0)$ and $\theta_0$ the polar angle of $M$ with respect to the major axis of the ellipse and $\lambda_0$ the mean anomaly of $M$ on its ellipse, the Hamiltonian becomes, taking into account that for $\varepsilon = 0$ the ellipse axis rotates at speed $-\omega_0$,

$$\mathcal{H} = -\frac{g^2}{2L_0^2} - \omega_0 G_0 - \varepsilon\frac{g}{R}\left(\left|\frac{\varrho}{R} - \boldsymbol{i}\right|^{-1} - \frac{\varrho}{R}\cdot\boldsymbol{i}\right) \qquad [96]$$

which is convenient if we study the interior problem, i.e., $|\varrho| < R$. This can be expressed in the action–angle coordinates via [41], [42]:

$$\theta_0 = \lambda_0 + f_{\lambda_0}, \qquad \theta_0 + \gamma_0 = \lambda_0 + \gamma_0 + f_{\lambda_0}$$
$$e = \left(1 - \frac{G_0^2}{L_0^2}\right)^{1/2}, \quad \frac{|\varrho|}{R} = \frac{G_0^2}{gR} \frac{1}{1 + e\cos(\lambda_0 + f_{\lambda_0})} \qquad [97]$$

where (see [42]), $f_\lambda = f(e\sin\lambda, e\cos\lambda)$ and

$$f(x, y) = 2x\left(1 + \frac{5}{4}y + \cdots\right)$$

with the ellipsis denoting higher orders in $x, y$ even in $x$. The Hamiltonian takes the form, if $\omega^2 = gR^{-3}$,

$$\mathcal{H}_\varepsilon = -\frac{g^2}{2L_0^2} - \omega G_0 + \varepsilon \frac{g}{R} F(G_0, L_0, \lambda_0, \lambda_0 + \gamma_0) \qquad [98]$$

where the only important feature (for our purposes) is that $F(L, G, \alpha, \beta)$ is an analytic function of $L, G, \alpha, \beta$ near a datum with $|G| < L$ (i.e., $e > 0$) and $|\varrho| < R$. However, the domain of analyticity in $G$ is rather small as it is constrained by $|G| < L$ excluding in particular the circular orbit case $G = \pm L$.

Note that apparently the KAM theorem fails to be applicable to [98] because the matrix of the second derivatives of $\mathcal{H}_0(L, G)$ has vanishing determinant. Nevertheless, the proof of the theorem also goes through in this case, with minor changes. This can be checked by studying the proof or, following a remark by Poincaré, by simply noting that the "squared" Hamiltonian $\mathcal{H}'_\varepsilon \stackrel{\text{def}}{=} (\mathcal{H}_\varepsilon)^2$ has the form

$$\mathcal{H}'_\varepsilon = \left(-\frac{g^2}{2L_0^2} - \omega G_0\right)^2 + \varepsilon F'(G_0, L_0, \lambda_0, \lambda_0 + \gamma_0) \qquad [99]$$

with $F'$ still analytic. *But* this time

$$\det \frac{\partial^2 \mathcal{H}'_0}{\partial(G_0, L_0)} = -6g^2 L_0^{-4} \omega_0^2 h \neq 0$$
$$\text{if } h = -g^2 L_0^{-2} - 2\omega G_0 \neq 0$$

Therefore, the KAM theorem applies to $\mathcal{H}'_\varepsilon$ and the key observation is that the orbits generated by the Hamiltonian $(\mathcal{H}_\varepsilon)^2$ are geometrically the same as those generated by the Hamiltonian $\mathcal{H}_\varepsilon$: they are only run at a different speed because of the need of a time rescaling by the constant factor $2\mathcal{H}_\varepsilon$.

This shows that, given an unperturbed ellipse of parameters $(L_0, G_0)$ such that $\boldsymbol{\omega} = (g^2/L_0^3, -\omega)$, $G_0 > 0$, with $\omega_1/\omega_2$ Diophantine, then the perturbed system admits a motion which is quasiperiodic with spectrum proportional to $\boldsymbol{\omega}$ and takes place on an orbit which wraps around a torus remaining forever close to the unperturbed torus (which can be visualized as described by a point moving, according to the area law on an ellipse rotating at a rate $-\omega_0$) with actions $(L_0, G_0)$, provided $\varepsilon$ is small enough. Hence,

> The KAM theorem answers, at least conceptually, the classical question: can a solution of the three-body problem remain close to an unperturbed one forever? That is, is it possible that a solar system is stable forever?

Assuming $e, |\varrho|/R \ll 1$ and retaining only the lowest orders in $e$ and $|\varrho|/R \ll 1$ the Hamiltonian [98] simplifies into

$$\mathcal{H} = -\frac{g^2}{2L_0^2} - \omega G_0 + \delta_\varepsilon(G_0) - \frac{\varepsilon g}{2R} \frac{G_0^4}{g^2 R^2}\Big(3\cos 2(\lambda_0 + \gamma_0)$$
$$- e\cos\lambda_0 - \frac{9}{2} e\cos(\lambda_0 + 2\gamma_0)$$
$$+ \frac{3}{2} e\cos(3\lambda_0 + 2\gamma_0)\Big) \qquad [100]$$

where

$$\delta_\varepsilon(G_0) = -((1+\varepsilon)^{1/2} - 1)\omega G_0 - \frac{\varepsilon g}{2R} \frac{G_0^4}{g^2 R^2}$$
$$e = \left(1 - \frac{G_0^2}{L_0^2}\right)^{1/2}$$

It is an interesting exercise to estimate, assuming as model the Hamiltonian [100] and following the proof of the KAM theorem, how small has $\varepsilon$ to be if a planet with the data of Mercury can be stable forever on a (slowly precessing) orbit with actions close to the present-day values under the influence of a mass $\varepsilon$ times the solar mass orbiting on a circle, at a distance from the Sun equal to that of Jupiter. It is possible to follow either the above reduction to the ordinary KAM theorem or to apply directly to [100] the Lindstedt series expansion, proceeding along the lines of the section "Quasiperiodicity and KAM stability." The first approach is easy but the second is more efficient: in both cases, unless the estimates are done in a particularly careful manner, the value found for $\varepsilon m_S$ is not interesting from the viewpoint of astronomy.

The reader is refered to Arnol'd (1989) for more details.

## Rationalization and Regularization of Singularities

Often integrable systems have interesting data which lie on the boundary of the integrability domain. For instance, the central motion when $L = G$ (circular orbits) or the rigid body in a rotation around one of the principal axes or the two-body problem when $G = 0$ (collisional data). In such cases, perturbation

theory cannot be applied as discussed above. Typically, the perturbation depends on quantities like $\sqrt{L-G}$ and is *not analytic* at $L=G$. Nevertheless, it is sometimes possible to enlarge phase space and introduce new coordinates in the vicinity of the data which in the initial phase space are singular.

A notable example is the failure of the analysis of the circular restricted three-body problem: it apparently fails when the orbit that we want to perturb is circular.

It is convenient to introduce the canonical coordinates $L, \lambda$ and $G, \gamma$:

$$\begin{aligned} L &= L_0, \qquad G = L_0 - G_0 \\ \lambda &= \lambda_0 + \gamma_0, \qquad \gamma = -\gamma_0 \end{aligned} \qquad [101]$$

so that $e = \sqrt{2GL^{-1}}\sqrt{1-G(2L)^{-1}}$ and $\lambda_0 = \lambda + \gamma$ and $\theta_0 = \lambda_0 + f_{\lambda_0}$, where $f_{\lambda_0}$ is defined in [42] (see also [97]). Hence,

$$\begin{aligned} &\theta_0 = \lambda + \gamma + f_{\lambda+\gamma}, \qquad \theta_0 + \gamma_0 = \lambda + f_{\lambda+\gamma} \\ &e = \sqrt{2G}\sqrt{\frac{1}{L}\left(1 - \frac{G}{2L}\right)} \\ &\frac{|\varrho|}{R} = \frac{L^2(1-e^2)}{gR}\frac{1}{1+e\cos(\lambda+\gamma+f_{\lambda+\gamma})} \end{aligned} \qquad [102]$$

and the Hamiltonian [100] takes the form

$$\begin{aligned} \mathcal{H}_\varepsilon = &-\frac{g^2}{2L^2} - \omega L + \omega G \\ &+ \varepsilon\frac{g}{R}F(L-G, L, \lambda+\gamma, \lambda) \end{aligned} \qquad [103]$$

In the coordinates $L$,$G$ of [101] the unperturbed circular case corresponds to $G=0$ and [96], once expressed in the action–angle variables $G, L, \gamma, \lambda$, is analytic in a domain whose size is controlled by $\sqrt{G}$. Nevertheless, very often problems of perturbation theory can be "regularized."

This is done by "enlarging the integrability" domain by adding to it points (one or more) around the singularity (a boundary point of the domain of the coordinates) and introducing new coordinates to describe simultaneously the data close to the singularity and the newly added points: in many interesting cases, the equations of motion are no longer singular (i.e., become analytic) in the new coordinates and are therefore apt to describe the motions that reach the singularity in a finite time. One can say that the singularity was only apparent.

Perhaps this is best illustrated precisely in the above circular restricted three-body problem, with the singularity occurring where $G=0$, that is, at a circular unperturbed orbit. If we describe the points with $G$ small in a new system of coordinates obtained from the one in [101] by letting alone $L, \lambda$ and setting

$$p = \sqrt{2G}\cos\gamma, \qquad q = \sqrt{2G}\sin\gamma \qquad [104]$$

then $p$, $q$ vary in a neighborhood of the origin with the origin itself excluded.

Adding the origin of the $p$–$q$ plane then in a full neighborhood of the origin, the Hamiltonian [96] is analytic in $L, \lambda, p, q$. This is because it is analytic (cf. [96], [97]) as a function of $L, \lambda$ and $e\cos\theta_0$ and of $\cos(\lambda_0+\theta_0)$. Since $\theta_0 = \lambda+\gamma+f_{\lambda+\gamma}$ and $\theta_0+\lambda_0 = \lambda+f_{\lambda+\gamma}$ by [97], the Hamiltonian [96] is analytic in $L, \lambda, e\cos(\lambda+\gamma+f_{\lambda+\gamma})$, $\cos(\lambda+f_{\lambda+\gamma})$ for $e$ small (i.e., for $G$ small) and, by [42], $f_{\lambda+\gamma}$ is analytic in $e\sin(\lambda+\gamma)$ and $e\cos(\lambda+\gamma)$. Hence the trigonometric identities

$$\begin{aligned} e\sin(\lambda+\gamma) &= \frac{p\sin\lambda + q\cos\lambda}{\sqrt{L}}\sqrt{1-\frac{G}{2L}} \\ e\cos(\lambda+\gamma) &= \frac{p\cos\lambda - q\sin\lambda}{\sqrt{L}}\sqrt{1-\frac{G}{2L}} \end{aligned} \qquad [105]$$

together with $G=(1/2)(p^2+q^2)$ imply that [103] is analytic near $p=q=0$ and $L>0, \lambda\in[0,2\pi]$. The Hamiltonian becomes analytic and the new coordinates are suitable to describe motions crossing the origin: for example, by setting

$$C \stackrel{\text{def}}{=} \frac{1}{2}\left(1 - \frac{p^2+q^2}{4L}\right)L^{-1/2}$$

[100] becomes

$$\begin{aligned} \mathcal{H} = &-\frac{g^2}{2L^2} - \omega L + \omega\tfrac{1}{2}(p^2+q^2) \\ &+ \delta_\varepsilon(\tfrac{1}{2}(p^2+q^2)) - \frac{\varepsilon g}{2R}\frac{(L-\frac{1}{2}(p^2+q^2))^4}{g^2R^2} \\ &\times (3\cos 2\lambda - ((-11\cos\lambda + 3\cos 3\lambda)p \\ &- (7\sin\lambda + 3\sin 3\lambda)q)C) \end{aligned} \qquad [106]$$

The KAM theorem does not apply in the form discussed above to "Cartesian coordinates," that is, when, as in [106], the unperturbed system is not assigned in action–angle variables. However, there are versions of the theorem (actually its corollaries) which do apply and therefore it becomes possible to obtain some results even for the perturbations of circular motions by the techniques that have been illustrated here.

Likewise, the Hamiltonian of the rigid body with a fixed point $O$ and subject to analytic external forces becomes singular, if expressed in the action–angle coordinates of Deprit, when the body motion nears a rotation around a principal axis or, more generally, nears a configuration in which any two of

the axes $\boldsymbol{i}_3, \boldsymbol{z}$, or $\boldsymbol{z}_0$ coincide (i.e., any two among the principal axis, the angular momentum axis and the inertial $z$-axis coincide; see the section "Rigid body"). Nevertheless, by imitating the procedure just described in the simpler cases of the circular three-body problem, it is possible to enlarge the phase space so that in the new coordinates the Hamiltonian is analytic near the singular configurations.

A regularization also arises when considering collisional orbits in the unrestricted planar three-body problem. In this respect, a very remarkable result is the regularization of collisional orbits in the planar three-body problem. After proving that if the total angular momentum does not vanish, simultaneous collisions of the three masses cannot occur within any finite time interval, the question is reduced to the regularization of two-body collisions, under the assumption that the total angular momentum does not vanish.

The local change of coordinates, which changes the relative position coordinates $(x, y)$ of two colliding bodies as $(x, y) \to (\xi, \eta)$, with $x + iy = (\xi + i\eta)^2$, is not one to one, hence it has to be regarded as an enlargement of the positions space, if points with different $(\xi, \eta)$ are considered different. However, the equations of motion written in the variables $\xi, \eta$ have no singularity at $\xi, \eta = 0$ (Levi-Civita).

Another celebrated regularization is the regularization of the Schwartzschild metric, i.e., of the general relativity version of the two-body problem: it is, however, somewhat out of the scope of this review (Synge, Kruskal).

For more details, the reader is refered to Levi-Civita (1956).

## Appendix 1: KAM Resummation Scheme

The idea to control the "remaining contributions" is to reduce the problem to the case in which there are no pairs of lines that follow each other in the tree order and which have the same current. Mark by a scale label "0" the lines, see [74], [83], of a tree whose divisors $C/\boldsymbol{\omega}_0.\boldsymbol{\nu}(l)$ are >1: these are lines which give no problems in the estimates. Then mark by a scale label "≥1" the lines with current $\boldsymbol{\nu}(l)$ such that $|\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l)| \le 2^{-n+1}$ for $n = 1$ (i.e., the remaining lines).

The lines labeled 0 are said to be on scale 0, while those labeled ≥1 are said to be on scale ≥1. A cluster of scale 0 will be a maximal collection of lines of scale 0 forming a connected subgraph of a tree $\theta$.

Consider only trees $\theta_0 \in \Theta_0$ of the family $\Theta_0$ of trees containing no clusters of lines with scale label 0 which have only one line entering the cluster and one exiting it with equal current.

It is useful to introduce the notion of a line $\ell_1$ situated "between" two lines $\ell, \ell'$ with $\ell' > \ell$: this will mean that $\ell_1$ precedes $\ell'$ but not $\ell$.

All trees $\theta$ in which there are some pairs $l' > l$ of consecutive lines of scale label ≥1 which have equal current and such that all lines between them bear scale label 0 are obtained by "inserting" on the lines of trees in $\Theta_0$ with label ≥1 any number of clusters of lines and nodes, with lines of scale 0 and with the property that the sum of the harmonics of the nodes inserted vanishes.

Consider a line $l_0 \in \theta_0 \in \Theta_0$ linking nodes $v_1 < v_2$ and labeled ≥1 and imagine inserting on it a cluster $\gamma$ of lines of scale 0 with sum of the node harmonics vanishing and out of which emerges one line connecting a node $v_{\rm out}$ in $\gamma$ to $v_2$ and into which enters one line linking $v_1$ to a node $v_{\rm in} \in \gamma$. The insertion of a $k$–lines, $|\gamma| = (k+1)$-nodes, cluster changes the tree value by replacing the line factor, that will be briefly called "value of the cluster $\gamma$", as

$$\frac{\boldsymbol{\nu}_{v_1} \cdot \boldsymbol{\nu}_{v_2}}{\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l_0)^2} \to \frac{(\boldsymbol{\nu}_{v_1} \cdot M(\gamma; \boldsymbol{\nu}(l_0))\boldsymbol{\nu}_{v_2})}{\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l_0)^2} \frac{1}{\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l_0)^2} \quad [107]$$

where $M$ is an $\ell \times \ell$ matrix

$$M_{rs}(\gamma, \boldsymbol{\nu}(l_0)) = \frac{\varepsilon^{|\gamma|}}{k!} \nu_{out,r} \nu_{in,s} \prod_{v \in \gamma} (-f_{\boldsymbol{\nu}_v}) \prod_{l \in \gamma} \frac{\boldsymbol{\nu}_v \cdot \boldsymbol{\nu}_{v'}}{\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l)^2}$$

if $\ell = v'v$ denotes a line linking $v'$ and $v$. Therefore, if all possible connected clusters are inserted and the resulting values are added up, the result can be taken into account by attributing to the original line $l_0$ a factor like [107] with $M^{(0)}(\boldsymbol{\nu}(l_0)) \stackrel{\rm def}{=} \sum_\gamma M(\gamma; \boldsymbol{\nu}(l_0))$ replacing $M(\gamma; \boldsymbol{\nu}(l_0))$.

If several connected clusters $\gamma$ are inserted on the same line and their values are summed, the result is a modification of the factor associated with the line $l_0$ into

$$\sum_{k=0}^{\infty} \boldsymbol{\nu}_{v_1} \cdot \left( \frac{M^{(0)}(\boldsymbol{\nu}(l_0))}{\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l_0)^2} \right)^k \boldsymbol{\nu}_{v_2} \frac{1}{\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l_0)^2}$$
$$= \left( \boldsymbol{\nu}_{v_1} \cdot \frac{1}{\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l_0)^2 - M^{(0)}(\boldsymbol{\nu}(l_0))} \boldsymbol{\nu}_{v_2} \right) \quad [108]$$

The series defining $M^{(0)}$ involves, by construction, only trees with lines of scale 0, hence with large divisors, so that it converges to a matrix of small size of order $\varepsilon$ (actually $\varepsilon^2$, more precisely) if $\varepsilon$ is small enough.

Convergence can be established by simply remarking that the series defining $M^{(1)}$ is built with lines with values >(1/2) of the propagator, so that it certainly converges for $\varepsilon$ small enough (by the estimates in the section "Perturbing functions," where the propagators were identically 1) and the

sum is of order $\varepsilon$ (actually $\varepsilon^2$), hence <1. However, such an argument cannot be repeated when dealing with lines with smaller propagators (which still have to be discussed). Therefore, a method not relying on so trivial a remark on the size of the propagators has eventually to be used when considering lines of scale higher than 1, as it will soon become necessary.

The advantage of the collection of terms achieved with [108] is that we can represent $\boldsymbol{h}$ as a sum of values of trees which are simpler because they contain no pair of lines of scale $\geq 1$ with in between lines of scale 0 with total sum of the node harmonics vanishing. The price is that the divisors are now more involved and we even have a problem due to the fact that we have not proved that the series in [108] converges. In fact, it is a geometric series whose value is the RHS of [108] obtained by the sum rule [79] unless we can prove that the ratio of the geometric series is <1. This is trivial in this case by the previous remark: but it is better to note that there is another reason for convergence, whose use is not really necessary here but will become essential later.

The property that the ratio of the geometric series is <1 can be regarded as due to the consequence of the cancellation mentioned in the section "Quasi-periodicity and KAM stability" which can be shown to imply that the ratio is <1 because $M^{(0)}(\boldsymbol{\nu}) = \varepsilon^2(\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu})^2 m^{(0)}(\boldsymbol{\nu})$ with $C\,|m^{(0)}(\boldsymbol{\nu})| < D_0$ for some $D_0 > 0$ and for all $|\varepsilon| < \varepsilon_0$ for some $\varepsilon_0$. Then for small $\varepsilon$ the divisor in [108] is essentially still what it was before starting the resummation.

At this point, an induction can be started. Consider trees evaluated with the new rule and place a scale level "$\geq 2$" on the lines with $C\,|\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l)| \leq 2^{-n+1}$ for $n = 2$: leave the label "0" on the lines already marked so and label by "1" the other lines. The lines of scale "1" will satisfy $2^{-n} < |\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(l)| \leq 2^{-n+1}$ for $n = 1$. The graphs will now possibly contain lines of scale 0, 1 or $\geq 2$ while lines with label "$\geq 1$" no longer can appear, by construction.

A cluster of scale 1 will be a maximal collection of lines of scales 0, 1 forming a connected subgraph of a tree $\theta$ and containing at least one line of scale 1.

The construction carried out by considering clusters of scale 0 can be repeated by considering trees $\theta_1 \in \Theta_1$, with $\Theta_1$ the collection of trees with lines marked 0, 1, or $\geq 2$ and in which no pairs of lines with equal momentum appear to follow each other if between them there are only lines marked 0 or 1.

Insertion of connected clusters $\gamma$ of such lines on a line $l_0$ of $\theta_1$ leads to define a matrix $M^{(1)}$ formed by summing tree values of clusters $\gamma$ with lines of scales 0 or 1 evaluated with the line factors defined in [107] and with the restriction that in $\gamma$ there are no pairs of lines $\ell < \ell'$ with the same current and which follow each other while any line between them has lower scale (i.e., 0), here "between" means "preceding $l'$ but not preceding $l$," as above.

Therefore, a scale-independent method has to be devised to check the convergence for $M^{(1)}$ and for the matrices to be introduced later to deal with even smaller propagators. This is achieved by the following extension of Siegel's theorem mentioned in the section "Quasiperiodicity and KAM stability":

**Theorem 8** *Let $\boldsymbol{\omega}_0$ satisfy [74] and set $\boldsymbol{\omega} = C\boldsymbol{\omega}_0$. Consider the contribution to the sum in [82] from graphs $\theta$ in which*

(i) *no pairs $\ell' > \ell$ of lines which lie on the same path to the root carry the same current $\boldsymbol{\nu}$ if all lines $\ell_1$ between them have current $\boldsymbol{\nu}(\ell_1)$ such that $|\boldsymbol{\omega} \cdot \boldsymbol{\nu}(\ell_1)| > 2|\boldsymbol{\omega} \cdot \boldsymbol{\nu}|$;*
(ii) *the node harmonics are bounded by $|\boldsymbol{\nu}| \leq N$ for some $N$.*

*Then the number of lines $\ell$ in $\theta$ with divisor $\boldsymbol{\omega} \cdot \boldsymbol{\nu}_\ell$ satisfying $2^{-n} < |\boldsymbol{\omega} \cdot \boldsymbol{\nu}_\ell| \leq 2^{-n+1}$ does not exceed $4\,Nk2^{-n/\tau}$, $n = 1, 2, \ldots$.*

This implies, by the same estimates in [85], that the series defining $M^{(1)}$ converges. Again, it must be checked that there are cancellations implying that $M^{(1)}(\boldsymbol{\nu}) = \varepsilon^2(\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu})^2 m^{(1)}(\boldsymbol{\nu})$ with $|m^{(1)}(\boldsymbol{\nu})| < D_0$ for the same $D_0 > 0$ and the same $\varepsilon_0$.

At this point, one deals with trees containing only lines carrying labels $0, 1, \geq 2$, and the line factors for the lines $\ell = v'v$ of scale 0 are $\boldsymbol{\nu}_{v'} \cdot \boldsymbol{\nu}_v / (\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(\ell))^2$, those of the lines $\ell = v'v$ of scale 1 have line factors $\boldsymbol{\nu}_{v'} \cdot (\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(\ell)^2 - M^{(0)}(\boldsymbol{\nu}(\ell)))^{-1}\boldsymbol{\nu}_v$, and those of the lines $\ell = v'v$ of scale $\geq 2$ have line factors

$$\boldsymbol{\nu}_{v'} \cdot (\boldsymbol{\omega}_0 \cdot \boldsymbol{\nu}(\ell)^2 - M^{(1)}(\boldsymbol{\nu}(\ell)))^{-1}\boldsymbol{\nu}_v$$

*Furthermore*, no pair of lines of scale "1" or of scale "$\geq 2$" with the same momentum and with only lines of lower scale (i.e., of scale "0" in the first case or of scale "0", "1" in the second) between them can follow each other.

This procedure can be iterated until, after infinitely many steps, the problem is reduced to the evaluation of tree values in which each line carries a scale label $n$ and there are no pairs of lines which follow each other and which have only lines of lower scale in between. Then the Siegel argument applies once more and the series so resumed is an absolutely convergent series of functions analytic in $\varepsilon$: hence the original series is convergent.

Although at each step there is a lower bound on the denominators, it would not be possible to avoid using Siegel's theorem. In fact, the lower bound would become worse and worse as the scale increases. In order to check

the estimates of the constants $D_0, \varepsilon_0$ which control the scale independence of the convergence of the various series, it is necessary to take advantage of the theorem, and of the absence (at each step) of the necessity of considering trees with pairs of consecutive lines with equal momentum and intermediate lines of higher scale.

One could also perform the analysis by bounding $h^{(k)}$ order by order with no resummations (i.e., without changing the line factors) and exhibiting the necessary cancellations. Alternatively, the paths that Kolmogorov, Arnol'd and Moser used to prove the first three (somewhat different) versions of the theorem, by successive approximations of the equations for the tori, can be followed.

The invariant tori are Lagrangian manifolds just as the unperturbed ones (cf. comments after [31]) and, in the case of the Hamiltonian [80], the generating function $\boldsymbol{A} \cdot \boldsymbol{\psi} + \Phi(\boldsymbol{A}, \boldsymbol{\psi})$ can be expressed in terms of their parametric equations

$$\begin{aligned}
&\Phi(\boldsymbol{A}, \boldsymbol{\psi}) = G(\boldsymbol{\psi}) + \boldsymbol{a} \cdot \boldsymbol{\psi} + \boldsymbol{h}(\boldsymbol{\psi}) \cdot (\boldsymbol{A} - \boldsymbol{\omega} - \Delta \boldsymbol{h}(\boldsymbol{\psi})) \\
&\partial_{\boldsymbol{\psi}} G(\boldsymbol{\psi}) \stackrel{\text{def}}{=} -\Delta \boldsymbol{h}(\boldsymbol{\psi}) + \underset{\sim}{h}(\boldsymbol{\psi}) \partial_{\boldsymbol{\psi}} \Delta \underset{\sim}{h}(\boldsymbol{\psi}) - \boldsymbol{a} \\
&\boldsymbol{a} \stackrel{\text{def}}{=} \int (-\Delta \boldsymbol{h}(\boldsymbol{\psi}) + \underset{\sim}{h}(\boldsymbol{\psi}) \partial_{\boldsymbol{\psi}} \Delta \underset{\sim}{h}(\boldsymbol{\psi})) \frac{\mathrm{d}\boldsymbol{\psi}}{(2\pi)^{\ell}} \\
&\quad = \int \underset{\sim}{h}(\boldsymbol{\psi}) \partial_{\boldsymbol{\psi}} \Delta \underset{\sim}{h}(\boldsymbol{\psi}) \frac{\mathrm{d}\boldsymbol{\psi}}{(2\pi)^{\ell}}
\end{aligned} \qquad [109]$$

where $\Delta = (\boldsymbol{\omega} \cdot \boldsymbol{\partial}_{\boldsymbol{\psi}})$ and the invariant torus corresponds to $\boldsymbol{A}' = \boldsymbol{\omega}$ in the map $\boldsymbol{\alpha} = \boldsymbol{\psi} + \boldsymbol{\partial}_{\boldsymbol{A}} \boldsymbol{\Phi}(\boldsymbol{A}, \boldsymbol{\psi})$ and $\boldsymbol{A}' = \boldsymbol{A} + \boldsymbol{\partial}_{\boldsymbol{\psi}} \Phi(\boldsymbol{A}, \boldsymbol{\psi})$. In fact, by [109] the latter becomes $\boldsymbol{A}' = \boldsymbol{A} - \Delta \boldsymbol{h}$ and, from the second of [75] written for $f$ depending only on the angles $\boldsymbol{\alpha}$, it is $\boldsymbol{A} = \boldsymbol{\omega} + \Delta \boldsymbol{h}$ when $\boldsymbol{A}, \boldsymbol{\alpha}$ are on the invariant torus.

Note that if $\boldsymbol{a}$ exists it is necessarily determined by the third relation in [109] but the check that the second equation in [109] is soluble (i.e., that the RHS is an exact gradient up to a constant) is nontrivial. The canonical map generated by $\boldsymbol{A} \cdot \boldsymbol{\psi} + \boldsymbol{\Phi}(\boldsymbol{A}, \boldsymbol{\psi})$ is also defined for $\boldsymbol{A}'$ close to $\boldsymbol{\omega}$ and foliates the neighborhood of the invariant torus with other tori: of course, for $\boldsymbol{A}' \neq \boldsymbol{\omega}$ the tori defined in this way are, in general, not invariant.

The reader is referred to Gallavotti *et al.* (2004) for more details.

## Appendix 2: Coriolis and Lorentz Forces – Larmor Precession

Larmor precession refers to the motion of an electrically charged particle in a magnetic field $H$ (in an inertial frame of reference). It is due to the Lorentz force which, on a unit mass with unit charge, produces an acceleration $\ddot{\varrho} = \boldsymbol{v} \wedge \boldsymbol{H}$ if the speed of light is $c = 1$.

Therefore, if $\boldsymbol{H} = H\boldsymbol{k}$ is directed along the $\boldsymbol{k}$-axis, the acceleration it produces is the same that the Coriolis force would impress on a unit mass located in a reference frame which rotates with angular velocity $\omega_0 \boldsymbol{k}$ around the $\boldsymbol{k}$-axis if $\boldsymbol{H} = 2\omega_0 \boldsymbol{k}$.

The above remarks imply that a homogeneous sphere electrically charged uniformly with a unit charge and freely pivoting about its center in a constant magnetic field $H$ directed along the $\boldsymbol{k}$-axis undergoes the same motion as it would follow if not subject to the magnetic field but seen in a noninertial reference frame rotating at constant angular velocity $\omega_0$ around the $\boldsymbol{k}$-axis if $H$ and $\omega_0$ are related by $H = 2\omega_0$: in this frame, the Coriolis force is interpreted as a magnetic field.

This holds, however, only if the centrifugal force has zero moment with respect to the center: true in the spherical symmetry case only. In spherically nonsymmetric cases, the centrifugal forces have in general nonzero moment, so the equivalence between Coriolis force and the Lorentz force is only approximate.

The Larmor theorem makes this more precise. It gives a quantitative estimate of the difference between the motion of a general system of particles of mass $m$ in a magnetic field and the motion of the same particles in a rotating frame of reference but in the absence of a magnetic field. The approximation is estimated in terms of the size of the Larmor frequency $eH/2mc$, which should be small compared to the other characteristic frequencies of the motion of the system: the physical meaning is that the centrifugal force should be small compared to the other forces.

The vector potential $\boldsymbol{A}$ for a constant magnetic field in the $\boldsymbol{k}$-direction, $\boldsymbol{H} = 2\omega_0 \boldsymbol{k}$, is $\boldsymbol{A} = 2\omega_0 \boldsymbol{k} \wedge \varrho \equiv 2\omega_0 \varrho^{\perp}$. Therefore, from the treatment of the Coriolis force in the section "Three-body problem" (see [95]), the motion of a charge $e$ with mass $m$ in a magnetic field $\boldsymbol{H}$ with vector potential $\boldsymbol{A}$ and subject to other forces with potential $W$ can be described, in an inertial frame and in generic units, in which the speed of light is $c$, by a Hamiltonian

$$\mathcal{H} = \frac{1}{2m}\left(\boldsymbol{p} - \frac{e}{c}\boldsymbol{A}\right)^2 + W(\varrho) \qquad [110]$$

where $\boldsymbol{p} = m\dot{\varrho} + (e/c)\boldsymbol{A}$ and $\varrho$ are canonically conjugate variables.

# Introductory Article: Differential Geometry

**S Paycha**, Université Blaise Pascal, Aubière, France

Differential geometry is the study of differential properties of geometric objects such as curves, surfaces and higher-dimensional manifolds endowed with additional structures such as metrics and connections. One of the main ideas of differential geometry is to apply the tools of analysis to investigate geometric problems; in particular, it studies their “infinitesimal parts,” thereby linearizing the problem. However, historically, geometric concepts often anticipated the analytic tools required to define them from a differential geometric point of view; the notion of tangent to a curve, for example, arose well before the notion of derivative.

In its barely more than two centuries of existence, differential geometry has always had strong (often two-way) interactions with physics. Just to name a few examples, the theory of curves is used in kinematics, symplectic manifolds arise in Hamiltonian mechanics, pseudo-Riemannian manifolds in general relativity, spinors in quantum mechanics, Lie groups and principal bundles in gauge theory, and infinite-dimensional manifolds in the path-integral approach to quantum field theory.

## Curves and Surfaces

The study of differential properties of curves and surfaces resulted from a combination of the coordinate method (or analytic geometry) developed by Descartes and Fermat during the first half of the seventeenth century and infinitesimal calculus developed by Leibniz and Newton during the second half of the seventeenth and beginning of the eighteenth century.

Differential geometry appeared later in the eighteenth century with the works of Euler *Recherches sur la courbure des surfaces* (1760) (Investigations on the curvature of surfaces) and Monge *Une application de l'analyse à la géométrie* (1795) (An application of analysis to geometry). Until Gauss' fundamental article *Disquisitiones generales circa superficies curvas* (General investigations of curved surfaces) published in Latin in 1827 (of which one can find a partial translation to English in Spivak (1979)), surfaces embedded in $\mathbb{R}^3$ were either described by an equation, $W(x, y, z) = 0$, or by expressing one variable in terms of the others. Although Euler had already noticed that the coordinates of a point on a surface could be expressed as functions of two independent variables, it was Gauss who first made a systematic use of such a parametric representation, thereby initiating the concept of “local chart” which underlies differential geometry.

## Differentiable Manifolds

The actual notion of $n$-manifold independent of a particular embedding in a Euclidean space goes back to a lecture *Über die Hypothesen, welche der Geometrie zu Grunde liegen* (On the hypotheses which lie at the foundations of geometry) (of which one can find a translation to English and comments in Spivak (1979)) delivered by Riemann at Göttingen University in 1854, in which he makes clear the fact that $n$-manifolds are locally like $n$-dimensional Euclidean space. In his work, Riemann mentions the existence of infinite-dimensional manifolds, such as function spaces, which today play an important role since they naturally arise as configuration spaces in quantum field theories.

In modern language a differentiable manifold modeled on a topological space $V$ (which can be

finite dimensional, Fréchet, Banach, or Hilbert for example) is a topological space $M$ equipped with a family of local coordinate charts $(U_i, \phi_i)_{i \in I}$ such that the open subsets $U_i \subset M$ cover $M$ and where $\phi_i : U_i \to V$, $i \in I$, are homeomorphisms which give rise to smooth transition maps $\phi_i \circ \phi_j^{-1} : \phi_j(U_i \cap U_j) \to \phi_i(U_i \cap U_j)$. An $n$-dimensional differentiable manifold is a differentiable manifold modeled on $\mathbb{R}^n$. The sphere $S^{n-1} := \{(x_1, \ldots, x_n) \in \mathbb{R}^n, \sum_{i=1}^n x_i^2 = 1\}$ is a differentiable manifold of dimension $n - 1$.

Simple differentiable curves in $\mathbb{R}^n$ are one-dimensional differentiable manifolds locally specified by coordinates $x(t) = (x_1(t), \ldots, x_n(t)) \in \mathbb{R}^n$, where $t \mapsto x_j(t)$ is of class $C^k$. The tangent at point $x(t_0)$ to such a curve, which is a straight line passing through this point with direction given by the vector $x'(t_0)$, generalizes to the concept of tangent space $T_mM$ at point $m \in M$ of a smooth manifold $M$ modeled on $V$ which is a vector space isomorphic to $V$ spanned by tangent vectors at point $m$ to curves $\gamma(t)$ of class $C^1$ on $M$ such that $\gamma(t_0) = m$.

In order to make this more precise, one needs the notion of differentiable mapping. Given two differentiable manifolds $M$ and $N$, a mapping $f : M \to N$ is differentiable at point $m$ if, for every chart $(U, \phi)$ of $M$ containing $m$ and every chart $(V, \psi)$ of $N$ such that $f(U) \subset V$, the mapping $\psi \circ f \circ \phi^{-1} : \phi(U) \to \psi(V)$ is differentiable at point $\phi(m)$. In particular, differentiable mappings $f : M \to \mathbb{R}$ form the algebra $C^\infty(M, \mathbb{R})$ of smooth real-valued functions on $M$. Differentiable mappings $\gamma : [a, b] \to M$ from an interval $[a, b] \subset \mathbb{R}$ to a differentiable manifold $M$ are called "differentiable curves" on $M$. A differentiable mapping $f : M \to N$ which is invertible and with differentiable inverse $f^{-1} : N \to M$ is called a diffeomorphism.

The derivative of a function $f \in C^\infty(M, \mathbb{R})$ along a curve $\gamma : [a, b] \to M$ at point $\gamma(t_0) \in M$ with $t_0 \in [a, b]$ is given by

$$Xf := \frac{\mathrm{d}}{\mathrm{d}t_{|_{t=t_0}}} f \circ \gamma(t)$$

and the map $f \mapsto Xf$ is called the tangent vector to the curve $\gamma$ at point $\gamma(t_0)$. Tangent vectors to some curve $\gamma : [a, b] \to M$ at a given point $m \in \gamma([a, b])$ form a vector space $T_mM$ called the "tangent space" to $M$ at point $m$.

A (smooth) map which, to a point $m \in M$, assigns a tangent vector $X \in T_mM$ is called a (smooth) vector field. It can also be seen as a derivation $\tilde{X} : f \mapsto Xf$ on $C^\infty(M, \mathbb{R})$ defined by $(\tilde{X}f)(m) := X(m)f$ for any $m \in M$ and the bracket of vector fields is thereby defined from the operator bracket $\widetilde{[X, Y]} := \tilde{X} \circ \tilde{Y} - \tilde{Y} \circ \tilde{X}$. The linear operations on tangent vectors carry out to vector fields $(X + Y)(m) := X(m) + Y(m), (\lambda X)(m) := \lambda X(m)$ for any $m \in M$ and for any $X, Y \in T_mM, \lambda \in \mathbb{R}$ so that vector fields on $M$ build a linear space.

One can generate tangent vectors to $M$ via local one-parameter groups of differentiable transformations of $M$, that is, mappings $(t, m) \mapsto \phi_t(m)$ from $]-\epsilon, \epsilon[ \times U$ to $U$ (with $\epsilon > 0$ and $U \subset M$ an open subset of $M$) such that $\phi_0 = \mathrm{Id}, \phi_{t+s} = \phi_t \circ \phi_s$ $\forall s, t \in ]-\epsilon, \epsilon[$ with $t + s \in ]-\epsilon, \epsilon[$ and $m \mapsto \phi_t(m)$ is a diffeomorphism of $U$ onto an open subset $\phi_t(U)$. The tangent vector at $t = 0$ to the curve $\gamma(t) = \phi_t(m)$ yields a tangent vector to $M$ at point $m = \gamma(0)$. Conversely, when $M$ is finite dimensional, the fundamental theorem for systems of ordinary equations yields, for any vector field $X$ on $M$, the existence (around any point $m \in M$) of a local one-parameter group of local transformations $\phi : ]-\epsilon, \epsilon[ \times U \to M$ (with $U$ an open subset containing $m$) which induces the tangent vector $X(m) \in T_mM$.

A differentiable mapping $\phi : M \to N$ induces a map $\phi_*(m) : T_mM \to T_{\phi(m)}M$ defined by $\phi_* Xf = X(f \circ \phi)$. An "immersion" of a manifold $M$ in a manifold $N$ is a differentiable mapping $\phi : M \to N$ such that the maps $\phi_*(m)$ are injective at any point $m \in M$. Such a map is an embedding if it is moreover injective in which case $\phi(M) \subset N$ is a submanifold of $N$. The unit sphere $S^n$ is a submanifold of $\mathbb{R}^{n+1}$. Whitney showed that every smooth real $n$-dimensional manifold can be embedded in $\mathbb{R}^{2n+1}$.

A differentiable manifold whose coordinate charts take values in a complex vector space $V$ and whose transition maps are holomorphic is called a complex manifold, which is complex $n$-dimensional if $V = \mathbb{C}^n$. The complex projective space $\mathbb{C}P^n$, the union of complex straight lines through 0 in $\mathbb{C}^{n+1}$, is a compact complex manifold of dimension $n$. Similarly to the notion of differentiable mapping between differentiable manifolds, we have the notion of holomorphic mapping between complex manifolds.

A smooth family $m \mapsto J_m$ of endomorphisms of the tangent spaces $T_mM$ to a differentiable manifold $M$ such that $J_m^2 = -\mathrm{Id}$ gives rise to an almost-complex manifold. The prototype is the almost-complex structure on $\mathbb{C}^n$ defined by $J(\partial_{x_i}) = \partial_{y_i}; J(\partial_{y_i}) = -\partial_{x_i}$ with $z = (x_1 + \mathrm{i}y_1, \ldots, x_n + \mathrm{i}y_n) \in \mathbb{C}^n$ which can be transferred to a complex manifold $M$ by means of local charts. An almost-complex structure $J$ on a manifold $M$ is called complex if $M$ is the underlying differentiable manifold of a complex manifold which induces $J$ in this way.

Studying smooth functions on a differentiable manifold can provide information on the topology of the manifold: for example, the behavior of a smooth function on a compact manifold as its critical points strongly restricted by the topological properties of the manifold. This leads to the Morse

critical point theory which extends to infinite-dimensional manifolds and, among other consequences, leads to conclusions on extremals or closed extremals of variational problems. Rather than privileging points on a manifold, one can study instead the geometry of manifolds from the point of view of spaces of functions, which leads to an algebraic approach to differential geometry. The initial concept there is a commutative ring (which becomes a possibly noncommutative algebra in the framework of noncommutative geometry), namely the ring of smooth functions on the manifold, while the manifold itself is defined in terms of the ring as the space of maximal ideals. In particular, this point of view proves to be fruitful to understand supermanifolds, a generalization of manifolds which is important for supersymmetric field theories.

One can further consider the sheaf of smooth functions on an open subset of the manifold; this point of view leads to sheaf theory which provides a unified approach to establishing connections between local and global properties of topological spaces.

## Metric Properties

Riemann focused on the metric properties of manifolds but the first clear formulation of the concept of a manifold equipped with a metric was given by Weyl in *Die Idee der Riemannsche Fläche*. A Riemannian metric on a differentiable manifold $M$ is a positive-definite scalar product $g_m$ on $T_mM$ for every point $m \in M$ depending smoothly on the point $m$. A manifold equipped with a Riemannian metric is called a Riemannian manifold. A Weyl transformation, which is multiplying the metric by a smooth positive function, yields a new Riemannian metric with the same angle measurement as the original one, and hence leaves the "conformal" structure on $M$ unchanged.

Riemann also suggested considering metrics on the tangent spaces that are not induced from scalar products; metrics on the manifold built this way were first systematically investigated by Finsler and are therefore called Finsler metrics. Geodesics on a Riemannian manifold $M$ which correspond to smooth curves $\gamma : [a, b] \to M$ that minimize the length functional

$$L(\gamma) := \frac{1}{2}\int_a^b \sqrt{g_{\gamma(t)}\left(\frac{\mathrm{d}\gamma}{\mathrm{d}t}, \frac{\mathrm{d}\gamma}{\mathrm{d}t}\right)}\,\mathrm{d}t$$

then generalize to curves which realize the shortest distance between two points chosen sufficiently close.

Euclid's axioms which naturally lead to Riemannian geometry are also satisfied up to the axiom of parallelism by a geometry developed by Lobatchevsky in 1829 and Bolyai in 1832. Non-Euclidean geometries actually played a major role in the development of differential geometry and Lobachevsky's work inspired Riemann and later Klein.

Dropping the positivity assumption for the bilinear forms $g_m$ on $T_mM$ leads to Lorentzian manifolds which are $(n+1)$-dimensional smooth manifolds equipped with bilinear forms on the tangent spaces with signature $(1, n)$. These occur in general relativity and tangent vectors with negative, positive, or vanishing squared length are called timelike, spacelike, and lightlike, respectively.

Just as complex vector spaces can be equipped with positive-definite Hermitian products, a complex manifold $M$ can come equipped with a Hermitian metric, namely a positive-definite Hermitian product $h_m$ on $T_mM$ for every point $m \in M$ depending smoothly on the point $m$; every Hermitian metric induces a Riemannian one given by its real part. The complex projective space $\mathbb{C}P^n$ comes naturally equipped with the Fubini–Study Hermitian metric.

## Transformation Groups

Metric properties can be seen from the point of view of transformation groups. Poncelet in his *Traité projectif des figures* (1822) had investigated classical Euclidean geometry from a projective geometric point of view, but it was not until Cayley (1858) that metric properties were interpreted as those stable under any "projective" transformation which leaves "cyclic points" (points at infinity on the imaginary axis of the complex plane) invariant. Transformation groups were further investigated by Lie, leading to the modern concept of Lie group, a smooth manifold endowed with a group structure such that the group operations are smooth.

A vector field $X$ on a Lie group $G$ is called left- (resp. right-) invariant if it is invariant under left translations $L_g : h \mapsto gh$ (resp. right translations $R_g : h \mapsto hg$) for every $g \in G$, that is, if $(L_g)_* X(h) = X(gh)\ \forall (g, h) \in G^2$ (resp. $(R_g)_* X(h) = X(gh)\ \forall (g, h) \in G^2$). The set of all left-invariant vector fields equipped with the sum, scalar multiplication, and the bracket operation on vector fields form an algebra called the Lie algebra of $G$.

The group $\mathrm{Gl}_n(\mathbb{R})$ (resp. $\mathrm{Gl}_n(\mathbb{C})$) of all real (resp. complex) invertible $n \times n$ matrices is a Lie group with Lie algebra, the algebra $\mathrm{gl}_n(\mathbb{R})$ (resp. $\mathrm{gl}_n(\mathbb{C})$) of all real (resp. complex) $n \times n$ matrices and the bracket operation reads $[A, B] = AB - BA$.

The orthogonal (resp. unitary) group $\mathrm{O}_n(\mathbb{R}) := \{A \in \mathrm{Gl}_n(\mathbb{R}), A^{\mathrm{t}}A = 1\}$, where $A^{\mathrm{t}}$ denotes the transposed matrix (resp. $U_n(\mathbb{C}) := \{A \in \mathrm{Gl}_n(\mathbb{C}), A^*A = 1\}$, where $A^* = \bar{A}^{\mathrm{t}}$), is a compact Lie group with Lie

algebra $o_n(\mathbb{R}) := \{A \in \mathrm{Gl}_n(\mathbb{R}), A^t = -A\}$ (resp. $u_n(\mathbb{C}) := \{A \in \mathrm{Gl}_n(\mathbb{C}), A^* = -A\}$).

A left-invariant vector field $X$ on a finite-dimensional Lie group $G$ (or equivalently an element $X$ of the Lie algebra of $G$) generates a global one-parameter group of transformations $\phi_X(t), t \in \mathbb{R}$. The mapping from the Lie algebra of $G$ into $G$ defined by $\exp(X) := \phi_X(1)$ is called the exponential mapping. The exponential mapping on $\mathrm{Gl}_n(\mathbb{R})$ (resp. $\mathrm{Gl}_n(\mathbb{C})$) is given by the series $\exp(A) = \sum_{i=0}^{\infty} A^i/i!$.

As symmetry groups of physical systems, Lie groups play an important role in physics, in particular in quantum mechanics and Yang–Mills theory. Infinite-dimensional Lie groups arise as symmetry groups, such as the group of diffeomorphisms of a manifold in general relativity, the group of gauge transformations in Yang–Mills theory, and the group of Weyl transformations of metrics on a surface in string theory. The principle "the physics should not depend on how it is described" translates to an invariance under the action of the (possibly infinite-dimensional group) of symmetries of the theory. Anomalies arise when such an invariance holds for the classical action of a physical theory but "breaks" at the quantized level.

In his Erlangen program (1872), Klein puts the concept of transformation group in the foreground introducing a novel idea by which one should consider a space endowed with some properties as a set of objects invariant under a given group of transformations. One thereby reaches a classification of geometric results according to which group is relevent in a particular problem as, for example, the projective linear group for projective geometry, the orthogonal group for Riemannian geometry, or the symplectic group for "symplectic" geometry.

## Fiber Bundles

Transformation groups give rise to principal fiber bundles which play a major role in Yang–Mills theory. The notion of fiber bundle first arose out of questions posed in the 1930s on the topology and the geometry of manifolds, and by 1950 the definition of fiber bundle had been clearly formulated by Steenrod.

A smooth fiber bundle with typical fiber a manifold $F$ is a triple $(E, \pi, B)$, where $E$ and $B$ are smooth manifolds called the total space and the base space, and $\pi : E \to B$ is a smooth surjective map called the projection of the bundle such that the preimage $\pi^{-1}(b)$ of a point $b \in B$ called the fiber of the bundle over $b$ is isomorphic to $F$ and any base point $b$ has a neighborhood $U \subset B$ with preimage $\pi^{-1}(U)$ diffeomorphic to $U \times F$, where the diffeomophisms commute with the projection on the base space. Smooth sections of $E$ are maps $\sigma : B \to E$ such that $\pi \circ \sigma = I_B$.

When $F$ is a vector space and when, given open subsets $U_i \subset B$ that cover $B$ with corresponding coordinate charts $(U_i, \phi_i)_{i\in I}$, the local diffeomorphisms $\tau_i : \pi^{-1}(U_i) \simeq \phi_i(U_i) \times F$ give rise to transition maps $\tau_i \circ \tau_j^{-1} : \phi_j(U_i \cap U_j) \times F \to \phi_i(U_i \cap U_j) \times F$ that are linear in the fiber, the bundle is called a "vector bundle." The tangent bundle $TM = \bigcup_{m\in M} T_m M$ to a differentiable manifold $M$ modeled on a vector space $V$ is a vector bundle with typical fiber $V$ and transition maps $\tau_{ij} = (\phi_i \circ \phi_j^{-1}, \mathrm{d}(\phi_i \circ \phi_j^{-1}))$ expressed in terms of the differentials of the transition maps on the manifold $M$. So are the cotangent bundle, the dual of the tangent bundle, and tensor products of the tangent and cotangent vector bundles with typical fiber the dual $V^*$ and tensor products of $V$ and $V^*$. Vector fields defined previously are sections of the tangent bundle, 1-forms on $M$ are sections of the cotangent bundle, and contravariant tensors, resp. covariant tensors are sections of tensor products of the tangent, resp. cotangent bundles. A differentiable mapping $\phi : M \to N$ takes covariant $p$-tensor fields on $N$ to their pullbacks by $\phi$, covariant $p$-tensors on $M$ given by

$$(\phi^* T)(X_1, \ldots, X_p) := T(\phi_* X_1, \ldots, \phi_* X_p)$$

for any vector fields $X_1, \ldots, X_p$ on $M$.

Differentiating a smooth function $f$ on $M$ gives rise to a 1-form $\mathrm{d}f$ on $M$. More generally, exterior $p$-forms are antisymmetric smooth covariant $p$-tensors so that $\omega(X_{\sigma(1)}, \ldots, X_{\sigma(p)}) = \epsilon(\sigma)\omega(X_1, \ldots, X_p)$ for any vector fields $X_1, \ldots, X_p$ on $M$ and any permutation $\sigma \in \Sigma_p$ with signature $\epsilon(\sigma)$.

Riemannian metrics are covariant 2-tensors and the space of Riemannian metrics on a manifold $M$ is an infinite-dimensional manifold which arises as a configuration space in string theory and general relativity.

A principal bundle is a fiber bundle $(P, \pi, B)$ with typical fiber a Lie group $G$ acting freely and properly on the total space $P$ via a right action $(p, g) \in P \times G \mapsto pg = R_g(p) \in P$ and such that the local diffeomorphisms $\pi^{-1}(U) \simeq U \times G$ are $G$-equivariant. Given a principal fiber bundle $(P, \pi, B)$ with structure group a finite-dimensional Lie group $G$, the action of $G$ on $P$ induces a homomorphism which to an element $X$ of the Lie algebra of $G$ assigns a vector field $X^*$ on $P$ called the "fundamental vector field" generated by $X$. It is defined at $p \in P$ by

$$X^*(p) := \frac{\mathrm{d}}{\mathrm{d}t_{|_{t=0}}} R_{\exp(tX)}(p)$$

where exp is the exponential map on $G$.

Given an action of $G$ on a vector space $V$, one builds from a principal bundle with typical fiber $G$ an associated vector bundle with typical fiber $V$. Principal bundles are essential in gauge theory; $U(1)$-principal bundles arise in electro-magnetism and nonabelian structure groups arise in Yang–Mills theory. There the fields are connections on the principal bundle, and the action of gauge transformations on (irreducible) connections gives rise to an infinite-dimensional principal bundle over the moduli space with structure group given by gauge transformations. Infinite-dimensional bundles arise in other field theories such as string theory where the moduli space corresponds to inequivalent complex structures on a Riemann surface and the infinite-dimensional structure group is built up from Weyl transformations of the metric and diffeomorphisms of the surface.

## Connections

On a manifold there is no canonical method to identify tangent spaces at different points. Such an identification, which is needed in order to differentiate vector fields, can be achieved on a Riemannian manifold via "parallel transport" of the vector fields. The basic concepts of the theory of covariant differentiation on a Riemannian manifold were given at the end of the nineteenth century by Ricci and, in a more complete form, in 1901 in collaboration with Levi-Civita in *Méthodes de calcul différentiel absolu et leurs applications*; on a Riemannian manifold, it is possible to define in a canonical manner a parallel displacement of tangent vectors and thereby to differentiate vector field covariantly using the since then called Levi-Civita connection.

More generally, a (linear) connection (or equivalently a covariant derivation) on a vector bundle $E$ over a manifold $M$ provides a way to identify fibers of the vector bundle at different points; it is a map $\nabla$ taking sections $\sigma$ of $E$ to $E$-valued 1-forms on $M$ which satisfies a Leibniz rule, $\nabla(f\sigma) = \mathrm{d}f\sigma + f\nabla\sigma$, for any smooth function $f$ on $M$. When $E$ is the tangent bundle over $M$, curves $\gamma$ on the manifold with covariantly constant velocity $\nabla\dot{\gamma}(t) = 0$ give rise to geodesics. Given an initial velocity $\dot{\gamma}(0) = X \in T_mM$ and provided $X$ has small enough norm, $\gamma_X(1)$ defines a point on the corresponding geodesic and the map $exp : X \mapsto \gamma_X(1)$ a diffeomorphism from a neighborhood of 0 in $T_mM$ to a neighborhood of $m \in M$ called the "exponential map" of $\nabla$.

The concept of connection extends to principal bundles where it was developed by Ehresmann building on the work of Cartan. A connection on a principal bundle $(P, \pi, B)$ with structure group $G$, which is a smooth equivariant (under the action of the group $G$) decomposition of the tangent space $T_pP = H_pP \oplus V_pP$ at each point $p$ into a horizontal space $H_pP$ and the vertical space $V_pP = \mathrm{Ker}\, \mathrm{d}\pi_p$, gives rise to a linear connection on the associated vector bundle.

A connection on $P$ gives rise to a 1-form $\omega$ on $P$ with values in the Lie algebra of the structure group $G$ called the connection 1-form and defined as follows. For each $X \in T_pP, \omega(X)$ is the unique element $U$ of the Lie algebra of $G$ such that the corresponding fundamental vector field $U^*(p)$ at point $p$ coincides with the vertical component of $X$. In particular, $\omega(U^*) = U$ for any element $U$ of the Lie algebra of $G$.

The space of connections which is an infinite-dimensional manifold arises as a configuration space in Yang–Mills theory and also comes into play in the Seiberg–Witten theory.

## Geometric Differential Operators

From connections one defines a number of differential operators on a Riemannian manifold, among them second-order Laplacians. In particular, the Laplace–Beltrami operator $f \mapsto -\mathrm{tr}(\nabla^{T*M}\,\mathrm{d}f)$ on smooth functions, where $\nabla^{T^*M}$ is the connection on the cotangent bundle induced by the Levi-Civita connection on $M$, generalizes the ordinary Laplace operator on Euclidean space. This in turn generalizes to second-order operators $\Delta^E := -\mathrm{tr}(\nabla^{T^*M\otimes E}\nabla^E)$ acting on smooth sections of a vector bundle $E$ over a Riemannian manifold $M$, where $\nabla^E$ is a connection on $E$ and $\nabla^{T^*M\otimes E}$ the connection on $T^*M \otimes E$ induced by $\nabla^E$ and the Levi-Civita connection on $M$.

The Dirac operator on a spin Riemannian manifold, a first-order differential operator whose square coincides with the Laplace–Beltrami operator up to zeroth-order terms, can be best understood going back to the initial idea of Dirac. A first-order differential operator with constant matrix coefficients $\sum_{i=1}^n \gamma_i(\partial/\partial x_i)$ has square given by the Laplace operator $-\sum_{i=1}^n \partial^2/\partial x_i^2$ on $\mathbb{R}^n$ if and only if its coefficients satisfy the the Clifford relations

$$\gamma_i^2 = -1 \quad \forall\, i = 1, \ldots, n$$
$$\gamma_i\gamma_j + \gamma_j\gamma_i = 0 \quad \forall\, i \neq j$$

The resulting Clifford algebra, once complexified, is isomorphic in even dimensions $n = 2k$ to the space $\mathrm{End}(S_n)$ (and $\mathrm{End}(S_n) \oplus \mathrm{End}(S_n)$ in odd dimensions $n = 2k + 1$) of endomorphisms of the space $S_n = \mathbb{C}^{2^k}$ of complex $n$-spinors. When instead of the canonical metric on $\mathbb{R}^n$ one starts from the the metric on the tangent bundle $TM$ induced by the Riemannian

metric on $M$ and provided the corresponding spinor spaces patch up to a "spinor bundle" over $M$, $M$ is called a spin manifold. The Dirac operator on a spin Riemannian manifold $M$ is a first-order differential operator acting on spinors given by $D_g = \sum_{i=1}^{n} \gamma_i \nabla_{e_i}$, where $\nabla$ is the connection on spinors (sections of the spinor bundle $S$) induced by the Levi-Civita connection and $e_1, \ldots, e_n$ is an orthonormal frame of the tangent bundle $TM$. This is a particular case of more general twisted Dirac operators $D_g^W$ on a twisted spinor bundle $S \otimes W$ equipped with the connection $\nabla^{S\otimes W}$ which combines the connection $\nabla$ with a connection $\nabla^W$ on an auxilliary vector bundle $W$. Their square $(D_g^W)^2$ relates to the Laplacian $\Delta^{S\otimes W}$ built from this twisted connection via the Lichnerowicz formula which is useful for estimates on the spectrum of the Dirac operator in terms of the underling geometric data.

When there is no spin structure on $M$, one can still hope for a Spin$^c$ structure and a Dirac $D^c$ operator associated with a connection compatible with that structure. In particular, every compact orientable 4-manifold can be equipped with a Spin$^c$ structure and one can build invariants of the differentiable manifold called Seiberg–Witten invariants from solutions of a system of two partial differential equations, one of which is the Dirac equation $D^c\Phi = 0$ associated with a connection compatible with the Spin$^c$ structure and the other a nonlinear equation involving the curvature.

## Curvature

The concept of "curvature," which is now understood in terms of connections (the curvature of a connection $\nabla$ is defined by $\Omega = \nabla^2$), historically arose prior to that of connection. In its modern form, the concept of curvature dates back to Gauss. Using a spherical representation of surfaces – the Gauss map $\nu$, which sends a point $m$ of an oriented surface $\Sigma \subset \mathbb{R}^3$ to the outward pointing unit normal vector $\nu_m$ – Gauss defined what is since then called the Gaussian curvature $K_m$ at point $m \in U \subset \Sigma$ as the limit when the area of $U$ tends to zero of the ratio $\text{area}(\nu(U))/\text{area}(U)$. It measures the obstruction to finding a distance-preserving map from a piece of the surface around $m$ to a region in the standard plane. Gauss' *Teorema Egregium* says that the Gaussian curvature of a smooth surface in $\mathbb{R}^3$ is defined in terms of the metric on the surface so that it agrees for two isometric surfaces.

From the curvature $\Omega$ of a connection on a Riemannian manifold $(M, g)$, one builds the Riemannian curvature tensor, a 4-tensor which in local coordinates reads

$$R_{ijkl} := g\left(\Omega\left(\frac{\partial}{\partial_i}, \frac{\partial}{\partial_j}\right)\frac{\partial}{\partial_k}, \frac{\partial}{\partial_l}\right)$$

further taking a partial trace leads to the Ricci curvature given by the 2-tensor $\text{Ric}_{ij} = \sum_k R_{ikjk}$, the trace of which gives in turn the scalar curvature $R = \sum_i \text{Ric}_{ii}$. Sectional curvature at a point $m$ in the direction of a two-dimensional plane spanned by two vectors $U$ and $V$ corresponds to $K(U, V) = g(\Omega(U, V)V, U)$. A manifold has constant sectional curvature whenever $K(U, V)/\|U \wedge V\|^2$ is a constant $K$ for all linearly independent vectors $U, V$. A Riemannian manifold with constant sectional curvature is said to be spherical, flat, or hyperbolic type depending on whether $K > 0, K = 0$, or $K < 0$, respectively. One owes to Cartan the discovery of an important class of Riemannian manifolds, symmetric spaces, which contains the spheres, the Euclidean spaces, the hyperbolic spaces, and compact Lie groups. A connected Riemannian manifold $M$ equipped at every point $m$ with an isometry $\sigma_m$ such that $\sigma_m(m) = m$ and the tangent map $T_m\sigma_m$ equals –Id on the tangent space (it therefore reverses the geodesics through $m$) is called symmetric. $\mathbb{C}P^n$ equipped with the Fubini–Study metric is a symmetric space with the isometry given by the reflection with respect to a line in $\mathbb{C}^{n+1}$. A compact symmetric space has non-negative sectional curvature $K$.

Constraints on the curvature can have topological consequences. Spheres are the only simply connected manifolds with constant positive sectional curvature; if a simply connected complete Riemannian manifold of dimension $>1$ has non-positive sectional curvature along every plane, then it is homeomorphic to the Euclidean space.

A manifold with Ricci curvature tensor proportional to the metric tensor is called an Einstein manifold. Since Einstein, curvature is a cornerstone of general relativity with gravitational force being interpreted in terms of curvature. For example, the vacuum Einstein equation reads $\text{Ric}_g = (1/2)R_g\, g$ with $\text{Ric}_g$ the Ricci curvature of a metric $g$ and $R_g$ its scalar curvature. In addition, Kaluza–Klein supergravity is a unified theory modeled on a direct product of the Mikowski four-dimensional space and an Einstein manifold with positive scalar curvature.

The Ricci flow $\text{d}g(t)/\text{d}t = -2\text{Ric}_{g(t)}$, which is related with the Einstein equation in general relativity, was only fairly recently introduced in the mathematical literature. Hopes are strong to get a classification of closed 3-manifolds using the Ricci flow as an essential ingredient.

## Cohomology

Differentiation of functions $f \mapsto \mathrm{d}f$ on a differentiable manifold $M$ generalizes to exterior differentiation $\alpha \mapsto d\alpha$ of differential forms. A form $\alpha$ is closed whenever it is in the kernel of $d$ and it is exact whenever it lies in the range of $d$. Since $d^2 = 0$, exact forms are closed.

Cartan's structure equations $d\omega = -(1/2)[\omega, \omega] + \Omega$ relate the exterior differential of the connection 1-form $\omega$ on a principal bundle to its curvature $\Omega$ given by the exterior covariant derivative $D\omega := d\omega \circ h$, where $h : T_pP \to H_pP$ is the projection onto the horizontal space.

On a complex manifold, forms split into sums of $(p, q)$-forms, those with $p$-holomorphic and $q$-antiholomorphic components, and exterior differentiation splits as $d = \partial + \bar{\partial}$ into holomorphic and antiholomorphic derivatives, with $\partial^2 = \bar{\partial}^2 = 0$.

Geometric data are often expressed in terms of closedness conditions on certain differential forms. For example, a "symplectic manifold" is a manifold $M$ equipped with a closed nondegenerate differential 2-form called the "symplectic form." The theory of $J$-holomorphic curves on a manifold equipped with an almost-complex structure $J$ has proved fruitful in building invariants on symplectic manifolds. A Kähler manifold is a complex manifold equipped with a Hermitian metric $h$ whose imaginary part $\mathrm{Im}\, h$ yields a closed $(1, 1)$-form. The complex projective space $\mathbb{C}P^n$ is Kähler.

The exterior differentation $d$ gives rise to de Rham cohomology as $\mathrm{Ker}\, d/\mathrm{Im}\, d$, and de Rham's theorem establishes an isomorphism between de Rham cohomology and the real singular cohomology of a manifold. Chern (or characteristic) classes are topological invariants associated to fiber bundles and play a crucial role in index theory. Chern–Weil theory builds representatives of these de Rham cohomology classes from a connection $\nabla$ of the form $\mathrm{tr}(f(\nabla^2))$, where $f$ is some analytic function.

When the manifold is Riemannian, the Laplace–Beltrami operator on functions generalizes to differential forms in two different ways, namely to the Bochner Laplacian $\Delta^{\Lambda T^* M}$ on forms (i.e., sections of $\Lambda T^* M$), where the contangent bundle $T^* M$ is equipped with a connection induced by the Levi-Civita connection and to the Laplace–Beltrami operator on forms $(d + d^*)^2 = d^* d + d\, d^*$, where $d^*$ is the (formal) adjoint of the exterior differential $d$. These are related via Weitzenböck's formula which in the particular case of 1-forms states that the difference of those two operators is measured by the Ricci curvature.

When the manifold is compact, Hodge's theorem asserts that the de Rham cohomology groups are isomorphic to the space of harmonic (i.e., annihilated by the Laplace–Beltrami operator) differential forms. Thus, the dimension of the set of harmonic $k$-forms equals the $k$th Betti numbers from which one can define the Euler characteristic $\chi(M)$ of the manifold $M$ taking their alternate sum. Hodge theory plays an important role in mirror symmetry which posits a duality between different manifolds on the geometric side and between different field theories via their correlation functions on the physics side. Calabi–Yau manifolds, which are Ricci-flat Kähler manifolds, are studied extensively in the context of duality.

## Index Theory

While the Gaussian curvature is the solution to a local problem, it has strong influence on the global topology of a surface. The Gauss–Bonnet formula (1850) relates the Euler characteristic on a closed surface to the Gaussian curvature by

$$\chi(M) = \frac{1}{2\pi} \int_M K_m \, \mathrm{d}A_m$$

where $\mathrm{d}A_m$ is the volume element on $M$. This is the first result relating curvature to global properties and can be seen as one of the starting points for index theory. It generalizes to the Chern–Gauss–Bonnet theorem (1944) on an even-dimensional closed manifold and can be interpreted as an example of the Atiyah–Singer index theorem (1963)

$$\mathrm{ind}(D_g^W) = \int_M \hat{A}(\Omega_g) \, \mathrm{e}^{-\mathrm{tr}(\Omega^W)}$$

where $g$ denotes a Riemannian metric on a spin manifold $M$, $D_g^W$ a Dirac operator acting on sections of some twisted bundle $S \otimes W$ with $S$ the spinor bundle on $M$ and $W$ an auxiliary vector bundle over $M$, $\mathrm{ind}(D_g^W)$ the "index" of the Dirac operator, and $\Omega_g$, $\Omega^W$ respectively the curvatures of the Levi-Civita connection and a connection on $W$, and $\hat{A}(\Omega_g)$ a particular Chern form called the $\hat{A}$-genus. Index theorems are useful to compute anomalies in gauge theories arising from functional quantisation of classical actions.

Given an even-dimensional closed spin manifold $(M, g)$ and a Hermitian vector bundle $W$ over $M$, the index of the associated Dirac operator $D_g^W$ yields the so-called Atiyah map $K^0(M) \mapsto \mathbb{Z}$ defined by $W \mapsto \mathrm{ind}(D_g^W)$, where $K^0(M)$ is the group of formal differences of stable homotopy classes of smooth vector bundles over $M$. This is the starting point for the noncommutative geometry approach to index theory, in which the space of smooth functions on a

manifold which arises here in a disguised from since $K^0(M) \simeq K_0(C^\infty(M))$ (which consists of formal differences of smooth homotopy classes of idempotents in the inductive limit of spaces of matrices $\mathrm{gl}_n(C^\infty(M))$) is generalized to any noncommutative smooth algebra.

## Introduction

The modern theory of electromagnetism is built on the foundations of Maxwell's equations:

$$\operatorname{div} \boldsymbol{E} = \frac{\rho}{\epsilon_0} \quad [1]$$

$$\operatorname{div} \boldsymbol{B} = 0 \quad [2]$$

$$\operatorname{curl} \boldsymbol{B} - \frac{1}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} = \mu_0 \boldsymbol{J} \quad [3]$$

$$\operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \quad [4]$$

On the left-hand side are the electric and magnetic fields, $\boldsymbol{E}$ and $\boldsymbol{B}$, which are vector-valued functions of position and time. On the right are the sources, the charge density $\rho$, which is a scalar function of position and time, and the current density $\boldsymbol{J}$. The source terms encode the distribution and velocities of charges, and the equations, together with boundary conditions at infinity, determine the fields that they generate. From these equations, one can derive the familiar predictions of electrostatics and magnetostatics, as well as the dynamical behavior of fields and charges, in particular, the generation and propagation of electromagnetic waves – light waves.

Maxwell would not have recognized the equations in this compact vector notation – still less in the tensorial form that they take in special relativity. It is notable that although his contribution is universally acknowledged in the naming of the equations, it is rare to see references to "Maxwell's theory." This is for a good reason. In his early studies of electromagnetism, Maxwell worked with elaborate mechanical models, which he saw as analogies rather than as literal descriptions of the underlying physical reality. In his later work, the mechanical models, in particular the mechanical properties of the "lumiferous ether" through which light waves propagate, were put forward more literally as the foundations of his electromagnetic theory. The equations survive in the modern theory, but the mechanical models with which Maxwell, Faraday, and others wrestled live on only in the survival of archaic terminology, such as "lines of force" and "magnetic flux." The luminiferous ether evaporated with the advent of special relativity.

Maxwell's legacy is not his "theory," but his equations: a consistent system of partial differential equations that describe the whole range of known interactions of electric and magnetic fields with

moving charges. They unify the treatment of electricity and magnetism by revealing for the first time the full duality between the electric and magnetic fields. They have been verified over an almost unimaginable variety of physical processes, from the propagation of light over cosmological distances, through the behavior of the magnetic fields of stars and the everyday applications in electrical engineering and laboratory experiments, down – in their quantum version – to the exchange of photons between individual electrons.

The history of Maxwell's equations is convoluted, with many false turns. Maxwell himself wrote down an inconsistent form of the equations, with a different sign for $\rho$ in the first equation, in his 1865 work "A dynamical theory of the electromagnetic field." The consistent form appeared later in his *Treatise on Electricity and Magnetism* (1873); see Chalmers (1975).

In this article, we shall not follow the historical route to the equations. Some of the complex story of the development hinted at in the remarks above can be found in the articles by Chalmers (1975), Siegel (1985), and Roche (1998). Neither shall we follow the traditional pedagogic route of many textbooks in building up to the full dynamical equations through the study of basic electrical and magnetic phenomena. Instead, we shall follow a path to Maxwell's equations that is informed by knowledge of their most critical feature, invariance under Lorentz transformations. Maxwell, of course, knew nothing of this.

We shall start with a summary of basic facts about the behavior of charges in electric and magnetic fields, and then establish the full dynamical framework by considering this behavior as seen from moving frames of reference. It is impossible, of course, to do this consistently within the framework of classical ideas of space and time since Maxwell's equations are inconsistent with Galilean relativity. But it is at least possible to understand some of the key features of the equations, in particular the need for the term involving the time derivative of $\boldsymbol{E}$, the so-called "displacement current," in the third of Maxwell's equations.

We shall begin with some remarks concerning the role of relativity in classical dynamics.

## Relativity in Newtonian Dynamics

Newton's laws hold in all inertial frames. The formalism of classical mechanics is invariant under Galilean transformations and it is impossible to tell by observing the dynamical behavior of particles and other bodies whether a frame of reference is at rest or in uniform motion. In the world of classical mechanics, therefore:

**Principle of Relativity** There is no absolute standard of rest; only relative motion is observable.

In his "Dialogue concerning the two chief world systems," Galileo illustrated the principle by arguing that the uniform motion of a ship on a calm sea does not affect the behavior of fish, butterflies, and other moving objects, as observed in a cabin below deck.

Relativity theory takes the principle as fundamental, as a statement about the nature of space and time as much as about the properties of the Newtonian equations of motion. But if it is to be given such universal significance, then it must apply to all of physics, and not just to Newtonian dynamics. At first this seems unproblematic – it is hard to imagine that it holds at such a basic level, but not for more complex physical interactions. Nonetheless, deep problems emerge when we try to extend it to electromagnetism since Galilean invariance conflicts with Maxwell's equations.

All appears straightforward for systems involving slow-moving charges and slowly varying electric and magnetic fields. These are governed by laws that appear to be invariant under transformations between uniformly moving frames of reference. One can imagine a modern version of Galileo's ship also carrying some magnets, batteries, semiconductors, and other electrical components. Salviati's argument for relativity would seem just as compelling.

The problem arises when we include rapidly varying fields – in particular, when we consider the propagation of light. As Einstein (1905) put it, "Maxwell's electrodynamics . . . , when applied to moving bodies, leads to asymmetries which do not appear to be inherent in the phenomena." The central difficulty is that Maxwell's equations give light, along with other electromagnetic waves, a definite velocity: in empty space, it travels with the same speed in every direction, independently of the motion of the source – a fact that is incompatible with Galilean invariance. Light traveling with speed $c$ in one frame should have speed $c + u$ in a frame moving towards the source of the light with speed $u$. Thus, it should be possible for light to travel with any speed. Light that travels with speed $c$ in a frame in which its source is at rest should have some other speed in a moving frame; so Galilean invariance would imply dependence of the velocity of light on the motion of the source.

A full resolution of the conflict can only be achieved within the special theory of relativity: here, remarkably, Maxwell's equations retain exactly

their classical form, but the transformations between the space and time coordinates of frames of reference in relative motion do not. The difference appears when the velocities involved are not insignificant when compared with the velocity of light. So long as one can ignore terms of order $u^2/c^2$, Maxwell's equations are compatible with the Galilean principle of relativity.

## Charges, Fields, and the Lorentz-Force Law

The basic objects in the modern form of electromagnetic theory are

- charged particles; and
- the electric and magnetic fields $\boldsymbol{E}$ and $\boldsymbol{B}$, which are vector quantities that depend on position and time.

The charge $e$ of a particle, which can be positive or negative, is an intrinsic quantity analogous to gravitational mass. It determines the strength of the particle's interaction with the electric and magnetic fields – as its mass determines the strength of its interaction with gravitational fields.

The interaction is in two directions. First, electric and magnetic fields exert a force on a charged particle which depends on the value of the charge, the particle's velocity, and the values of $\boldsymbol{E}$ and $\boldsymbol{B}$ at the location of the particle. The force is given by the Lorentz-force law

$$\boldsymbol{f} = e(\boldsymbol{E} + \boldsymbol{u} \wedge \boldsymbol{B}) \qquad [5]$$

in which $e$ is the charge and $\boldsymbol{u}$ is the velocity. It is analogous to the gravitational force

$$\boldsymbol{f} = m\boldsymbol{g} \qquad [6]$$

on a particle of mass $m$ in a gravitational field $\boldsymbol{g}$. It is through the force law that an observer can, in principle, measure the electric and magnetic fields at a point, by measuring the force on a standard charge moving with known velocity.

Second, moving charges generate electric and magnetic fields. We shall not yet consider in detail the way in which they do this, beyond stating the following basic principles.

**EM1.** The fields depend linearly on the charges.

This means that if we superimpose two distributions of charge, then the resultant $\boldsymbol{E}$ and $\boldsymbol{B}$ fields are the sums of the respective fields that the two distributions generate separately.

**EM2.** A stationary point charge $e$ generates an electric field, but no magnetic field. The electric field is given by

$$\boldsymbol{E} = \frac{ke\boldsymbol{r}}{r^3} \qquad [7]$$

where $\boldsymbol{r}$ is the position vector from the charge, $r = |\boldsymbol{r}|$, and k is a positive constant, analogous to the gravitational constant.

By combining [7] and [5], we obtain an inverse-square law electrostatic force

$$\frac{kee'}{r^2} \qquad [8]$$

between two stationary charges; unlike gravity, it is repulsive when the charges have the same sign.

**EM3.** A point charge moving with velocity $\boldsymbol{v}$ generates a magnetic field

$$\boldsymbol{B} = \frac{k' e\boldsymbol{v} \wedge \boldsymbol{r}}{r^3} \qquad [9]$$

where $k'$ is a second positive constant.

This is extrapolated from measurements of the magnetic field generated by currents flowing in electrical circuits.

The constants $k$ and $k'$ in EM2 and EM3 determine the strengths of electric and magnetic interactions. They are usually denoted by

$$k = \frac{1}{4\pi\epsilon_0}, \qquad k' = \frac{\mu_0}{4\pi} \qquad [10]$$

Charge $e$ is measured in coulombs, $|\boldsymbol{B}|$ in teslas, and $|\boldsymbol{E}|$ in volts per meter. With other quantities in SI units,

$$\epsilon_0 = 8.9 \times 10^{-12}, \qquad \mu_0 = 1.3 \times 10^{-6} \qquad [11]$$

The charge of an electron is $-1.6 \times 10^{-19}$ C; the current through an electric fire is a flow of 5–10 C s$^{-1}$. The earth's magnetic field is about $4 \times 10^{-5}$ T; a bar magnet's is about 1 T; there is a field of about 50 T on the second floor of the Clarendon Laboratory in Oxford; and the magnetic field on the surface of a neutron star is about $10^8$ T.

Although we are more aware of gravity in everyday life, it is very much weaker than the electrostatic force – the electrostatic repulsion between two protons is a factor of $1.2 \times 10^{36}$ greater than their gravitational attraction (at any separation, both forces obey the inverse-square law).

Our aim is to pass from EM1–EM3 to Maxwell's equations, by replacing [7] and [9] by partial differential equations that relate the field strengths to the charge and current densities $\rho$ and $\boldsymbol{J}$ of a

continuous distribution of charge. The densities are defined as the limits

$$\rho = \lim_{V\to 0}\left(\frac{\sum e}{V}\right), \qquad \boldsymbol{J} = \lim_{V\to 0}\left(\frac{\sum e\boldsymbol{v}}{V}\right) \qquad [12]$$

where $V$ is a small volume containing the point, $e$ is a charge within the volume, and $\boldsymbol{v}$ is its velocity; the sums are over the charges in $V$ and the limits are taken as the volume is shrunk (although we shall not worry too much about the precise details of the limiting process).

## Stationary Distributions of Charge

We begin the task of converting the basic principles into partial differential equations by looking at the electric field of a stationary distribution of charge, where the passage to the continuous limit is made by using the Gauss theorem to restate the inverse-square law.

The Gauss theorem relates the integral of the electric field over a closed surface to the total charge contained within it. For a point charge, the electric field is given by EM2:

$$\boldsymbol{E} = \frac{e\boldsymbol{r}}{4\pi\epsilon_0 r^3}$$

Since $\operatorname{div}\boldsymbol{r} = 3$ and $\operatorname{grad} r = \boldsymbol{r}/r$, we have

$$\operatorname{div}(\boldsymbol{E}) = \operatorname{div}\left(\frac{e\boldsymbol{r}}{\pi\epsilon_0 r^3}\right) = \frac{e}{4\pi\epsilon_0}\left(\frac{3}{r^3} - \frac{3\boldsymbol{r}\cdot\boldsymbol{r}}{r^5}\right) = 0$$

everywhere except at $r = 0$. Therefore, by the divergence theorem,

$$\int_{\partial V} \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} = 0 \qquad [13]$$

for any closed surface $\partial V$ bounding a volume $V$ that does not contain the charge.

What if the volume does contain the charge? Consider the region bounded by the sphere $S_R$ of radius $R$ centered on the charge; $S_R$ has outward unit normal $\boldsymbol{r}/r$. Therefore,

$$\int_{S_R} \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} = \frac{e}{4\pi R^2\epsilon_0}\int_{S_R} \mathrm{d}S = \frac{e}{\epsilon_0}$$

In particular, the value of the surface integral on the left-hand side does not depend on $R$.

Now consider arbitrary finite volume bounded by a closed surface $S$. If the charge is not inside the volume, then the integral of $\boldsymbol{E}$ over $S$ vanishes by [13]. If it is, then we can apply [13] to the volume $V$ between $S$ and a small sphere $S_R$ to deduce that

$$\int_S \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} - \int_{S_R} \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} = \int_{\partial V} \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} = 0$$

and that the integrals of $\boldsymbol{E}$ over $S$ and $S_R$ are the same. Therefore,

$$\int_S \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} = \begin{cases} e/\epsilon_0 & \text{if the charge is in the volume bounded by } S \\ 0 & \text{otherwise} \end{cases}$$

When we sum over a distribution of charges, the integral on the left picks out the total charge within $S$. Therefore, we have the Gauss theorem.

**The Gauss theorem.** For any closed surface $\partial V$ bounding a volume $V$,

$$\int_{\partial V} \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} = Q/\epsilon_0$$

where $\boldsymbol{E}$ is the total electric field and $Q$ is the total charge within $V$.

Now we can pass to the continuous limit. Suppose that $\boldsymbol{E}$ is generated by a distribution of charges with density $\rho$ (charge per unit volume). Then by the Gauss theorem,

$$\int_{\partial V} \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S} = \frac{1}{\epsilon_0}\int_V \rho\, \mathrm{d}V$$

for any volume $V$. But then, by the divergence theorem,

$$\int_V (\operatorname{div}\boldsymbol{E} - \rho/\epsilon_0)\, \mathrm{d}V = 0$$

Since this holds for any volume $V$, it follows that

$$\operatorname{div}\boldsymbol{E} = \rho/\epsilon_0 \qquad [14]$$

By an argument in a similar spirit, we can also show that the electric field of a stationary distribution of charge is conservative in the sense that the total work done by the field when a charge is moved around a closed loop vanishes; that is,

$$\oint \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{s} = 0$$

for any closed path. This is equivalent to

$$\operatorname{curl}\boldsymbol{E} = 0 \qquad [15]$$

since, by Stokes' theorem,

$$\oint \boldsymbol{E}\cdot \mathrm{d}\boldsymbol{s} = \int_S \operatorname{curl}\boldsymbol{E}\cdot \mathrm{d}\boldsymbol{S}$$

where $S$ is any surface spanning the path. This vanishes for every path and for every $S$ if and only if [15] holds.

The field of a single stationary charge is conservative since

$$\boldsymbol{E} = -\mathrm{grad}\ \phi, \quad \phi = \frac{e}{4\pi\epsilon_0 r}$$

and therefore $\mathrm{curl}\,\boldsymbol{E} = 0$ since the curl of a gradient vanishes identically. For a continuous distribution, $\boldsymbol{E} = -\mathrm{grad}\ \phi$, where

$$\phi(\boldsymbol{r}) = \frac{1}{4\pi\epsilon_0} \int_{\boldsymbol{r}' \in V} \frac{\rho(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|}\, \mathrm{d}V' \qquad [16]$$

In the integral, $\boldsymbol{r}$ (the position of the point at which $\phi$ is evaluated) is fixed, and the integration is over the positions $\boldsymbol{r}'$ of the individual charges. In spite of the singularity at $\boldsymbol{r} = \boldsymbol{r}'$, the integral is well defined. So, [15] also holds for a continuous distribution of stationary charge.

## The Divergence of the Magnetic Field

We can apply the same argument that established the Gauss theorem to the magnetic field of a slow-moving charge. Here,

$$\boldsymbol{B} = \frac{\mu_0 e \boldsymbol{v} \wedge \boldsymbol{r}}{4\pi r^3}$$

where $\boldsymbol{r}$ is the vector from the charge to the point at which the field is measured. Since $\boldsymbol{r}/r^3 = -\mathrm{grad}(1/r)$, we have

$$\mathrm{div}\left(\boldsymbol{v} \wedge \frac{\boldsymbol{r}}{r^3}\right) = \boldsymbol{v} \wedge \mathrm{curl}\left(\mathrm{grad}\frac{1}{r}\right) = 0$$

Therefore, $\mathrm{div}\,\boldsymbol{B} = 0$ except at $r = 0$, as in the case of the electric field. However, in the magnetic case, the integral of the field over a surface surrounding the charge also vanishes, since if $S_R$ is a sphere of radius $R$ centered on the charge, then

$$\int_{S_R} \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} = \frac{\mu_0 e}{4\pi} \int_{S_R} \frac{\boldsymbol{v} \wedge \boldsymbol{r}}{r^3} \cdot \frac{\boldsymbol{r}}{r}\, \mathrm{d}S = 0$$

By the divergence theorem, the same is true for any surface surrounding the charge. We deduce that if magnetic fields are generated only by moving charges, then

$$\int_{\partial V} \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} = 0$$

for any volume $V$, and hence that

$$\mathrm{div}\,\boldsymbol{B} = 0 \qquad [17]$$

Of course, if there were free "magnetic poles" generating magnetic fields in the same way that charges generate electric fields, then this would not hold; there would be a "magnetic pole density" on the right-hand side, by analogy with the charge density in [14].

## Inconsistency with Galilean Relativity

Our central concern is the compatibility of the laws of electromagnetism with the principle of relativity. As Einstein observed, simple electromagnetic interactions do indeed depend only on relative motion; the current induced in a conductor moving through the field of a magnet is the same as that generated in a stationary conductor when a magnet is moved past it with the same relative velocity (Einstein 1905). Unfortunately, this symmetry is not reflected in our basic principles. We very quickly come up against contradictions if we assume that they hold in every inertial frame of reference.

One emerges as follows. An observer $O$ can measure the values of $\boldsymbol{B}$ and $\boldsymbol{E}$ at a point by measuring the force on a particle of standard charge, which is related to the velocity $\boldsymbol{v}$ of the charge by the Lorentz-force law,

$$\boldsymbol{f} = e(\boldsymbol{E} + \boldsymbol{v} \wedge \boldsymbol{B})$$

A second observer $O'$ moving relative to the first with velocity $\boldsymbol{v}$ will see the same force, but now acting on a particle at rest. He will therefore measure the electric field to be $\boldsymbol{E}' = \boldsymbol{f}/e$. We conclude that an observer moving with velocity $\boldsymbol{v}$ through a magnetic field $\boldsymbol{B}$ and an electric field $\boldsymbol{E}$ should see an electric field

$$\boldsymbol{E}' = \boldsymbol{E} + \boldsymbol{v} \wedge \boldsymbol{B} \qquad [18]$$

By interchanging the roles of the two observers, we should also have

$$\boldsymbol{E} = \boldsymbol{E}' - \boldsymbol{v} \wedge \boldsymbol{B}' \qquad [19]$$

where $\boldsymbol{B}'$ is the magnetic field measured by the second observer. If both are to hold, then $\boldsymbol{B} - \boldsymbol{B}'$ must be a scalar multiple of $\boldsymbol{v}$.

But this is incompatible with EM3; if the fields are those of a point charge at rest relative to the first observer, then $\boldsymbol{E}$ is given by [7], and

$$\boldsymbol{B} = 0$$

On the other hand, the second observer sees the field of a point charge moving with velocity $-\boldsymbol{v}$. Therefore,

$$\boldsymbol{B}' = -\frac{\mu_0 e \boldsymbol{v} \wedge \boldsymbol{r}}{4\pi r^3}$$

So $\boldsymbol{B} - \boldsymbol{B}'$ is orthogonal to $\boldsymbol{v}$, not parallel to it.

This conspicuous paradox is resolved, in part, by the realization that EM3 is not exact; it holds only when the velocities are small enough for the magnetic force between two particles to be negligible in comparison with the electrostatic force. If $v$ is a typical velocity, then the condition is that $v^2\mu_0$

should be much less than $1/\epsilon_0$. That is, the velocities involved should be much less than

$$c = \frac{1}{\sqrt{\epsilon_0 \mu_0}} = 3 \times 10^8 \ \mathrm{m\,s^{-1}}$$

This, of course, is the velocity of light.

## The Limits of Galilean Invariance

Our basic principles EM1–EM3 must now be seen to be approximations – they describe the interactions of particles and fields when the particles are moving relative to each other at speeds much less than that of light. To emphasize that we cannot expect, in particular, EM3 to hold for particles moving at speeds comparable with $c$, we must replace it by

**EM3′**. A charge moving with velocity $\boldsymbol{v}$, where $v \ll c$, generates a magnetic field

$$\boldsymbol{B} = \frac{\mu_0 e \boldsymbol{v} \wedge \boldsymbol{r}}{4\pi r^3} + \mathrm{O}(v^2/c^2) \qquad [20]$$

The magnetic field of a system of charges in general motion satisfies

$$\operatorname{div} \boldsymbol{B} = 0 \qquad [21]$$

In the second part, we have retained [21] as a differential form of the statement that there are no free magnetic poles; the magnetic field is generated only by the motion of the charges. With this change, the theory is consistent with the principle of relativity, provided that we ignore terms of order $v^2/c^2$. The substitution of EM3′ for EM3 resolves the conspicuous paradox; the symmetry noted by Einstein between the current generated by the motion of the conductor in a magnetic field and by the motion of a magnet past a conductor is explained, provided that the velocities are much less than that of light.

The central problem remains however; the equations of electromagnetism are not invariant under a Galilean transformation with velocity comparable to $c$. The paradox is still there, but it is more subtle than it appeared to be at first. There are three possible ways out: (1) the noninvariance is real and has observable effects (necessarily of order $v^2/c^2$ or smaller); (2) Maxwell's theory is wrong; or (3) the Galilean transformation is wrong. Disconcertingly, it is the last path that physics has taken. But that is to jump ahead in the story. Our task is to complete the derivation of Maxwell's equations.

## Faraday's Law of Induction

The magnetic field of a slow-moving charge will always be small in relation to its electric field (even when we replace $\boldsymbol{B}$ by $c\boldsymbol{B}$ to put it into the same units as $\boldsymbol{E}$). The magnetic fields generated by currents in electrical circuits are not, however, dominated by large electric fields. This is because the currents are created by the flow, at slow velocity, of electrons, while overall the matter in the wire is roughly electrically neutral, with the electric fields of the positively charged nuclei and negatively charged electrons canceling.

This is the physical context to keep in mind in the following deduction of Faraday's law of induction from Galilean invariance for velocities much less than $c$. The law relates the electromotive force or "voltage" around an electrical circuit to the rate of change of the magnetic field $\boldsymbol{B}$ over a surface spanning the circuit. In its differential form, the law becomes one of Maxwell's equations.

Suppose first that the fields are generated by charges all moving relative to a given inertial frame of reference $R$ with the same velocity $\boldsymbol{v}$. Then in a second frame $R'$ moving relative to $R$ with velocity $\boldsymbol{v}$, there is a stationary distribution of charge. If the velocity is much less than that of light, then the electric field $\boldsymbol{E}'$ measured in $R'$ is related to the electric and magnetic $\boldsymbol{E}$ and $\boldsymbol{B}$ measured in $R$ by

$$\boldsymbol{E}' = \boldsymbol{E} + \boldsymbol{v} \wedge \boldsymbol{B}$$

Since the field measured in $R'$ is that of a stationary distribution of charge, we have

$$\operatorname{curl} \boldsymbol{E}' = 0$$

In $R$, the charges are all moving with velocity $\boldsymbol{v}$, so their configuration looks exactly the same from the point $\boldsymbol{r}$ at time $t$ as it does from the point $\boldsymbol{r} + \boldsymbol{v}\tau$ at time $t + \tau$. Therefore,

$$\boldsymbol{B}(\boldsymbol{r} + \boldsymbol{v}\tau, t + \tau) = \boldsymbol{B}(\boldsymbol{r}, t)$$
$$\boldsymbol{E}(\boldsymbol{r} + \boldsymbol{v}\tau, t + \tau) = \boldsymbol{E}(\boldsymbol{r}, t)$$

and hence by taking derivatives with respect to $\tau$ at $\tau = 0$,

$$\begin{aligned} \boldsymbol{v} \cdot \operatorname{grad} \boldsymbol{B} + \frac{\partial \boldsymbol{B}}{\partial t} &= 0 \\ \boldsymbol{v} \cdot \operatorname{grad} \boldsymbol{E} + \frac{\partial \boldsymbol{E}}{\partial t} &= 0 \end{aligned} \qquad [22]$$

So we must have

$$\begin{aligned} 0 &= \operatorname{curl} \boldsymbol{E}' \\ &= \operatorname{curl} \boldsymbol{E} + \operatorname{curl}(\boldsymbol{v} \wedge \boldsymbol{B}) \\ &= \operatorname{curl} \boldsymbol{E} + \boldsymbol{v} \operatorname{div} \boldsymbol{B} - \boldsymbol{v} \cdot \operatorname{grad} \boldsymbol{B} \\ &= \operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} \end{aligned} \qquad [23]$$

since $\operatorname{div} \boldsymbol{B} = 0$. It follows that

$$\operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \qquad [24]$$

Equation [24] is linear in $\boldsymbol{B}$ and $\boldsymbol{E}$; so by adding the magnetic and electric fields of different streams of charges moving relative to $R$ with different velocities, we deduce that it holds generally for the electric and magnetic fields generated by moving charges.

Equation [24] encodes Faraday's law of electromagnetic induction, which describes how changing magnetic fields can generate currents. In the static case

$$\frac{\partial \boldsymbol{B}}{\partial t} = 0$$

and the equation reduces to $\operatorname{curl} \boldsymbol{E} = 0$ – the condition that the electrostatic field should be conservative; that is, it should do no net work when a charge is moved around a closed loop.

More generally, consider a wire loop in the shape of a closed curve $\gamma$. Let $S$ be a fixed surface spanning $\gamma$. Then we can deduce from eqn [24] that

$$\begin{aligned} \oint_\gamma \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{s} &= \int_S \operatorname{curl} \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{S} \\ &= -\int_S \frac{\partial \boldsymbol{B}}{\partial t} \cdot \mathrm{d}\boldsymbol{S} \\ &= -\frac{\mathrm{d}}{\mathrm{d}t} \int_S (\boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S}) \end{aligned} \qquad [25]$$

If the magnetic field is varying, so that the integral of $\boldsymbol{B}$ over $S$ is not constant, then the integral of $\boldsymbol{E}$ around the loop will not be zero. There will be a nonzero electric field along the wire, which will exert a force on the electrons in the wire and cause a current to flow.

The quantity

$$\oint \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{s}$$

which is measured in volts, is the work done by the electric field when a unit charge makes one circuit of the wire. It is called the electromotive force around the circuit. The integral is the magnetic flux linking the circuit. The relationship [25] between electromotive force and rate of change of magnetic flux is Faraday's law.

## The Field of Charges in Uniform Motion

We can extract another of Maxwell's equations from this argument. By EM3′, a single charge $e$ with velocity $\boldsymbol{v}$ generates an electric field $\boldsymbol{E}$ and a magnetic field

$$\boldsymbol{B} = \frac{\mu_0 e \boldsymbol{v} \wedge \boldsymbol{r}}{4\pi r^3} + \mathrm{O}(v^2/c^2)$$

where $\boldsymbol{r}$ is the vector from the charge to the point at which the field is measured. In the frame of reference $R'$ in which the charge is at rest, its electric field is

$$\boldsymbol{E}' = \frac{e\boldsymbol{r}}{4\pi\epsilon_0 r^3}$$

In the frame in which it is moving with velocity $\boldsymbol{v}$, $\boldsymbol{E} = \boldsymbol{E}' + \mathrm{O}(v/c)$. Therefore,

$$c\boldsymbol{B} = \frac{\boldsymbol{v} \wedge \boldsymbol{E}'}{c} = \frac{\boldsymbol{v} \wedge \boldsymbol{E}}{c} + \mathrm{O}\left(\frac{v^2}{c^2}\right)$$

By taking the curl of both sides, and dropping terms of order $v^2/c^2$,

$$\begin{aligned} \operatorname{curl}(c\boldsymbol{B}) &= \operatorname{curl}\left(\frac{\boldsymbol{v} \wedge \boldsymbol{E}}{c}\right) \\ &= \frac{1}{c}(\boldsymbol{v} \operatorname{div} \boldsymbol{E} - \boldsymbol{v} \cdot \operatorname{grad} \boldsymbol{E}) \end{aligned}$$

But

$$\operatorname{div} \boldsymbol{E} = \rho/\epsilon_0, \qquad \boldsymbol{v} \cdot \operatorname{grad} \boldsymbol{E} = -\frac{\partial \boldsymbol{E}}{\partial t}$$

by [22]. Therefore,

$$\operatorname{curl}(c\boldsymbol{B}) - \frac{1}{c}\frac{\partial \boldsymbol{E}}{\partial t} = \frac{1}{c\epsilon_0}\boldsymbol{J} = c\mu_0 \boldsymbol{J}$$

where $\boldsymbol{J} = \rho\boldsymbol{v}$. By summing over the separate particle velocities, we conclude that

$$\operatorname{curl} \boldsymbol{B} - \frac{1}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} = \mu_0 \boldsymbol{J}$$

holds for an arbitrary distribution of charges, provided that their velocities are much less than that of light.

## Maxwell's Equations

The basic principles, together with the assumption of Galilean invariance for velocities much less than that of light, have allowed us to deduce that the electric and magnetic fields generated by a continuous distribution of moving charges in otherwise empty space satisfy

$$\operatorname{div} \boldsymbol{E} = \frac{\rho}{\epsilon_0} \qquad [26]$$

$$\operatorname{div} \boldsymbol{B} = 0 \qquad [27]$$

$$\operatorname{curl} \boldsymbol{B} - \frac{1}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} = \mu_0 \boldsymbol{J} \qquad [28]$$

$$\operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \qquad [29]$$

where $\rho$ is the charge density, $\boldsymbol{J}$ is the current density, and $c^2 = 1/\epsilon_0\mu_0$. These are Maxwell's equations, the basis of modern electrodynamics. Together with the Lorentz-force law, they describe the dynamics of charges and electromagnetic fields.

We have arrived at them by considering how basic electromagnetic processes appear in moving frames of reference – an unsatisfactory route because we have seen on the way that the principles on which we based the derivation are incompatible with Galilean invariance for velocities comparable with that of light. Maxwell derived them by analyzing an elaborate mechanical model of electric and magnetic fields – as displacements in the luminiferous ether. That is also unsatisfactory because the model has long been abandoned. The reason that they are accepted today as the basis of theoretical and practical applications of electromagnetism has little to do with either argument. It is first that they are self-consistent, and second that they describe the behavior of real fields with unreasonable accuracy.

## The Continuity Equation

It is not immediately obvious that the equations are self-consistent. Given $\rho$ and $\boldsymbol{J}$ as functions of the coordinates and time, Maxwell's equations are two scalar and two vector equations in the unknown components of $\boldsymbol{E}$ and $\boldsymbol{B}$. That is, a total of eight equations for six unknowns – more equations than unknowns. Therefore, it is possible that they are in fact inconsistent.

If we take the divergence of eqn [29], then we obtain

$$\frac{\partial}{\partial t}(\mathrm{div}\,\boldsymbol{B}) = 0$$

which is consistent with eqn [27]; so no problem arises here. However, by taking the divergence of eqn [28] and substituting from eqn [26], we get

$$\begin{aligned} 0 &= \mathrm{div\,curl}\,\boldsymbol{B} \\ &= \frac{1}{c^2}\frac{\partial}{\partial t}(\mathrm{div}\,\boldsymbol{E}) + \mu_0 \mathrm{div}\boldsymbol{J} \\ &= \mu_0\left(\frac{\partial \rho}{\partial t} + \mathrm{div}\boldsymbol{J}\right) \end{aligned}$$

This gives a contradiction unless

$$\frac{\partial \rho}{\partial t} + \mathrm{div}\boldsymbol{J} = 0 \qquad [30]$$

So the choice of $\rho$ and $\boldsymbol{J}$ is not unconstrained; they must be related by the continuity equation [30]. This holds for physically reasonable distributions of charge; it is a differential form of the statement that charges are neither created nor destroyed.

## Conservation of Charge

To see the connection between the continuity equation and charge conservation, let us look at the total charge within a fixed $V$ bounded by a surface $S$. If charge is conserved, then any increase or decrease in a short period of time must be exactly balanced by an inflow or outflow of charge across $S$.

Consider a small element $\mathrm{d}\boldsymbol{S}$ of $S$ with outward unit normal and consider all the particles that have a particular charge $e$ and a particular velocity $\boldsymbol{v}$ at time $t$. Suppose that there are $\sigma$ of these per unit volume ($\sigma$ is a function of position). Those that cross the surface element between $t$ and $t + \delta t$ are those that at time $t$ lie in the region of volume

$$|\boldsymbol{v}\cdot\boldsymbol{n}\,\mathrm{d}S\,\delta t|$$

shown in Figure 1. They contribute $e\sigma\boldsymbol{v}\cdot\mathrm{d}\boldsymbol{S}\delta t$ to the outflow of charge through the surface element. But the value of $\boldsymbol{J}$ at the surface element is the sum of $e\sigma\boldsymbol{v}$ over all possible values of $\boldsymbol{v}$ and $e$. By summing over $\boldsymbol{v}$, $e$, and the elements of the surface, therefore, and by passing to the limit of a continuous distribution, the total rate of outflow is

$$\int_S \boldsymbol{J}\cdot\mathrm{d}\boldsymbol{S}$$

Charge conservation implies that the rate of outflow should be equal to the rate of decrease in the total charge within $V$. That is,

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_V \rho\,\mathrm{d}V + \int_S \boldsymbol{J}\cdot\mathrm{d}\boldsymbol{S} = 0 \qquad [31]$$

By differentiating the first term under the integral sign and by applying the divergence theorem to the second integral,

$$\int_V \left(\frac{\partial \rho}{\partial t} + \mathrm{div}\boldsymbol{J}\right)\mathrm{d}V = 0 \qquad [32]$$

If this is to hold for any choice of $V$, then $\rho$ and $\boldsymbol{J}$ must satisfy the continuity equation. Conversely, the continuity equation implies charge conservation.

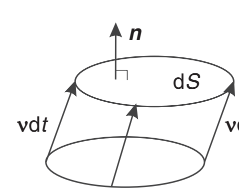

**Figure 1** The outflow through a surface element.

## The Displacement Current

The third of Maxwell's equations can be written as

$$\operatorname{curl} \boldsymbol{B} = \mu_0 \left( \boldsymbol{J} + \epsilon_0 \frac{\partial \boldsymbol{E}}{\partial t} \right) \quad [33]$$

in which form it can be read as an equation for an unknown magnetic field $\boldsymbol{B}$ in terms of a known current distribution $\boldsymbol{J}$ and electric field $\boldsymbol{E}$. When $\boldsymbol{E}$ and $\boldsymbol{J}$ are independent of $t$, it reduces to

$$\operatorname{curl} \boldsymbol{B} = \mu_0 \boldsymbol{J}$$

which determines the magnetic field of a steady current, in a way that was already familiar to Maxwell's contemporaries. But his second term on the right-hand side of [33] was new; it adds to $\boldsymbol{J}$ the so-called vacuum displacement current

$$\epsilon_0 \frac{\partial \boldsymbol{E}}{\partial t}$$

The name comes from an analogy with the behavior of charges in an insulating material. Here no steady current can flow, but the distribution of charges within the material is distorted by an external electric field. When the field changes, the distortion also changes, and the result appears as a current – the displacement current – which flows during the period of change. Maxwell's central insight was that the same term should be present even in empty space. The consequence was profound; it allowed him to explain the propagation of light as an electromagnetic phenomenon.

## The Source-Free Equations

In a region of empty space, away from the charges generating the electric and magnetic fields, we have $\rho = 0 = \boldsymbol{J}$, and Maxwell's equations reduce to

$$\operatorname{div} \boldsymbol{E} = 0 \quad [34]$$

$$\operatorname{div} \boldsymbol{B} = 0 \quad [35]$$

$$\operatorname{curl} \boldsymbol{B} - \frac{1}{c^2} \frac{\partial \boldsymbol{E}}{\partial t} = 0 \quad [36]$$

$$\operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \quad [37]$$

where $c = 1/\sqrt{\epsilon_0 \mu_0}$. By taking the curl of eqn [36] and by substituting from eqns [35] and [37], we obtain

$$\begin{aligned} 0 &= \operatorname{grad}(\operatorname{div} \boldsymbol{B}) - \nabla^2 \boldsymbol{B} - \frac{1}{c^2} \operatorname{curl}\left( \frac{\partial \boldsymbol{E}}{\partial t} \right) \\ &= -\nabla^2 \boldsymbol{B} - \frac{1}{c^2} \frac{\partial}{\partial t} (\operatorname{curl} \boldsymbol{E}) \\ &= -\nabla^2 \boldsymbol{B} + \frac{1}{c^2} \frac{\partial^2 \boldsymbol{B}}{\partial t^2} \end{aligned} \quad [38]$$

Therefore, the three components of $\boldsymbol{B}$ in empty space satisfy the (scalar) wave equation

$$\Box u = 0$$

Here $\Box$ is the d'Alembertian operator, defined by

$$\Box = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} - \nabla^2 = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial y^2} - \frac{\partial^2}{\partial z^2}$$

By taking the curl of eqn [37], we also obtain $\Box \boldsymbol{E} = 0$.

## Monochromatic Plane Waves

The fact that $\boldsymbol{E}$ and $\boldsymbol{B}$ are vector-valued solutions of the wave equation in empty space suggests that we look for "plane wave" solutions of Maxwell's equations in which

$$\boldsymbol{E} = \boldsymbol{\alpha} \cos \Omega + \boldsymbol{\beta} \sin \Omega \quad [39]$$

where $\boldsymbol{\alpha}, \boldsymbol{\beta}$ are constant vectors and

$$\Omega = \frac{\omega}{c}(ct - \boldsymbol{r} \cdot \boldsymbol{e}), \quad \boldsymbol{e} \cdot \boldsymbol{e} = 1 \quad [40]$$

with $\omega > 0$, $\alpha, \beta$, and $\boldsymbol{e}$ constant; $\omega$ is the frequency and $\boldsymbol{e}$ is a unit vector that gives the direction of propagation (adding $\tau$ to $t$ and $c\tau\boldsymbol{e}$ to $\boldsymbol{r}$ leaves $u$ unchanged). This satisfies the wave equation, but for a general choice of the constants, it will not be possible to find $\boldsymbol{B}$ such that eqns [34]–[37] also hold.

By taking the divergence of eqn [39], we obtain

$$\operatorname{div} \boldsymbol{E} = \frac{\omega}{c} (\boldsymbol{e} \cdot \boldsymbol{\alpha} \sin \Omega - \boldsymbol{e} \cdot \boldsymbol{\beta} \cos \Omega) \quad [41]$$

For eqn [34] to hold, therefore, we must choose $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ orthogonal to $\boldsymbol{e}$. For eqn [37] to hold, we must find $\boldsymbol{B}$ such that

$$\operatorname{curl} \boldsymbol{E} = \frac{\omega}{c} (\boldsymbol{e} \wedge \boldsymbol{\alpha} \sin \Omega - \boldsymbol{e} \wedge \boldsymbol{\beta} \cos \Omega) = -\frac{\partial \boldsymbol{B}}{\partial t} \quad [42]$$

A possible choice is

$$\boldsymbol{B} = \frac{\boldsymbol{e} \wedge \boldsymbol{E}}{c} = \frac{1}{c} (\boldsymbol{e} \wedge \boldsymbol{\alpha} \cos \Omega + \boldsymbol{e} \wedge \boldsymbol{\beta} \sin \Omega) \quad [43]$$

and it is not hard to see that $\boldsymbol{E}$ and $\boldsymbol{B}$ then satisfy [35] and [36] as well.

The solutions obtained in this way are called "monochromatic electromagnetic plane waves."

Note that such waves are transverse in the sense that $\boldsymbol{E}$ and $\boldsymbol{B}$ are orthogonal to the direction of propagation. The definition $\boldsymbol{E}$ can be written more concisely in the form

$$\boldsymbol{E} = \mathrm{Re}\left[(\boldsymbol{\alpha} + \mathrm{i}\boldsymbol{\beta})\mathrm{e}^{-\mathrm{i}\Omega}\right] \qquad [44]$$

It is an exercise in Fourier analysis to show every solution in empty space is a combination of monochromatic plane waves. A plane wave has "plane" or "linear" polarization if $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are proportional. It has "circular" polarization if $\boldsymbol{\alpha} \cdot \boldsymbol{\alpha} = \boldsymbol{\beta} \cdot \boldsymbol{\beta}, \boldsymbol{\alpha} \cdot \boldsymbol{\beta} = 0$.

At the heart of Maxwell's theory was the idea that a light wave with definite frequency or color is represented by a monochromatic plane solution of his equations.

## Potentials

For every solution of Maxwell's equations *in vacuo*, the components of $\boldsymbol{E}$ and $\boldsymbol{B}$ satisfy the three-dimensional wave equation; but the converse is not true. That is, it is not true in general that if

$$\Box \boldsymbol{B} = 0, \qquad \Box \boldsymbol{E} = 0$$

then $\boldsymbol{E}$ and $\boldsymbol{B}$ satisfy Maxwell's equations. For this to happen, the divergence of both fields must vanish, and they must be related by [36] and [37]. These additional constraints are somewhat simpler to handle if we work not with the fields themselves, but with auxiliary quantities called "potentials."

The definition of the potentials depends on standard integrability conditions from vector calculus. Suppose that $\boldsymbol{v}$ is a vector field, which may depend on time. If $\mathrm{curl}\,\boldsymbol{v} = 0$, then there exists a function $\phi$ such that

$$\boldsymbol{v} = \mathrm{grad}\,\phi \qquad [45]$$

If $\mathrm{div}\,\boldsymbol{v} = 0$, then there exists a second vector field $\boldsymbol{a}$ such that

$$\boldsymbol{v} = \mathrm{curl}\,\boldsymbol{a} \qquad [46]$$

Neither $\phi$ nor $\boldsymbol{a}$ is uniquely determined by $\boldsymbol{v}$. In the first case, if [45] holds, then it also holds when $\phi$ is replaced by $\phi' = \phi + f$, where $f$ is a function of time alone; in the second, if [46] holds, then it also holds when $\boldsymbol{a}$ is replaced by

$$\boldsymbol{a}' = \boldsymbol{a} + \mathrm{grad}\,u$$

for any scalar function $u$ of position and time. It should be kept in mind that the existence statements are local. If $\boldsymbol{v}$ is defined on a region $U$ with nontrivial topology, then it may not be possible to find a suitable $\phi$ or $\boldsymbol{a}$ throughout the whole of $U$.

Suppose now that we are given fields $\boldsymbol{E}$ and $\boldsymbol{B}$ satisfying Maxwell's equations [26]–[29] with sources represented by the charge density $\rho$ and the current density $\boldsymbol{J}$. Since $\mathrm{div}\,\boldsymbol{B} = 0$, there exists a time-dependent vector field $\boldsymbol{A}(t, x, y, z)$ such that

$$\boldsymbol{B} = \mathrm{curl}\,\boldsymbol{A}$$

If we substitute $\boldsymbol{B} = \mathrm{curl}\,\boldsymbol{A}$ into [29] and interchange curl with the time derivative, then we obtain

$$\mathrm{curl}\left(\boldsymbol{E} + \frac{\partial \boldsymbol{A}}{\partial t}\right) = 0$$

It follows that there exists a scalar $\phi(t, x, y, z)$ such that

$$\boldsymbol{E} = -\mathrm{grad}\,\phi - \frac{\partial \boldsymbol{A}}{\partial t} \qquad [47]$$

Such a vector field $\boldsymbol{A}$ is called a "magnetic vector potential"; a function $\phi$ such that eqn [47] holds is called an "electric scalar potential."

Conversely, given scalar and vector functions $\phi$ and $\boldsymbol{A}$ of $t$, $x$, $y$, $z$, we can define $\boldsymbol{B}$ and $\boldsymbol{E}$ by

$$\boldsymbol{B} = \mathrm{curl}\,\boldsymbol{A}, \qquad \boldsymbol{E} = -\mathrm{grad}\,\phi - \frac{\partial \boldsymbol{A}}{\partial t} \qquad [48]$$

Then two of Maxwell's equations hold automatically, since

$$\mathrm{div}\,\boldsymbol{B} = 0, \qquad \mathrm{curl}\,\boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0$$

The remaining pair translate into conditions on $\boldsymbol{A}$ and $\phi$. Equation [26] becomes

$$\mathrm{div}\,\boldsymbol{E} = -\nabla^2\phi - \frac{\partial}{\partial t}(\mathrm{div}\,\boldsymbol{A}) = \frac{\rho}{\epsilon_0}$$

and eqn [28] becomes

$$\begin{aligned}\mathrm{curl}\,\boldsymbol{B} - \frac{1}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} &= -\nabla^2\boldsymbol{A} + \mathrm{grad}\ \mathrm{div}\,\boldsymbol{A} \\ &\quad + \frac{1}{c^2}\frac{\partial}{\partial t}\left(\mathrm{grad}\,\phi + \frac{\partial \boldsymbol{A}}{\partial t}\right) \\ &= \mu_0 \boldsymbol{J}\end{aligned}$$

If we put

$$\alpha = \frac{1}{c^2}\frac{\partial \phi}{\partial t} + \mathrm{div}\,(\boldsymbol{A})$$

then we can rewrite the equations for $\boldsymbol{A}$ and $\phi$ more simply as

$$\Box\phi - \frac{\partial \alpha}{\partial t} = \frac{\rho}{\epsilon_0}$$

$$\Box\boldsymbol{A} + \mathrm{grad}\ \alpha = \mu_0 \boldsymbol{J}$$

Here we have four equations (one scalar, one vector) in four unknowns ($\phi$ and the components of $\boldsymbol{A}$). Any set of solutions $\phi, \boldsymbol{A}$ determines a solution of Maxwell's equations via [48].

## Gauge Transformations

Given solutions $\boldsymbol{E}$ and $\boldsymbol{B}$ of Maxwell's equations, what freedom is there in the choice of $\boldsymbol{A}$ and $\phi$? First, $\boldsymbol{A}$ is determined by $\operatorname{curl} \boldsymbol{A} = \boldsymbol{B}$ up to the replacement of $\boldsymbol{A}$ by

$$\boldsymbol{A}' = \boldsymbol{A} + \operatorname{grad} u$$

for some function $u$ of position and time. The scalar potential $\phi'$ corresponding to $\boldsymbol{A}'$ must be chosen so that

$$\begin{aligned} -\operatorname{grad} \phi' &= \boldsymbol{E} + \frac{\partial \boldsymbol{A}'}{\partial t} \\ &= \boldsymbol{E} + \frac{\partial \boldsymbol{A}}{\partial t} + \operatorname{grad}\left(\frac{\partial u}{\partial t}\right) \\ &= -\operatorname{grad}\left(\phi - \frac{\partial u}{\partial t}\right) \end{aligned}$$

That is, $\phi' = \phi - \partial u/\partial t + f(t)$, where $f$ is a function of $t$ alone. We can absorb $f$ into $u$ by subtracting

$$\int f \, \mathrm{d}t$$

(this does not alter $\boldsymbol{A}'$). So the freedom in the choice of $\boldsymbol{A}$ and $\phi$ is to make the transformation

$$\boldsymbol{A} \mapsto \boldsymbol{A}' = \boldsymbol{A} + \operatorname{grad} u, \qquad \phi \mapsto \phi' = \phi - \frac{\partial u}{\partial t} \qquad [49]$$

for any $u = u(t, x, y, z)$. The transformation [49] is called a "gauge transformation."

Under [49],

$$\alpha \mapsto \alpha' = \frac{1}{c^2}\frac{\partial \phi'}{\partial t} + \operatorname{div}(\boldsymbol{A}') = \alpha - \Box u$$

It is possible to show, under certain very mild conditions on $\alpha$, that the inhomogeneous wave equation

$$\Box u = \alpha \qquad [50]$$

has a solution $u = u(t, x, y, z)$. If we choose $u$ so that [50] holds, then the transformed potentials $\boldsymbol{A}'$ and $\phi'$ satisfy

$$\operatorname{div}(\boldsymbol{A}') + \frac{1}{c^2}\frac{\partial \phi'}{\partial t} = 0$$

This is the "Lorenz gauge condition," named after L Lorenz (not the H A Lorentz of the "Lorentz contraction").

If we impose the Lorenz condition, then the only remaining freedom in the choice of $\boldsymbol{A}$ and $\phi$ is to make gauge transformations [49] in which $u$ is a solution of the wave equation $\Box u = 0$. Under the Lorenz condition, Maxwell's equations take the form

$$\Box \phi = \rho/\epsilon_0, \qquad \Box \boldsymbol{A} = \mu_0 \boldsymbol{J} \qquad [51]$$

Consistency with the Lorenz condition follows from the continuity equation on $\phi$ and $\boldsymbol{J}$.

In the absence of sources, therefore, Maxwell's equations for the potential in the Lorenz gauge reduce to

$$\Box \phi = 0, \qquad \Box \boldsymbol{A} = 0 \qquad [52]$$

together with the constraint

$$\operatorname{div} \boldsymbol{A} + \frac{1}{c^2}\frac{\partial \phi}{\partial t} = 0$$

We can, for example, choose three arbitrary solutions of the scalar wave equation for the components of the vector potential, and then define $\phi$ by

$$\phi = c^2 \int \operatorname{div} \boldsymbol{A} \mathrm{d}t$$

Whatever choice we make, we shall get a solution of Maxwell's equations, and every solution of Maxwell's equations (without sources) will arise from some such choice.

## Historical Note

At the end of the eighteenth century, four types of electromagnetic phenomena were known, but not the connections between them.

- *Magnetism*, the word derives from the Greek for "stone from Magnesia."
- *Static electricity*, produced by rubbing amber with fur; the word "electricity" derives from the Greek for "amber."
- *Light*.
- *Galvanism* or "animal electricity" – the electricity produced by batteries, discovered by Luigi Galvani.

The construction of a unified theory was a slow and painful business. It was hindered by attempts, which seem bizarre in retrospect, to understand electromagnetism in terms of underlying mechanical models involving such inventions as "electric fluids" and "magnetic vortices." We can see the legacy of this period, which ended with Einstein's work in 1905, in the misleading and archaic terms that still survive in modern terminology: "magnetic flux," "lines of force," "electric displacement," and so on.

Maxwell's contribution was decisive, although much of what we now call "Maxwell's theory" is due to his successors (Lorentz, Hertz, Einstein, and so on); and, as we shall see, a key element in Maxwell's own description of electromagnetism – the "electromagnetic ether," an all-pervasive medium which was supposed to transmit electromagnetic waves – was thrown out by Einstein.

A rough chronology is as follows.

- 1800 Volta demonstrated the connection between galvanism and static electricity.
- 1820 Oersted showed that the current from a battery generates a force on a magnet.
- 1822 Ampère suggested that light was a wave motion in a "luminiferous ether" made up of two types of electric fluid. In the same year, Galileo's "Dialogue concerning the two chief world systems" was removed from the index of prohibited books.
- 1831 Faraday showed that moving magnets can induce currents.
- 1846 Faraday suggested that light is a vibration in magnetic lines of force.
- 1863 Maxwell published the equations that describe the dynamics of electric and magnetic fields.
- 1905 Einstein's paper "On the electrodynamics of moving bodies."

# Introductory Article: Equilibrium Statistical Mechanics

**G Gallavotti**, Università di Roma "La Sapienza," Rome, Italy

## Foundations: Atoms and Molecules

Classical statistical mechanics studies properties of macroscopic aggregates of particles, atoms, and molecules, based on the assumption that they are point masses subject to the laws of classical mechanics. Distinction between macroscopic and microscopic systems is evanescent and in fact the foundations of statistical mechanics have been laid on properties, proved or assumed, of few-particle systems.

Macroscopic systems are often considered in stationary states, which means that their microscopic configurations follow each other as time evolves while looking the same macroscopically. Observing time evolution is the same as sampling ("not too closely" time-wise) independent copies of the system prepared in the same way.

A basic distinction is necessary: a stationary state may or may not be in equilibrium. The first case arises when the particles are enclosed in a container $\Omega$ and are subject only to their mutual conservative interactions and, possibly, to external conservative forces: a typical example is a gas in a container subject to forces due to the walls of $\Omega$ and gravity, besides the internal interactions. This is a very restricted class of systems and states.

A more general case is when the system is in a stationary state but it is also subject to nonconservative forces: a typical example is a gas or fluid in which a wheel rotates, as in the Joule experiment, with some device acting to keep the temperature constant. The device is called a thermostat and in statistical mechanics it has to be modeled by forces, including nonconservative ones, which prevent an indefinite energy transfer from the external forcing to the system: such a transfer would impede the occurrence of stationary states. For instance, the thermostat could simply be a constant friction force (as in stirred incompressible liquids or as in electric wires in which current circulates because of an electromotive force).

A more fundamental approach would be to imagine that the thermostat device is not a phenomenologically introduced nonconservative force (e.g., a friction force) but is due to the interaction with an external infinite system which is in "equilibrium at infinity."

In any event nonequilibrium stationary states are intrinsically more complex than equilibrium states. Here attention will be confined to equilibrium

statistical mechanics of systems of $N$ identical point particles $\boldsymbol{Q}=(\boldsymbol{q}_1,\ldots,\boldsymbol{q}_N)$ enclosed in a cubic box $\Omega$, with volume $V$ and side $L$, normally assumed to have perfectly reflecting walls.

Particles of mass $m$ located at $\boldsymbol{q},\boldsymbol{q}'$ will be supposed to interact via a pair potential $\varphi(\boldsymbol{q}-\boldsymbol{q}')$. The microscopic motion follows the equations

$$m\ddot{\boldsymbol{q}}_i = -\sum_{j=1}^{N}\partial_{\boldsymbol{q}_i}\varphi(\boldsymbol{q}_i-\boldsymbol{q}_j)+\sum_i W_{\text{wall}}(\boldsymbol{q}_i) \stackrel{\text{def}}{=} -\partial_{\boldsymbol{q}_i}\Phi(\boldsymbol{Q}) \qquad [1]$$

where the potential $\varphi$ is assumed to be smooth except, possibly, for $|\boldsymbol{q}-\boldsymbol{q}'|\le r_0$ where it could be $+\infty$, that is, the particles cannot come closer than $r_0$, and at $r_0$ [1] is interpreted by imagining that they undergo elastic collisions; the potential $W_{\text{wall}}$ models the container and it will be replaced, unless explicitly stated, by an elastic collision rule.

The time evolution $(\boldsymbol{Q},\dot{\boldsymbol{Q}})\to S_t(\boldsymbol{Q},\dot{\boldsymbol{Q}})$ will, therefore, be described on the position – velocity space, $\widehat{\mathcal{F}}(N)$, of the $N$ particles or, more conveniently, on the phase space, i.e., by a time evolution $S_t$ on the momentum – position ($\boldsymbol{P},\boldsymbol{Q}$, with $\boldsymbol{P}=m\dot{\boldsymbol{Q}}$) space, $\mathcal{F}(N)$. The motion being conservative, the energy

$$U \stackrel{\text{def}}{=} \sum_i \frac{1}{2m}\boldsymbol{p}_i^2+\sum_{i<j}\varphi(\boldsymbol{q}_i-\boldsymbol{q}_j)+\sum_i W_{\text{wall}}(\boldsymbol{q}_i) \stackrel{\text{def}}{=} K(\boldsymbol{P})+\Phi(\boldsymbol{Q})$$

will be a constant of motion; the last term in $\Phi$ is missing if walls are perfect. This makes it convenient to regard the dynamics as associated with two dynamical systems $(\mathcal{F}(N),S_t)$ on the $6N$-dimensional phase space, and $(\mathcal{F}_U(N),S_t)$ on the $(6N-1)$-dimensional surface of energy $U$. Since the dynamics [1] is Hamiltonian on phase space, with Hamiltonian

$$H(\boldsymbol{P},\boldsymbol{Q}) \stackrel{\text{def}}{=} \sum_i \frac{1}{2m}\boldsymbol{p}_i^2+\Phi(\boldsymbol{Q}) \stackrel{\text{def}}{=} K+\Phi$$

it follows that the volume $\mathrm{d}^{3N}\boldsymbol{P}\mathrm{d}^{3N}\boldsymbol{Q}$ is conserved (i.e., a region $E$ has the same volume as $S_tE$) and also the area $\delta(H(\boldsymbol{P},\boldsymbol{Q})-U)\mathrm{d}^{3N}\boldsymbol{P}\mathrm{d}^{3N}\boldsymbol{Q}$ is conserved.

The above dynamical systems are well defined, i.e., $S_t$ is a map on phase space globally defined for all $t\in(-\infty,\infty)$, when the interaction potential is bounded below: this is implied by the *a priori* bounds due to energy conservation. For gravitational or Coulomb interactions, much more has to be said, assumed, and done in order to even define the key quantities needed for a statistical theory of motion.

Although our world is three dimensional (or at least was so believed to be until recent revolutionary theories), it will be useful to consider also systems of particles in dimension $d\neq 3$: in this case the above $6N$ and $3N$ become, respectively, $2dN$ and $dN$. Systems with dimension $d=1,2$ are in fact sometimes very good models for thin filaments or thin films. For the same reason, it is often useful to imagine that space is discrete and particles can only be located on a lattice, for example, on $\mathbb{Z}^d$ (see the section "Lattice models").

The reader is referred to Gallavotti (1999) for more details.

## Pressure, Temperature, and Kinetic Energy

The beginning was BERNOULLI's derivation of the perfect gas law via the identification of the *pressure* at *numerical density* $\rho$ with the average momentum transferred per unit time to a surface element of area $\mathrm{d}S$ on the walls: that is, the average of the observable $2mv\rho v\,\mathrm{d}S$, with $v$ the normal component of the velocity of the particles that undergo collisions with $\mathrm{d}S$. If $f(v)\mathrm{d}v$ is the distribution of the normal component of velocity and $f(\boldsymbol{v})\mathrm{d}^3\boldsymbol{v}\equiv\prod_i f(v_i)\mathrm{d}^3\boldsymbol{v}$, $\boldsymbol{v}=(v_1,v_2,v_3)$, is the total velocity distribution, the average of the momentum transferred is $p\mathrm{d}S$ given by

$$\mathrm{d}S\int_{v>0}2mv^2\rho f(v)\mathrm{d}v=\mathrm{d}S\int mv^2\rho f(v)\mathrm{d}v = \rho\frac{2}{3}\mathrm{d}S\int\frac{m}{2}\boldsymbol{v}^2 f(\boldsymbol{v})\mathrm{d}^3\boldsymbol{v}=\rho\frac{2}{3}\left\langle\frac{K}{N}\right\rangle\mathrm{d}S \qquad [2]$$

Furthermore $(2/3)\langle K/N\rangle$ was identified as proportional to the absolute temperature $\langle K/N\rangle \stackrel{\text{def}}{=}$ const $(3/2)T$ which, with present-day notations, is written as $(2/3)\langle K/N\rangle=k_{\text{B}}T$. The constant $k_{\text{B}}$ was (later) called Boltzmann's constant and it is the same for at least all perfect gases. Its independence on the particular nature of the gas is a consequence of *Avogadro's law* stating that equal volumes of gases at the same conditions of temperature and pressure contain equal number of molecules.

Proportionality between average kinetic energy and temperature via the universal constant $k_{\text{B}}$ became in fact a fundamental assumption extending to all aggregates of particles gaseous or not, never challenged in all later works (until quantum mechanics, where this is no longer true, see the section "Quantum statistics".

For more details, we refer the reader to Gallavotti (1999).

## Heat and Entropy

After Clausius' discovery of entropy, Boltzmann, in order to explain it mechanically, introduced the *heat theorem*, which he developed to full generality between 1866 and 1884. Together with the mentioned identification of absolute temperature with average kinetic energy, the heat theorem can also be considered a founding element of statistical mechanics.

The theorem makes precise the notion of time average and then states in great generality that given any mechanical system one can associate with its dynamics four quantities $U, V, p, T$, defined as time averages of suitable mechanical observables (i.e., functions on phase space), so that when the external conditions are infinitesimally varied and the quantities $U, V$ change by $\mathrm{d}U, \mathrm{d}V$, respectively, the ratio $(\mathrm{d}U + p\mathrm{d}V)/T$ is exact, i.e., there is a function $S(U, V)$ whose corresponding variation equals the ratio. It will be better, for the purpose of considering very large boxes ($V \to \infty$) to write this relation in terms of intensive quantities $u \overset{\text{def}}{=} U/N$ and $v = V/N$ as

$$\frac{\mathrm{d}u + p\mathrm{d}v}{T} \text{ is exact} \qquad [3]$$

i.e., the ratio equals the variation $\mathrm{d}s$ of $s(U/N, V/N) \equiv (1/N)S(U, V)$.

The proof originally dealt with *monocyclic* systems, i.e., systems in which all motions are periodic. The assumption is clearly much too restrictive and justification for it developed from the early "nonperiodic motions can be regarded as periodic with infinite period" (1866), to the later *ergodic hypothesis* and finally to the realization that, after all, the heat theorem does not really depend on the ergodic hypothesis (1884).

Although for a one-dimensional system the proof of the heat theorem is a simple check, it was a real breakthrough because it led to an answer to the general question as to under which conditions one could define mechanical quantities whose variations were constrained to satisfy [3] and therefore could be interpreted as a mechanical model of Clausius' macroscopic thermodynamics. It is reproduced in the following.

Consider a one-dimensional system subject to forces with a confining potential $\varphi(x)$ such that $|\varphi'(x)| > 0$ for $|x| > 0, \varphi''(0) > 0$ and $\varphi(x) \xrightarrow[x\to\infty]{} +\infty$. All motions are periodic, so that the system is monocyclic. Suppose that the potential $\varphi(x)$ depends on a parameter $V$ and define a *state* to be a motion with given energy $U$ and given $V$; let

$$\begin{aligned} &U = \text{total energy of the system} \equiv K + \Phi \\ &T = \text{time average of the kinetic energy } K = \langle K \rangle \\ &V = \text{the parameter on which } \varphi \text{ is supposed to depend} \\ &p = -\text{time average of } \partial_{V\varphi}, -\langle \partial_{V\varphi} \rangle \end{aligned} \qquad [4]$$

A state is thus parametrized by $U$, $V$. If such parameters change by $\mathrm{d}U, \mathrm{d}V$, respectively, and if $\mathrm{d}L \overset{\text{def}}{=} -p\mathrm{d}V, \mathrm{d}Q \overset{\text{def}}{=} \mathrm{d}U + p\mathrm{d}V$, then [3] holds. In fact, let $x_\pm(U, V)$ be the extremes of the oscillations of the motion with given $U$, $V$ and define $S$ as

$$S = 2 \log \int_{x_-(U,V)}^{x_+(U,V)} \sqrt{(U - \varphi(x))}\mathrm{d}x$$
$$\Rightarrow \mathrm{d}S = \frac{\int (\mathrm{d}U - \partial_{V\varphi}(x)\mathrm{d}V)(\mathrm{d}x/\sqrt{K})}{\int (\mathrm{d}x/\sqrt{K})K} \qquad [5]$$

Noting that $\mathrm{d}x/\sqrt{K} = \sqrt{2/m}\,\mathrm{d}t$, [3] follows because time averages are given by integrating with respect to $\mathrm{d}x/\sqrt{K}$ and dividing by the integral of $1/\sqrt{K}$.

For more details, the reader is referred to Boltzmann (1968b) and Gallavotti (1999).

## Heat Theorem and Ergodic Hypothesis

Boltzmann tried to extend the result beyond the one-dimensional systems (e.g., to Keplerian motions, which are not monocyclic unless only motions with a fixed eccentricity are considered). However, the early statement that "aperiodic motions can be regarded as periodic with infinite period" is really the heart of the application of the heat theorem for monocyclic systems to the far more complex gas in a box.

Imagine that the gas container $\Omega$ is closed by a piston of section $A$ located to the right of the origin at distance $L$ and acting as a lid, so that the volume is $V = AL$. The microscopic model for the piston will be a potential $\overline{\varphi}(L - \xi)$ if $x = (\xi, \eta, \zeta)$ are the coordinates of a particle. The function $\overline{\varphi}(r)$ will vanish for $r > r_0$, for some $r_0 \ll L$, and diverge to $+\infty$ at $r = 0$. Thus, $r_0$ is the width of the layer near the piston where the force of the wall is felt by the particles that happen to be roaming there.

The contribution to the total potential energy $\Phi$ due to the walls is $W_{\text{wall}} = \sum_j \overline{\varphi}(L - \xi_j)$ and $\partial_V \overline{\varphi} = A^{-1} \partial_L \overline{\varphi}$; assuming monocyclicity, it is necessary to evaluate the time average of $\partial_L \Phi(x) = \partial_L W_{\text{wall}} \equiv -\sum_j \overline{\varphi}'(L - \xi_j)$. As time evolves, the particles $x_j$ with $\xi_j$ in the layer within $r_0$ of the wall will feel the force exercised by the wall and

bounce back. One particle in the layer will contribute to the average of $\partial_L \Phi(x)$ the amount

$$\frac{1}{\text{total time}} 2 \int_{t_0}^{t_1} -\overline{\varphi}'(L - \xi_j) \mathrm{d}t \qquad [6]$$

if $t_0$ is the first instant when the point $j$ enters the layer and $t_1$ is the instant when the $\xi$-component of the velocity vanishes "against the wall." Since $-\overline{\varphi}'(L - \xi_j)$ is the $\xi$-component of the force, the integral is $2m|\dot{\xi}_j|$ (by Newton's law), provided, of course, $\dot{\xi}_j > 0$.

Suppose that no collisions between particles occur while the particles travel within the range of the potential of the wall, i.e., the mean free path is much greater than the range of the potential $\overline{\varphi}$ defining the wall. The contribution of collisions to the average momentum transfer to the wall per unit time is therefore given by, see [2],

$$\int_{v>0} 2mv\, f(v) \rho_{\text{wall}} A v \, \mathrm{d}v$$

if $\rho_{\text{wall}}, f(v)$ are the average density near the wall and, respectively, the average fraction of particles with a velocity component normal to the wall between $v$ and $v + \mathrm{d}v$. Here $p$, $f$ are supposed to be independent of the point on the wall: this should be true up to corrections of size $o(A)$.

Thus, writing the average kinetic energy per particle and per velocity component, $\int (m/2) v^2 f(v) \mathrm{d}v$, as $(1/2)\beta^{-1}$ (cf. [2]) it follows that

$$p \stackrel{\text{def}}{=} - \langle \partial_V \Phi \rangle = \rho_{\text{wall}} \beta^{-1} \qquad [7]$$

has the physical interpretation of pressure. $(1/2)\beta^{-1}$ is the average kinetic energy per degree of freedom: hence, it is proportional to the absolute temperature $T$ (cf. see the section "Pressure, temperature, and kinetic energy").

On the other hand, if motion on the energy surface takes place on a single periodic orbit, the quantity $p$ in [7] is the right quantity that would make the heat theorem work; see [4]. Hence, regarding the trajectory on each energy surface as periodic (i.e., the system as monocyclic) leads to the heat theorem with $p, U, V, T$ having the right physical interpretation corresponding to their appellations. This shows that monocyclic systems provide natural models of thermodynamic behavior.

Assuming that a chaotic system like a gas in a container of volume $V$ will satisfy, for practical purposes, the above property, a quantity $p$ can be defined such that $\mathrm{d}U + p\mathrm{d}V$ admits the inverse of the average kinetic energy $\langle K \rangle$ as an integrating factor and, furthermore, $p, U, V, \langle K \rangle$ have the physical interpretations of pressure, energy, volume, and (up to a proportionality factor) absolute temperature, respectively.

Boltzmann's conception of space (and time) as discrete allowed him to conceive the property that the energy surface is constituted by "points" all of which belong to a single trajectory: a property that would be impossible if the phase space was really a continuum. Regarding phase space as consisting of a finite number of "cells" of finite volume $h^{dN}$, for some $h > 0$ (rather than of a continuum of points), allowed him to think, without logical contradiction, that the energy surface consisted of a single trajectory and, hence, that motion was a cyclic permutation of its points (actually cells).

Furthermore, it implied that the time average of an observable $F(\boldsymbol{P}, \boldsymbol{Q})$ had to be identified with its average on the energy surface computed via the Liouville distribution

$$C^{-1} \int F(\boldsymbol{P}, \boldsymbol{Q}) \delta(H(\boldsymbol{P}, \boldsymbol{Q}) - U) \mathrm{d}\boldsymbol{P}\, \mathrm{d}\boldsymbol{Q}$$

with

$$C = \int \delta(H(\boldsymbol{P}, \boldsymbol{Q}) - U) \mathrm{d}\boldsymbol{P}\, \mathrm{d}\boldsymbol{Q}$$

(the appropriate normalization factor): a property that was written symbolically

$$\frac{\mathrm{d}t}{T} = \frac{\mathrm{d}\boldsymbol{P}\, \mathrm{d}\boldsymbol{Q}}{\int \mathrm{d}\boldsymbol{P}\, \mathrm{d}\boldsymbol{Q}}$$

or

$$\lim_{T \to \infty} \frac{1}{T} \int_0^T F(S_t(\boldsymbol{P}, \boldsymbol{Q})) \mathrm{d}t = \frac{\int F(\boldsymbol{P}', \boldsymbol{Q}') \delta(H(\boldsymbol{P}', \boldsymbol{Q}') - U)\, \mathrm{d}\boldsymbol{P}' \mathrm{d}\boldsymbol{Q}'}{\int \delta(H(\boldsymbol{P}', \boldsymbol{Q}') - U)\, \mathrm{d}\boldsymbol{P}' \mathrm{d}\boldsymbol{Q}'} \qquad [8]$$

The validity of [8] for all (piecewise smooth) observables $F$ and for all points of the energy surface, with the exception of a set of zero area, is called the ergodic hypothesis.

For more details, the reader is referred to Boltzmann (1968) and Gallavotti (1999).

## Ensembles

Eventually Boltzmann in 1884 realized that the validity of the heat theorem for averages computed via the right-hand side (rhs) of [8] held independently of the ergodic hypothesis, that is, [8] was not necessary because the heat theorem (i.e., [3]) could also be derived under the only assumption that the averages involved in its formulation were computed

as averages over phase space with respect to the probability distribution on the rhs of [8].

Furthermore, if $T$ was identified with the average kinetic energy, $U$ with the average energy, and $p$ with the average force per unit surface on the walls of the container $\Omega$ with volume $V$, the relation [3] held for a variety of families of probability distributions on phase space, besides [8]. Among these are:

1. The "microcanonical ensemble," which is the collection of probability distributions on the rhs of [8] parametrized by $u = U/N, v = V/N$ (energy and volume per particle),

$$\mu^{\mathrm{mc}}_{u,v}(\mathrm{d}\boldsymbol{P}\,\mathrm{d}\boldsymbol{Q}) = \frac{1}{Z_{\mathrm{mc}}(U,N,V)}\delta(H(\boldsymbol{P},\boldsymbol{Q}) - U)\frac{\mathrm{d}\boldsymbol{P}\,\mathrm{d}\boldsymbol{Q}}{N!h^{dN}} \qquad [9]$$

   where $h$ is a constant with the dimensions of an action which, in the discrete representation of phase space mentioned in the previous section, can be taken such that $h^{dN}$ equals the volume of the cells and, therefore, the integrals with respect to [9] can be interpreted as an (approximate) sum over the cells conceived as microscopic configurations of $N$ indistinguishable particles (whence the $N!$).

2. The "canonical ensemble," which is the collection of probability distributions parametrized by $\beta, v = V/N$,

$$\mu^{\mathrm{c}}_{\beta,v}(\mathrm{d}\boldsymbol{P}\mathrm{d}\boldsymbol{Q}) = \frac{1}{Z_{\mathrm{c}}(\beta,N,V)}\mathrm{e}^{-\beta H(\boldsymbol{P},\boldsymbol{Q})}\frac{\mathrm{d}\boldsymbol{P}\mathrm{d}\boldsymbol{Q}}{N!h^{dN}} \qquad [10]$$

   to which more ensembles can be added, such as the grand canonical ensemble (Gibbs).

3. The "grand canonical ensemble" which is the collection of probability distributions parameterized by $\beta, \lambda$ and defined over the space $\mathcal{F}_{\mathrm{gc}} = \cup_{N=0}^{\infty}\mathcal{F}(N)$,

$$\mu^{\mathrm{gc}}_{\beta,\lambda}(\mathrm{d}\boldsymbol{P}\mathrm{d}\boldsymbol{Q}) = \frac{1}{Z_{\mathrm{gc}}(\beta,\lambda,V)}\mathrm{e}^{\beta\lambda N - \beta H(\boldsymbol{P},\boldsymbol{Q})}\frac{\mathrm{d}\boldsymbol{P}\mathrm{d}\boldsymbol{Q}}{N!h^{dN}} \qquad [11]$$

Hence, there are several different models of thermodynamics. The key tests for accepting them as real microscopic descriptions of macroscopic thermodynamics are as follows.

1. A correspondence between the macroscopic states of thermodynamic equilibrium and the elements of a collection of probability distributions on phase space can be established by identifying, on the one hand, macroscopic thermodynamic states with given values of the thermodynamic functions and, on the other, probability distributions attributing the same average values to the corresponding microscopic observables (i.e., whose averages have the interpretation of thermodynamic functions).
2. Once the correct correspondence between the elements of the different ensembles is established, that is, once the pairs $(u,v), (\beta,v), (\beta,\lambda)$ are so related to produce the same values for the averages $U, V, k_{\mathrm{B}}T \stackrel{\mathrm{def}}{=} \beta^{-1}, p|\partial\Omega|$ of

$$H(\boldsymbol{P},\boldsymbol{Q}), V, \frac{2K(\boldsymbol{P})}{3N}, \int \delta_{\partial\Omega}(\boldsymbol{q}_1)2m(\boldsymbol{v}_1\cdot\boldsymbol{n})^2\,\mathrm{d}\boldsymbol{q}_1 \qquad [12]$$

where ($\delta_{\partial\Omega}(\boldsymbol{q}_1)$ is a delta-function pinning $\boldsymbol{q}_1$ to the surface $\partial\Omega$), then the averages of all physically interesting observables *should coincide* at least in the thermodynamic limit, $\Omega \to \infty$. In this way, the elements $\mu$ of the considered collection of probability distributions can be identified with the states of macroscopic equilibrium of the system. The $\mu$'s depend on parameters and therefore they form an ensemble: each of them corresponds to a macroscopic equilibrium state whose thermodynamic functions are appropriate averages of microscopic observables and therefore are functions of the parameters identifying $\mu$.

**Remark** The word "ensemble" is often used to indicate the individual probability distributions of what has been called here an ensemble. The meaning used here seems closer to the original sense in the 1884 paper of Boltzmann (in other words, often by "ensemble" one means that collection of the phase space points on which a given probability distribution is considered, and this does not seem to be the original sense).

For instance, in the case of the microcanonical distributions this means interpreting energy, volume, temperature, and pressure of the equilibrium state with specific energy $u$ and specific volume $v$ as proportional, through appropriate universal proportionality constants, to the integrals with respect to $\mu^{\mathrm{mc}}_{u,v}(\mathrm{d}\boldsymbol{P}\,\mathrm{d}\boldsymbol{Q})$ of the mechanical quantities in [12]. The averages of other thermodynamic observables in the state with specific energy $u$ and specific volume $v$ should be given by their integrals with respect to $\mu^{\mathrm{mc}}_{u,v}$.

Likewise, one can interpret energy, volume, temperature, and pressure of the equilibrium state with specific energy $u$ and specific volume $v$ as the averages of the mechanical quantities [12] with respect to the canonical distribution $\mu^{\mathrm{c}}_{\beta,v}(\mathrm{d}\boldsymbol{P}\,\mathrm{d}\boldsymbol{Q})$ which has average specific energy precisely $u$. The averages of other thermodynamic observables in the state with specific energy and volume $u$ and $v$ are

given by their integrals with respect to $\mu^{c}_{\beta,v}$. A similar definition can be given for the description of thermodynamic equilibria via the grand canonical distributions.

For more details, see Gibbs (1981) and Gallavotti (1999).

## Equivalence of Ensembles

BOLTZMANN proved that, computing averages via the microcanonical or canonical distributions, the essential property [3] was satisfied when changes in their parameters (i.e., $u, v$ or $\beta, v$, respectively) induced changes $\mathrm{d}u$ and $\mathrm{d}v$ on energy and volume, respectively. He also proved that the function $s$, whose existence is implied by [3], was the same function once expressed as a function of $u, v$ (or of any pair of thermodynamic parameters, e.g., of $T, v$ or $p, u$). A close examination of Boltzmann's proof shows that the [3] holds exactly in the canonical ensemble and up to corrections tending to 0 as $\Omega \to \infty$ in the microcanonical ensemble. Identity of thermodynamic functions evaluated in the two ensembles holds, as a consequence, up to corrections of this order. In addition, Gibbs added that the same held for the grand canonical ensemble.

Of course, not every collection of stationary probability distributions on phase space would provide a model for thermodynamics: Boltzmann called "orthodic" the collections of stationary distributions which generated models of thermodynamics through the above-mentioned identification of its elements with macroscopic equilibrium states. The microcanonical, canonical, and the later grand canonical ensembles are the chief examples of orthodic ensembles. Boltzmann and Gibbs proved these ensembles to be not only orthodic but to generate the same thermodynamic functions, that is to generate the same thermodynamics.

This meant freedom from the analysis of the truth of the doubtful ergodic hypothesis (still unproved in any generality) or of the monocyclicity (manifestly false if understood literally rather than regarding the phase space as consisting of finitely many small, discrete cells), and allowed Gibbs to formulate the problem of statistical mechanics of equilibrium as follows.

**Problem** Study the properties of the collection of probability distributions constituting (any) one of the above ensembles.

However, by no means the three ensembles just introduced exhaust the class of orthodic ensembles producing the same models of thermodynamics in the limit of infinitely large systems. The wealth of ensembles with the orthodicity property, hence leading to equivalent mechanical models of thermodynamics, can be naturally interpreted in connection with the phenomenon of phase transition (see the section "Phase transitions and boundary conditions").

Clearly, the quoted results do not "prove" that thermodynamic equilibria "are" described by the microcanonical, canonical, or grand canonical ensembles. However, they certainly show that, for most systems, independently of the number of degrees of freedom, one can define quite unambiguously a mechanical model of thermodynamics establishing parameter-free, system-independent, physically important relations between thermodynamic quantities (e.g., $\partial_u(p(u,v)/T(u,v)) \equiv \partial_v(1/T(u,v))$, from [3]).

The ergodic hypothesis which was at the root of the mechanical theorems on heat and entropy cannot be taken as a justification of their validity. Naively one would expect that the time scale necessary to see an equilibrium attained, called recurrence time scale, would have to be at least the time that a phase space point takes to visit all possible microscopic states of given energy: hence, an explanation of why the necessarily enormous size of the recurrence time is not a problem becomes necessary.

In fact, the recurrence time can be estimated once the phase space is regarded as discrete: for the purpose of countering mounting criticism, Boltzmann assumed that momentum was discretized in units of $(2mk_{\mathrm{B}}T)^{1/2}$ (i.e., the average momentum size) and space was discretized in units of $\rho^{-1/3}$ (i.e., the average spacing), implying a volume of cells $h^{3N}$ with $h \stackrel{\mathrm{def}}{=} \rho^{-1/3}(2mk_{\mathrm{B}}T)^{1/2}$; then he calculated that, even with such a gross discretization, a cell representing a microscopic state of $1\,\mathrm{cm}^3$ of hydrogen at normal condition would require a time (called "recurrence time") of the order of $\sim 10^{10^{19}}$ times the age of the Universe (!) to visit the entire energy surface. In fact, the phase space volume is $\Gamma = (\rho^{-3}N(2mk_{\mathrm{B}}T)^{3/2})^N \equiv h^{3N}$ and the number of cells of volume $h^{3N}$ is $\Gamma/(N!h^{3N}) \simeq \mathrm{e}^{3N}$; and the time to visit all will be $\mathrm{e}^{3N}\tau_0$, with $\tau_0$ a typical atomic unit, e.g., $10^{-12}\,\mathrm{s}$ – but $N = 10^{19}$. In this sense, the statement boldly made by young Boltzmann that "aperiodic motions can be regarded as periodic with infinite period" was even made quantitative.

The recurrence time is clearly so long to be irrelevant for all purposes: nevertheless, the correctness of the microscopic theory of thermodynamics can still rely on the microscopic dynamics once it is understood (as stressed by Boltzmann) that the reason why we observe approach to equilibrium, and equilibrium itself, over "human" timescales

(which are far shorter than the recurrence times) is due to the property that on most of the energy surface the (very few) observables whose averages yield macroscopic thermodynamic functions (namely pressure, temperature, energy, ...) *assume the same value* even if $N$ is only very moderately large (of the order of $10^3$ rather than $10^{19}$). This implies that this value coincides with the average and therefore satisfies the heat theorem without any contradiction with the length of the recurrence time. The latter rather concerns the time needed to the *generic observable* to thermalize, that is, to reach its time average: the generic observable will indeed take a very long time to "thermalize" but no one will ever notice, because the generic observable (e.g., the position of a pre-identified particle) is not relevant for thermodynamics.

The word "proof" is not used in the mathematical sense so far in this article: the relevance of a mathematically rigorous analysis was widely realized only around the 1960s at the same time when the first numerical studies of the thermodynamic functions became possible and rigorous results were needed to check the correctness of various numerical simulations.

For more details, the reader is referred to Boltzmann (1968a, b) and Gallavotti (1999).

## Thermodynamic Limit

Adopting Gibbs axiomatic point of view, it is interesting to see the path to be followed to achieve an equivalence proof of three ensembles introduced in the section "Heat theorem and ergodic hypothesis."

A preliminary step is to consider, given a cubic box $\Omega$ of volume $V = L^d$, the normalization factors $Z^{gc}(\beta, \lambda, V), Z^{c}(\beta, N, V)$, and $Z^{mc}(U, N, V)$ in [9], [10], and [11], respectively, and to check that the following thermodynamic limits exist:

$$\begin{aligned} \beta p_{gc}(\beta,\lambda) &\stackrel{\text{def}}{=} \lim_{V\to\infty} \frac{1}{V} \log Z^{gc}(\beta,\lambda,V) \\ -\beta f_c(\beta,\rho) &\stackrel{\text{def}}{=} \lim_{V\to\infty, \frac{N}{V}=\rho} \frac{1}{N} \log Z^{c}(\beta,N,V) \\ k_B^{-1} s_{mc}(u,\rho) & \\ &\stackrel{\text{def}}{=} \lim_{V\to\infty, N/V=\rho,\, U/N=u} \frac{1}{N} \log Z^{mc}(U,N,V) \end{aligned} \qquad [13]$$

where the density $\rho \stackrel{\text{def}}{=} v^{-1} \equiv N/V$ is used, instead of $v$, for later reference. The normalization factors play an important role because they have simple thermodynamic interpretation (see the next section): they are called grand canonical, canonical, and microcanonical partition functions, respectively.

Not surprisingly, assumptions on the interparticle potential $\varphi(q - q')$ are necessary to achieve an existence proof of the limits in [13]. The assumptions on $\varphi$ are not only quite general but also have a clear physical meaning. They are

1. *stability*: that is, existence of a constant $B \ge 0$ such that $\sum_{i<j}^{N} \varphi(q_i - q_j) \ge -BN$ for all $N \ge 0$, $q_1, \dots, q_N \in \mathbb{R}^d$, and
2. *temperedness*: that is, existence of constants $\varepsilon_0$, $R > 0$ such that $|\varphi(q - q')| < B|q - q'|^{-d-\varepsilon_0}$ for $|q - q'| > R$.

The assumptions are satisfied by essentially all microscopic interactions with the notable exceptions of the gravitational and Coulombic interactions, which require a separate treatment (and lead to somewhat different results on the thermodynamic behavior).

For instance, assumptions (1), (2) are satisfied if $\varphi(q)$ is $+\infty$ for $|q| < r_0$ and smooth for $|q| > r_0$, for some $r_0 \ge 0$, and furthermore $\varphi(q) > B_0|q|^{-(d+\varepsilon_0)}$ if $r_0 < |q| \le R$, while for $|q| > R$ it is $|\varphi(q)| < B_1|q|^{-(d+\varepsilon_0)}$, for some $B_0, B_1, \varepsilon_0 > 0, R > r_0$. Briefly, $\varphi$ is fast diverging at contact and fast approaching 0 at large distance. This is called a (generalized) Lennard–Jones potential. If $r_0 > 0$, $\varphi$ is called a hard-core potential. If $B_1 = 0$, the potential is said to have finite range. (See Appendix 1 for physical implications of violations of the above stability and temperedness properties.) However, in the following, it will be necessary, both for simplicity and to contain the length of the exposition, to restrict consideration to the case $B_1 = 0$, i.e., to

$$\begin{aligned} \varphi(q) &> B_0|q|^{-(d+\varepsilon_0)}, \quad r_0 < |q| \le R, \\ |\varphi(q)| &\equiv 0, \quad |q| > R \end{aligned} \qquad [14]$$

unless explicitly stated.

Assuming stability and temperedness, the existence of the limits in [13] can be mathematically proved: in Appendix 2, the proof of the first is analyzed to provide the simplest example of the technique. A remarkable property of the functions $\beta p_{gc}(\beta, \lambda)$, $-\beta\rho f_c(\beta, \rho)$, and $\rho s_{mc}(u, \rho)$ is that they are convex functions: hence, they are continuous in the interior of their domains of definition and, at one variable fixed, are differentiable with respect to the other with at most countably many exceptions.

In the case of a potential without hard core ($\rho_{max} = \infty$), $-\rho f_c(\beta, \rho)$ can be checked to tend to 0 slower than $\rho$ as $\rho \to 0$, and to $-\infty$ faster than $-\rho$ as $\rho \to \infty$ (essentially proportionally to $-\rho \log \rho$ in both cases). Likewise, in the same case, $s_{mc}(u, \rho)$ can be shown to tend to 0 slower than $u - u_{min}$ as $u \to u_{min}$, and to $-\infty$ faster than $-u$ as $u \to \infty$. The latter

asymptotic properties can be exploited to derive, from the relations between the partition functions in [13],

$$Z^{gc}(\beta,\lambda,V)=\sum_{N=0}^{\infty} e^{\beta\lambda N}Z^{c}(\beta,N,V)$$
$$Z^{c}(\beta,N,V)=\int_{-B}^{\infty} e^{-\beta U}Z^{mc}(U,N,V)\,dU \qquad [15]$$

and, from the above-mentioned convexity, the consequences

$$\beta p_{mc}(\beta,\lambda)=\max_{v}(\beta\lambda v^{-1}-\beta v^{-1}f_c(\beta,v^{-1}))$$
$$-\beta f_c(\beta,v^{-1})=\max_{u}(-\beta u+k_B^{-1}s_{mc}(u,v^{-1})) \qquad [16]$$

and that the maxima are attained in points, or intervals, internal to the intervals of definition. Let $v_{gc}, u_c$ be points where the maxima are, respectively, attained in [16].

Note that the quantity $e^{\beta\lambda N}Z^c(\beta,N,V)/Z^{gc}(\beta,\lambda,V)$ has the interpretation of probability of a density $v^{-1}=N/V$ evaluated in the grand canonical distribution. It follows that, if the maximum in the first of [16] is strict, that is, it is reached at a single point, the values of $v^{-1}$ in closed intervals not containing the maximum point $v_{gc}^{-1}$ have a probability behaving as $<e^{-cV}$, $c>0$, as $V\to\infty$, compared to the probability of $v^{-1}$'s in any interval containing $v_{gc}^{-1}$. Hence, $v_{gc}$ has the interpretation of average value of $v$ in the grand canonical distribution, in the limit $V\to\infty$.

Likewise, the interpretation of

$$e^{-\beta uN}Z^{mc}(uN,\ N,\ V)/Z^c(\beta,\ N,\ V)$$

as probability in the canonical distribution of an energy density $u$ shows that, if the maximum in the second of [16] is strict, the values of $u$ in closed intervals not containing the maximum point $u_c$ have a probability behaving as $<e^{-cV}, c>0$, as $V\to\infty$, compared to the probability of $u$'s in any interval containing $u_c$. Hence, in the limit $\Omega\to\infty$, the average value of $u$ in the canonical distribution is $u_c$.

If the maxima are strict, [16] also establishes a relation between the grand canonical density, the canonical free energy and the grand canonical parameter $\lambda$, or between the canonical energy, the microcanonical entropy, and the canonical parameter $\beta$:

$$\lambda=\partial_{v^{-1}}(v_{gc}^{-1}f_c(\beta,v_{gc}^{-1})),\qquad k_B\beta=\partial_u s_{mc}(u_c,v^{-1}) \qquad [17]$$

where convexity and strictness of the maxima imply the derivatives existence.

**Remark** Therefore, in the equivalence between canonical and microcanonical ensembles, the canonical distribution with parameters $(\beta,v)$ should correspond with the microcanonical with parameters $(u_c,v)$. The grand canonical distribution with parameters $(\beta,\lambda)$ should correspond with the canonical with parameters $(\beta,v_{gc})$.

For more details, the reader is referred to Ruelle (1969) and Gallavotti (1999).

## Physical Interpretation of Thermodynamic Functions

The existence of the limits [13] implies several properties of interest. The first is the possibility of finding the physical meaning of the functions $p_{gc}, f_c, s_{mc}$ and of the parameters $\lambda,\beta$

Note first that, for all $V$ the grand canonical average $\langle K\rangle_{\beta,\lambda}$ is $(d/2)\beta^{-1}\langle N\rangle_{\beta,\lambda}$ so that $\beta^{-1}$ is proportional to the temperature $T_{gc}=T(\beta,\lambda)$ in the grand canonical distribution: $\beta^{-1}=k_BT(\beta,\lambda)$. Proceeding heuristically, the physical meaning of $p(\beta,\lambda)$ and $\lambda$ can be found through the following remarks.

Consider the microcanonical distribution $\mu_{u,v}^{mc}$ and denote by $\int^*$ the integral over $(\boldsymbol{P},\boldsymbol{Q})$ extended to the domain of the $(\boldsymbol{P},\boldsymbol{Q})$ such that $H(\boldsymbol{P},\boldsymbol{Q})=U$ and, at the same time, $q_1\in dV$, where $dV$ is an infinitesimal volume surrounding the region $\Omega$. Then, by the microscopic definition of the pressure $p$ (see the introductory section), it is

$$p\,dV=\frac{N}{Z(U,N,V)}\int^*\delta\frac{2}{3}\frac{p_1^2}{2m}\frac{d\boldsymbol{P}\,d\boldsymbol{Q}}{N!h^{dN}}$$
$$\equiv\frac{2}{3Z(U,N,V)}\int^*\delta K(\boldsymbol{P})\frac{d\boldsymbol{P}\,d\boldsymbol{Q}}{N!h^{dN}} \qquad [18]$$

where $\delta\equiv\delta(H(\boldsymbol{P},\boldsymbol{Q})-U)$. The RHS of [18] can be compared with

$$\frac{\partial_V Z(U,N,V)dV}{Z(U,N,V)}=\frac{N}{Z(U,N,V)}\int^*\frac{d\boldsymbol{P}\,d\boldsymbol{Q}}{N!h^{dN}}$$

to give

$$\frac{\partial_V Z\,dV}{Z}=N\frac{p\,dV}{(2/3)\langle K\rangle^*}=\beta p\,dV$$

because $\langle K\rangle^*$, which denotes the average $\int^*K/\int^*1$, should be essentially the same as the microcanonical average $\langle K\rangle_{mc}$ (i.e., insensitive to the fact that one particle is constrained to the volume $dV$) if $N$ is large. In the limit $V\to\infty, V/N=v$, the latter remark together with the second of [17] yields

$$k_B^{-1}\partial_v s_{mc}(u,v^{-1})=\beta p(u,v),$$
$$k_B^{-1}\partial_u s_{mc}(u,v)=\beta \qquad [19]$$

respectively. Note that $p\geq 0$ and it is not increasing in $v$ because $s_{mc}(\rho)$ is concave as a function of $v=\rho^{-1}$ (in fact, by the remark following [14] $\rho s_{mc}(u,\rho)$ is convex in $\rho$ and, in general, if $\rho g(\rho)$ is convex in $\rho$ then $g(v^{-1})$ is always concave in $v=\rho^{-1}$).

Hence, $ds_{mc}(u,v) = (du + p dv)/T$, so that taking into account the physical meaning of $p$, $T$ (as pressure and temperature, see the section "Pressure, temperature, and kinetic energy"), $s_{mc}$ is, in thermodynamics, the entropy. Therefore (see the second of [16]), $-\beta f_c(\beta,\rho) = -\beta u_c + k_B^{-1} s_{mc}(u_c,\rho)$ becomes

$$f_c(\beta,\rho) = u_c - T_c s_{mc}(u_c,\rho), \qquad df_c = -p\,dv - s_{mc}\,dT \tag{20}$$

and since $u_c$ has the interpretation (as mentioned in the last section) of average energy in the canonical distribution $\mu^c_{\beta,v}$ it follows that $f_c$ has the thermodynamic interpretation of free energy (once compared with the definition of free energy, $F = U - TS$, in thermodynamics).

By [17] and [20],

$$\lambda = \partial_{v^{-1}}(v_{gc}^{-1} f_c(\beta, v_{gc}^{-1})) \equiv u_c - T_c s_{mc} + p v_{gc}$$

and $v_{gc}$ has the meaning of specific volume $v$. Hence, after comparison with the definition of chemical potential, $\lambda V = U - TS + pV$, in thermodynamics, it follows that the thermodynamic interpretation of $\lambda$ is the chemical potential and (see [16], [17]), the grand canonical relation

$$\beta p_{gc}(\beta,\lambda) = \beta\lambda v_{gc}^{-1} - \beta v_{gc}^{-1}(-\beta u_c + k_B^{-1} s_{mc}(u_c, v^{-1}))$$

shows that $p_{gc}(\beta,\lambda) \equiv p$, implying that $p_{gc}(\beta,\lambda)$ is the pressure expressed, however, as a function of temperature and chemical potential.

To go beyond the heuristic derivations above, it should be remarked that convexity and the property that the maxima in [16], [17] are reached in the interior of the intervals of variability of $v$ or $u$ are sufficient to turn the above arguments into rigorous mathematical deductions: this means that given [19] as definitions of $p(u,v), \beta(u,v)$, the second of [20] follows as well as $p_{gc}(\beta,\lambda) \equiv p(u_v, v_{gc}^{-1})$. But the values $v_{gc}$ and $u_c$ in [16] are not necessarily unique: convex functions can contain horizontal segments and therefore the general conclusion is that the maxima may possibly be attained in intervals. Hence, instead of a single $v_{gc}$, there might be a whole interval $[v_-, v_+]$, where the rhs of [16] reaches the maximum and, instead of a single $u_c$, there might be a whole interval $[u_-, u_+]$ where the rhs of [17] reaches the maximum.

Convexity implies that the values of $\lambda$ or $\beta$ for which the maxima in [16] or [17] are attained in intervals rather than in single points are rare (i.e., at most denumerably many): the interpretation is, in such cases, that the thermodynamic functions show discontinuities, and the corresponding phenomena are called phase transitions (see the next section).

For more details the reader is referred to Ruelle (1969) and Gallavotti (1999).

## Phase Transitions and Boundary Conditions

The analysis in the last two sections of the relations between elements of ensembles of distributions describing macroscopic equilibrium states not only allows us to obtain mechanical models of thermodynamics but also shows that the models, for a given system, coincide at least as $\Omega \to \infty$. Furthermore, the equivalence between the thermodynamic functions computed via corresponding distributions in different ensembles can be extended to a full equivalence of the distributions.

If the maxima in [16] are attained at single points $v_{gc}$ or $u_c$ the equivalence should take place in the sense that a correspondence between $\mu^{gc}_{\beta,\lambda}, \mu^c_{\beta,v}, \mu^{mc}_{u,v}$ can be established so that, given any local observable $F(\boldsymbol{P},\boldsymbol{Q})$, defined as an observable depending on $(\boldsymbol{P},\boldsymbol{Q})$ only through the $\boldsymbol{p}_i, \boldsymbol{q}_i$ with $\boldsymbol{q}_i \in \Lambda$, where $\Lambda \subset \Omega$ is a finite region, has the same average with respect to corresponding distributions in the limit $\Omega \to \infty$.

The correspondence is established by considering $(\lambda,\beta) \leftrightarrow (\beta, v_{gc}) \leftrightarrow (u_{mc}, v)$, where $v_{gc}$ is where the maximum in [16] is attained, $u_{mc} \equiv u_c$ is where the maximum in [17] is attained and $v_{gc} \equiv v$, (cf. also [19], [20]). This means that the limits

$$\lim_{V\to\infty} \int F(\boldsymbol{P},\boldsymbol{Q})\mu^a(d\boldsymbol{P}\,d\boldsymbol{Q}) \stackrel{\text{def}}{=} \langle F\rangle_a \qquad (a - \text{independent}),\ a = \text{gc}, \text{c}, \text{mc} \tag{21}$$

coincide if the averages are evaluated by the distributions $\mu^{gc}_{\beta,\lambda}, \mu^c_{\beta,v_c}, \mu^{mc}_{u_{mc},v_{mc}}$.

Exceptions to [21] are possible: and are certainly likely to occur at values of $u$, $v$ where the maxima in [16] or [17] are attained in intervals rather than in isolated points; but this does not exhaust, in general, the cases in which [21] may not hold.

However, no case in which [21] fails has to be regarded as an exception. It rather signals that an interesting and important phenomenon occurs. To understand it properly, it is necessary to realize that the grand canonical, canonical, and microcanonical families of probability distributions are by far not the only ensembles of probability distributions whose elements can be considered to generate models of thermodynamics, that is, which are orthodic in the sense of the discussion in the section "Equivalence of ensembles." More general families of orthodic statistical ensembles of probability

distributions can be very easily conceived. In particular:

**Definition** Consider the grand canonical, canonical, and microcanonical distributions associated with an energy function in which the potential energy contains, besides the interaction $\Phi$ between particles located inside the container, also the interaction energy $\Phi_{\text{in, out}}$ between particles inside the container and external particles, identical to the ones in the container but not allowed to move and fixed in positions such that in every unit cube $\Delta$ external to $\Omega$ there is a finite number of them bounded independently of $\Delta$. Such configurations of external particles will be called "boundary conditions of fixed external particles."

The thermodynamic limit with such boundary conditions is obtained by considering the grand canonical, canonical, and microcanonical distributions constructed with potential energy function $\Phi + \Phi_{\text{in, out}}$ in containers $\Omega$ of increasing size taking care that, while the size increases, the fixed particles that would become internal to $\Omega$ are eliminated. The argument used in the section "Thermodynamic limit" to show that the three models of thermodynamics, considered there, did define the same thermodynamic functions can be repeated to reach the conclusion that also the (infinitely many) "new" models of thermodynamics in fact give rise to the same thermodynamic functions and averages of local observables. Furthermore, the values of the limits corresponding to [13] can be computed using the new partition functions and coincide with the ones in [13] (i.e., they are independent of the boundary conditions).

However, it may happen, and in general it is the case, for many models and for particular values of the state parameters, that the limits in [21] do not coincide with the analogous limits computed in the new ensembles, that is, the averages of some local observables are unstable with respect to changes of boundary conditions with fixed particles.

There is a very natural interpretation of such apparent ambiguity of the various models of thermodynamics: namely, at the values of the parameters that are selected to describe the macroscopic states under consideration, there may correspond different equilibrium states with the same parameters. When the maximum in [16] is reached on an interval of densities, one should not think of any failure of the microscopic models for thermodynamics: rather one has to think that there are several states possible with the same $\beta, \lambda$ and that they can be identified with the probability distributions obtained by forming the grand canonical, canonical, or microcanonical distributions with different kinds of boundary conditions.

For instance, a boundary condition with high density may produce an equilibrium state with parameters $\beta, \lambda$ which also has high density, i.e., the density $v_+^{-1}$ at the right extreme of the interval in which the maximum in [16] is attained, while using a low-density boundary condition the limit in [21] may describe the averages taken in a state with density $v_-^{-1}$ at the left extreme of the interval or, perhaps, with a density intermediate between the two extremes. Therefore, the following definition emerges.

**Definition** If the grand canonical distributions with parameters $(\beta, \lambda)$ and different choices of fixed external particles boundary conditions generate for some local observable $F$ average values which are different by more than a quantity $\delta > 0$ for all large enough volumes $\Omega$ then one says that the system has a phase transition at $(\beta, \lambda)$. This implies that the limits in [21], when existing, will depend on the boundary condition and their values will represent averages of the observables in "different phases." A corresponding definition is given in the case of the canonical and microcanonical distributions when, given $(\beta, v)$ or $(u, v)$, the limit in [21] depends on the boundary conditions for some $F$.

**Remarks**

1. The idea is that by fixing one of the thermodynamic ensembles and by varying the boundary conditions one can realize all possible states of equilibrium of the system that can exist with the given values of the parameters determining the state in the chosen ensemble (i.e., $(\beta, \lambda)$, $(\beta, v)$, or $(u, v)$ in the grand canonical, canonical, or microcanonical cases, respectively).
2. The impression that in order to define a phase transition the thermodynamic limit is necessary is incorrect: the definition does not require considering the limit $\Omega \to \infty$. The phenomenon that occurs is that by changing boundary conditions the average of a local observable can change at least by amounts independent of the system size. Hence, occurrence of a phase transition is perfectly observable in finite volume: it suffices to check that by changing boundary conditions the average of some observable changes by an amount whose minimal size is volume independent. It is a manifestation of an instability of the averages with respect to changes in boundary conditions: an instability which does not fade away when the boundary recedes to infinity, i.e., boundary perturbations produce

bulk effects and at a phase transition the averages of the local observable, if existing at all, will exhibit a nontrivial dependence on the boundary conditions. This is also called "long range order."

3. It is possible to show that when this happens then some thermodynamic function whose value is independent of the boundary condition (e.g., the free energy in the canonical distributions) has discontinuous derivatives in terms of the parameters of the ensemble. This is in fact one of the frequently-used alternative definitions of phase transitions: the latter two natural definitions of first-order phase transition are equivalent. However, it is very difficult to prove that a given system shows a phase transition. For instance, existence of a liquid–gas phase transition is still an open problem in systems of the type considered until the section "Lattice models" below.
4. A remarkable unification of the theory of the equilibrium ensembles emerges: all distributions of any ensemble describe equilibrium states. If a boundary condition is fixed once and for all, then some equilibrium states might fail to be described by an element of an ensemble. However, if all boundary conditions are allowed then all equilibrium states should be realizable in a given ensemble by varying the boundary conditions.
5. The analysis leads us to consider as completely equivalent without exceptions grand canonical, canonical, or microcanonical ensembles enlarged by adding to them the distributions with potential energy augmented by the interaction with fixed external particles.
6. The above picture is really proved only for special classes of models (typically in models in which particles are constrained to occupy points of a lattice and in systems with hard core interactions, $r_0 > 0$ in [14]) but it is believed to be correct in general. At least it is consistent with all that is known so far in classical statistical mechanics. The difficulty is that, conceivably, one might even need boundary conditions more complicated than the fixed particles boundary conditions (e.g., putting different particles outside, interacting with the system with an arbitrary potential, rather than via $\varphi$).

The discussion of the equivalence of the ensembles and the question of the importance of boundary conditions has already imposed the consideration of several limits as $\Omega \to \infty$. Occasionally, it will again come up. For conciseness, it is useful to set up a formal definition of equilibrium states of an infinite-volume system: although infinite volume is an idealization void of physical reality, it is nevertheless useful to define such states because certain notions (e.g., that of pure state) can be sharply defined, with few words and avoiding wide circumvolutions, in terms of them. Therefore, let:

**Definition** An infinite-volume state with parameters $(\beta, v), (u, v)$ or $(\beta, \lambda)$ is a collection of average values $F \to \langle F \rangle$ obtained, respectively, as limits of finite-volume averages $\langle F \rangle_{\Omega_n}$ defined from canonical, microcanonical, or grand canonical distributions in $\Omega_n$ with fixed parameters $(\beta, v), (u, v)$ or $(\beta, \lambda)$ and with general boundary condition of fixed external particles, on sequences $\Omega_n \to \infty$ for which such limits exist simultaneously for all local observables $F$.

Having set the definition of infinite-volume state consider a local observable $G(X)$ and let $\tau_\xi G(X) = G(X + \xi), \xi \in \mathbb{R}^d$, with $X + \xi$ denoting the configuration $X$ in which all particles are translated by $\xi$: then an infinite-volume state is called a pure state if for any pair of local observables $F, G$ it is

$$\langle F \tau_\xi G \rangle - \langle F \rangle \langle \tau_\xi G \rangle \underset{\xi \to \infty}{\longrightarrow} 0 \qquad [22]$$

which is called a cluster property of the pair $F, G$.

The result alluded to in remark (6) is that at least in the case of hard-core systems (or of the simple lattice systems discussed in the section "Lattice models") the infinite-volume equilibrium states in the above sense exhaust at least the totality of the infinite-volume pure states. Furthermore, the other states that can be obtained in the same way are convex combinations of the pure states, i.e., they are "statistical mixtures" of pure phases. Note that $\langle \tau_\xi G \rangle$ cannot be replaced, in general, by $\langle G \rangle$ because not all infinite-volume states are necessarily translation invariant and in simple cases (e.g., crystals) it is even possible that no translation-invariant state is a pure state.

**Remarks**

1. This means that, in the latter models, generalizing the boundary conditions, for example considering external particles to be not identical to the ones inside the system, using periodic or partially periodic boundary conditions, or the widely used alternative of introducing a small auxiliary potential and first taking the infinite-volume states in presence of it and then letting the potential vanish, does not enlarge further the set of states (but may sometimes be useful: an example of a study of a phase transition by using the latter method of small fields will be given in the section "Continuous symmetries: 'no $d = 2$ crystal' theorem").

2. If $\chi$ is the indicator function of a local event, it will make sense to consider the probability of occurrence of the event in an infinite-volume state defining it as $\langle\chi\rangle$. In particular, the probability density for finding $p$ particles at $x_1, x_2, \ldots, x_p$, called the $p$-point correlation function, will thus be defined in an infinite-volume state. For instance, if the state is obtained as a limit of canonical states $\langle\cdot\rangle_{\Omega_n}$ with parameters $\beta, \rho, \rho = N_n/V_n$, in a sequence of containers $\Omega_n$, then

$$\rho(\boldsymbol{x}) = \lim_n \left\langle \sum_{j=1}^{N_n} \delta(\boldsymbol{x} - \boldsymbol{q}_j) \right\rangle_{\Omega_n}$$

$$\rho(\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_p) = \lim_n \left\langle \sum_{i_1,\ldots,i_p}^{N_n} \prod_{j=1}^{p} \delta(\boldsymbol{x}_j - \boldsymbol{q}_{i_j}) \right\rangle_{\Omega_n}$$

where the sum is over the ordered $p$-ples $(j_1, \ldots, j_p)$. Thus, the *pair correlation* $\rho(\boldsymbol{q}, \boldsymbol{q}')$ and its possible *cluster property* are

$$\rho(\boldsymbol{q}, \boldsymbol{q}') \stackrel{\text{def}}{=} \lim_n \frac{\int_{\Omega_n} \exp(-\beta U(\boldsymbol{q}, \boldsymbol{q}', \boldsymbol{q}_1, \ldots, \boldsymbol{q}_{N_n-2}))\, d\boldsymbol{q}_1 \cdots d\boldsymbol{q}_{N_n-2}}{(N_n-2)!\, Z_0^c(\beta, \rho, V_n)}$$

$$\rho(\boldsymbol{q}, (\boldsymbol{q}' + \boldsymbol{\xi})) - \rho(\boldsymbol{q})\rho(\boldsymbol{q}' + \boldsymbol{\xi}) \underset{\xi \to \infty}{\longrightarrow} 0 \qquad [23]$$

where

$$Z_0^c \stackrel{\text{def}}{=} \int e^{-\beta U(Q)} dQ$$

is the "configurational" partition function.

The reader is referred to Ruelle (1969), Dobrushin (1968), Lanford and Ruelle (1969), and Gallavotti (1999).

## Virial Theorem and Atomic Dimensions

For a long time it has been doubted that "just changing boundary conditions" could produce such dramatic changes as macroscopically different states (i.e., phase transitions in the sense of the definition in the last section). The first evidence that by taking the thermodynamic limit very regular analytic functions like $N^{-1} \log Z^c(\beta, N, V)$ (as a function of $\beta, v = V/N$) could develop, in the limit $\Omega \to \infty$, singularities like discontinuous derivatives (corresponding to the maximum in [16] being reached on a plateau and to a consequent existence of several pure phases) arose in the van der Waals' theory of liquid–gas transition.

Consider a real gas with $N$ identical particles with mass $m$ in a container $\Omega$ with volume $V$. Let the force acting on the $i$th particle be $\boldsymbol{f}_i$; multiplying both sides of the equations of motion, $m\ddot{\boldsymbol{q}}_i = \boldsymbol{f}_i$, by $-(1/2)\boldsymbol{q}_i$ and summing over $i$, it follows that

$$-\frac{1}{2}\sum_{i=1}^{N} m\boldsymbol{q}_i \cdot \ddot{\boldsymbol{q}}_i = -\frac{1}{2}\sum_{i=1}^{N} \boldsymbol{q}_i \cdot \boldsymbol{f}_i \stackrel{\text{def}}{=} \frac{1}{2} C(\boldsymbol{q})$$

and the quantity $C(\boldsymbol{q})$ defines the *virial of the forces* in the configuration $\boldsymbol{q}$. Note that $C(\boldsymbol{q})$ is not translation invariant because of the presence of the forces due to the walls.

Writing the force $\boldsymbol{f}_i$ as a sum of the internal and the external forces (due to the walls) the virial $C$ can be expressed naturally as sum of the virial $C_{\text{int}}$ of the internal forces (translation invariant) and of the virial $C_{\text{ext}}$ of the external forces.

By dividing both sides of the definition of the virial by $\tau$ and integrating over the time interval $[0, \tau]$, one finds in the limit $\tau \to +\infty$, that is, up to quantities relatively infinitesimal as $\tau \to \infty$, that

$$\langle K \rangle = \tfrac{1}{2}\langle C \rangle \quad \text{and} \quad \langle C_{\text{ext}} \rangle = 3pV$$

where $p$ is the pressure and $V$ the volume. Hence

$$\langle K \rangle = \tfrac{3}{2} pV + \tfrac{1}{2}\langle C_{\text{int}} \rangle$$

or

$$\frac{1}{\beta} = pv + \frac{\langle C_{\text{int}} \rangle}{3N} \qquad [24]$$

Equation [24] is Clausius' *virial theorem*: in the case of no internal forces, it yields $\beta pv = 1$, the ideal-gas equation.

The internal virial $C_{\text{int}}$ can be written, if $\boldsymbol{f}_{j\to i} = -\partial_{\boldsymbol{q}_i}\varphi(\boldsymbol{q}_i - \boldsymbol{q}_j)$, as

$$C_{\text{int}} = -\sum_{i=1}^{N}\sum_{i \neq j} \boldsymbol{f}_{j\to i} \cdot \boldsymbol{q}_i \equiv -\sum_{i<j} \partial_{\boldsymbol{q}_i}\varphi(\boldsymbol{q}_i - \boldsymbol{q}_j) \cdot (\boldsymbol{q}_i - \boldsymbol{q}_j)$$

which shows that the contribution to the virial by the internal repulsive forces is negative while that of the attractive forces is positive. The average of $C_{\text{int}}$ can be computed by the canonical distribution, which is convenient for the purpose. van der Waals first used the virial theorem to perform an actual computation of the corrections to the perfect-gas laws. Simply neglect the third-order term in the density and use the approximation $\rho(\boldsymbol{q}_1, \boldsymbol{q}_2) = \rho^2 e^{-\beta\varphi(\boldsymbol{q}_1 - \boldsymbol{q}_2)}$ for the pair correlation function, [23], then

$$\frac{1}{2}\langle C_{\text{int}} \rangle = V \frac{3}{2\beta} \rho^2 I(\beta) + VO(\rho^3) \qquad [25]$$

where

$$I(\beta) = \frac{1}{2}\int (e^{-\beta\varphi(q)} - 1)d^3 q$$

and the equation of state [24] becomes

$$pv + \frac{I(\beta)}{\beta v} + O(v^{-2}) = \beta^{-1}$$

For the purpose of illustration, the calculation of $I$ can be performed approximately at "high temperature" ($\beta$ small) in the case

$$\varphi(r) = 4\varepsilon\left(\left(\frac{r_0}{r}\right)^{12} - \left(\frac{r_0}{r}\right)^6\right)$$

(the classical Lennard–Jones potential), $\varepsilon, r_0 > 0$. The result is

$$I \cong -(b - \beta a)$$

$$b = 4v_0,\ a = \frac{32}{3}\varepsilon v_0,\ v_0 = \frac{4\pi}{3}\left(\frac{r_0}{2}\right)^3$$

Hence,

$$pv + \frac{a}{v} - \frac{b}{\beta v} = \frac{1}{\beta} + O\left(\frac{1}{\beta v^2}\right)$$

$$\left(p + \frac{a}{v^2}\right)v = \left(1 + \frac{b}{v}\right)\frac{1}{\beta} = \frac{1}{1 - b/v}\frac{1}{\beta} + O\left(\frac{1}{\beta v^2}\right)$$

or

$$\left(p + \frac{a}{v^2}\right)(v - b)\beta = 1 + O(v^{-2}) \qquad [26]$$

which gives the equation of state for $\beta\varepsilon \ll 1$. Equation [26] can be compared with the well-known empirical *van der Waals equation* of state:

$$\beta\left(p + \frac{a}{v^2}\right)(v - b) = 1$$

or

$$(p + An^2/V^2)(V - nB) = nRT \qquad [27]$$

where, if $N_A$ is Avogadro's number, $A = aN_A^2$, $B = bN_A, R = k_B N_A, n = N/N_A$. It shows the possibility of accessing the microscopic parameters $\varepsilon$ and $r_0$ of the potential $\varphi$ via measurements detecting deviations from the *Boyle–Mariotte law*, $\beta pv = 1$, of the rarefied gases: $\varepsilon = 3a/8b = 3A/8BN_A$ $r_0 = (3b/2\pi)^{1/3} = (3B/2\pi N_A)^{1/3}$.

As a final comment, it is worth stressing that the virial theorem gives in principle the exact corrections to the equation of state, in a rather direct and simple form, as time averages of the virial of the internal forces. Since the virial of the internal forces is easy to calculate from the positions of the particles as a function of time, the theorem provides a method for computing the equation of state in numerical simulations. In fact, this idea has been exploited in many numerical experiments, in which [24] plays a key role.

For more details, the reader is referred to Gallavotti (1999).

## van der Waals Theory

Equation [27] is empirically used beyond its validity region (small density and small $\beta$) by regarding $A, B$ as phenomenological parameters to be experimentally determined by measuring them near generic values of $p, V, T$. The measured values of $A, B$ do not "usually vary too much" as functions of $v, T$ and, apart from this small variability, the predictions of [27] have reasonably agreed with experience until, as experimental precision increased over the years, serious inadequacies eventually emerged.

Certain consequences of [27] are appealing: for example, Figure 1 shows that it does not give a $p$ monotonic nonincreasing in $v$ if the temperature is small enough. A critical temperature can be defined as the largest value, $T_c$, of the temperature below which the graph of $p$ as a function of $v$ is not monotonic decreasing; the critical volume $V_c$ is the value of $v$ at the horizontal inflection point occurring for $T = T_c$.

For $T < T_c$ the van der Waals interpretation of the equation of state is that the function $p(v)$ may describe metastable states while the actual equilibrium states would follow an equation with a monotonic dependence on $v$ and $p(v)$ becoming horizontal in the coexistence region of specific volumes. The precise value of $p$ where to draw the plateau (see Figure 1) would then be fixed by experiment or theoretically predicted via the simple rule that the plateau associated with the represented isotherm is drawn at a height such that the area of the two cycles in the resulting loop are equal.

This is *Maxwell's rule*: obtained by assuming that the isotherm curve joining the extreme points of the plateau and the plateau itself define a cycle

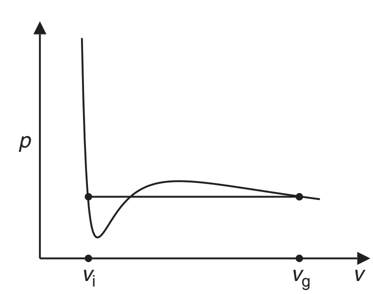

**Figure 1** The van der Waals equation of state at a temperature $T < T_c$ where the pressure is not monotonic. The horizontal line illustrates the "Maxwell rule."

(see **Figure 1**) representing a sequence of possible macroscopic equilibrium states (the ones corresponding to the plateau) or states with extremely long time of stability ("metastable") represented by the curved part. This would be an isothermal Carnot cycle which, therefore, could not produce work: since the work produced in the cycle (i.e., $\oint p\mathrm{d}v$) is the signed area enclosed by the cycle the rule just means that the area is zero. The argument is doubtful at least because it is not clear that the intermediate states with $p$ increasing with $v$ could be realized experimentally or could even be theoretically possible.

A striking prediction of [27], taken literally, is that the gas undergoes a gas–liquid phase transition with a critical point at a temperature $T_c$, volume $v_c$, and pressure $p_c$ that can be computed via [27] and are given by $RT_c = 8A/27B$, $V_c = 3B$ $(n = 1)$.

At the same time, the above prediction is interesting as it shows that there are simple relations between the critical parameters and the microscopic interaction constants, i.e., $\varepsilon \simeq k_B T_c$ and $r_0 \simeq (V_c/N_A))^{1/3}$: or more precisely $\varepsilon = 81 k_B T_c/64$, $r_0 = (V_c/2\pi N_A)^{1/3}$ if a classical Lennard–Jones potential (i.e., $\varphi = 4\varepsilon((r_0/|q|)^{12} - (r_0/|q|)^6)$; see the last section) is used for the interaction potential $\varphi$.

However, [27] cannot be accepted acritically not only because of the approximations (essentially the neglecting of $O(v^{-1})$ in the equation of state), but mainly because, as remarked above, for $T < T_c$ the function $p$ is no longer monotonic in $v$ as it must be; see comment following [19].

The van der Waals equation, refined and complemented by Maxwell's rule, predicts the following behavior:

$$(p - p_c) \propto (v - v_c)^{\delta}, \quad \delta = 3, \ T = T_c$$
$$(v_g - v_l) \propto (T_c - T)^{\beta}, \quad \beta = 1/2, \quad \text{for } T \to T_c^- \qquad [28]$$

which are in sharp contrast with the experimental data gathered in the twentieth century. For the simplest substances, one finds instead $\delta \cong 5$, $\beta \cong 1/3$.

Finally, blind faith in the equation of state [27] is untenable, last but not least, also because nothing in the analysis would change if the space dimension was $d = 2$ or $d = 1$: but for $d = 1$, it is easily proved that the system, if the interaction decays rapidly at infinity, does not undergo phase transitions (see next section).

In fact, it is now understood that van der Waals' equation represents rigorously only a limiting situation, in which particles have a hard-core interaction (or a strongly repulsive one at close distance) and a further smooth interaction $\varphi$ with very long range. More precisely, suppose that the part of the potential outside a hard-core radius $r_0 > 0$ is attractive (i.e., non-negative) and has the form $\gamma^d \varphi_1(\gamma^{-1}|q|) \leq 0$ and call $P_0(v)$ the ($\beta$-independent) product of $\beta$ times the pressure of the hard-core system without any attractive tail ($P_0(v)$ is not explicitly known except if $d = 1$, in which case it is $P_0(v)(v - b) = 1, b = r_0$), and let

$$a = -\frac{1}{2}\int_{|q|>r_0} |\varphi_1(q)| \mathrm{d}q$$

If $p(\beta, v; \gamma)$ is the pressure when $\gamma > 0$ then it can be proved that

$$\beta p(\beta, v) \overset{\text{def}}{=} \lim_{\gamma \to 0} \beta p(\beta, v; \gamma) = \left[-\frac{\beta a}{v^2} + P_0(v)\right]_{\text{Maxwell's rule}} \qquad [29]$$

where the subscript means that the graph of $p(\beta, v)$ as a function of $v$ is obtained from the function in square bracket by applying to it Maxwell's rule, described above in the case of the van der Waals equation. Equation [29] reduces exactly to the van der Waals equation for $d = 1$, and for $d > 1$ it leads to an equation with identical critical behavior (even though $P_0(v)$ cannot be explicitly computed).

The reader is referred to Lebowitz and Penrose (1979) and Gallavotti (1999) for more details.

## Absence of Phase Transitions: $d = 1$

One of the most quoted no-go theorems in statistical mechanics is that one-dimensional systems of particles interacting via short-range forces do not exhibit phase transitions (cf. the next section) unless the somewhat unphysical situation of having zero absolute temperature is considered. This is particularly easy to check in the case of "nearest-neighbor hard-core interactions." Let the hard-core size be $r_0$, so that the interaction potential $\varphi(r) = +\infty$ if $r \leq r_0$, and suppose also that $\varphi(r) \equiv 0$ if $f \geq 2r_0$. In this case, the thermodynamic functions can be exactly computed and checked to be analytic: hence the equation of state cannot have any phase transition plateau. This is a special case of *van Hove's theorem* establishing smoothness of the equation of state for interactions extending beyond the nearest neighbor and rapidly decreasing at infinity.

If the definition of phase transition based on the sensitivity of the thermodynamic limit to variations of boundary conditions is adopted then a more general, conceptually simple, argument can be given to show that in one-dimensional systems there cannot be any phase transition if the potential energy of mutual interaction between a

configuration $Q$ of particles to the left of a reference particle (located at the origin O, say) and a configuration $Q'$ to the right of the particle (with $Q \cup O \cup Q'$ compatible with the hard cores) is uniformly bounded below. Then a mathematical proof can be devised showing that the influence of boundary conditions disappears as the boundaries recede to infinity. One also says that no long-range order can be established in a one-dimensional case, in the sense that one loses any trace of the boundary conditions imposed.

The analysis fails if the space dimension is $\geq 2$: in this case, even if the interaction is short-ranged, the energy of interaction between two regions of space separated by a boundary is of the order of the boundary area. Hence, one cannot bound above and below the probability of any two configurations in two half-spaces by the product of the probabilities of the two configurations, each computed as if the other was not there. This is because such a bound would be proportional to the exponential of the surface of separation, which tends to $\infty$ when the surface grows large. This means that we cannot consider, at least not in general, the configurations in the two half-spaces as independently distributed.

Analytically, a condition on the potential sufficient to imply that the energy between a configuration to the left and one to the right of the origin is bounded below, if $d = 1$, is simply expressed by

$$\int_{r'}^{\infty} r|\varphi(r)|\mathrm{d}r < +\infty \quad \text{for } r' > r_0$$

Therefore, in order to have phase transitions in $d = 1$, a potential is needed that is "so long range" that it has a divergent first moment. It can be shown by counterexamples that if the latter condition fails there can be phase transitions even in $d = 1$ systems.

The results just quoted also apply to discrete models like lattice gases or lattice spin models that will be considered later in the article.

For more details, we refer the reader to Landau and Lifschitz (1967), Dyson (1969), Gallavotti (1999), and Gallavotti *et al.* (2004).

## Continuous Symmetries: "No $d = 2$ Crystal" Theorem

A second case in which it is possible to rule out existence of phase transitions or at least of certain kinds of transitions arises when the system under analysis enjoys large symmetry. By symmetry is meant a group of transformations acting on the configurations and transforming each of them into a configuration which, at least for one boundary condition (e.g., periodic or open), has the same energy.

A symmetry is said to be "continuous" if the group of transformations is a continuous group. For instance, continuous systems have translational symmetry if considered in a container $\Omega$ with periodic boundary conditions. Systems with "too much symmetry" sometimes cannot show phase transitions. For instance, the continuous translation symmetry of a gas in a container $\Omega$ with periodic boundary conditions is sufficient to exclude the possibility of crystallization in dimension $d = 2$.

To discuss this, which is a prototype of a proof which can be used to infer absence of many transitions in systems with continuous symmetries, consider the translational symmetry and a potential satisfying, besides the usual [14] and with the symbols used in [14], the further property that $|\boldsymbol{q}|^2|\partial^2_{ij}\varphi(\boldsymbol{q})| < \overline{B}|\boldsymbol{q}|^{-(d+\varepsilon_0)}$, with $\varepsilon_0 > 0$, for some $\overline{B}$ holds for $r_0 < |\boldsymbol{q}| \leq R$. This is a very mild extra requirement (and it allows for a hard-core interaction).

Consider an "ideal crystal" on a square lattice (for simplicity) of spacing a, exactly fitting in its container $\Omega$ of side $L$ assumed with periodic boundary conditions: so that $N = (L/a)^d$ is the number of particles and $a^{-d}$ is the density, which is supposed to be smaller than the close packing density if the interaction $\varphi$ has a hard core. The probability distribution of the particles is rather trivial:

$$\overline{\mu} = \sum_p \prod_{\boldsymbol{n}} \delta(\boldsymbol{q}_{p(\boldsymbol{n})} - a\,\boldsymbol{n}) \frac{\mathrm{d}Q}{N!}$$

the sum running over the permutations $\boldsymbol{m} \to p(\boldsymbol{m})$ of the sites $\boldsymbol{m} \in \Omega, \boldsymbol{m} \in \mathbb{Z}^d, 0 < m_i \leq La^{-1}$. The density at $\boldsymbol{q}$ is

$$\widehat{\rho}(\boldsymbol{q}) = \sum_{\boldsymbol{n}} \delta(\boldsymbol{q} - a\,\boldsymbol{n}) \equiv \left\langle \sum_{j=1}^{N} \delta(\boldsymbol{q} - \boldsymbol{q}_j) \right\rangle$$

and its Fourier transform is proportional to

$$\rho(\boldsymbol{k}) \stackrel{\mathrm{def}}{=} \frac{1}{N} \left\langle \sum_j \mathrm{e}^{-i\boldsymbol{k}\cdot\boldsymbol{q}_j} \right\rangle, \quad \boldsymbol{k} = \frac{2\pi}{L}\boldsymbol{n},\ \boldsymbol{n} \in \mathbb{Z}^d$$

$\rho(\boldsymbol{k})$ has value 1 for all $\boldsymbol{k}$ of the form $\boldsymbol{K} = (2\pi/a)\boldsymbol{n}$ and $(1/N)O(\max_{c=1,2} |\mathrm{e}^{\mathrm{i}k_c a} - 1|^{-2})$ otherwise. In presence of interaction, it has to be expected that, in a crystal state, $\rho(\boldsymbol{k})$ has peaks near the values $\boldsymbol{K}$: but the value of $\rho(\boldsymbol{k})$ can depend on the boundary conditions.

Since the system is translation invariant a crystal state defined as a state with a distribution "close" to $\overline{\mu}$,

i.e., with $\hat{\rho}(\boldsymbol{q})$ with peaks at the ideal lattice points $\boldsymbol{q} = \boldsymbol{n}a$, cannot be realized under periodic boundary conditions, even when the system state is crystalline. To realize such a state, a symmetry-breaking term is needed in the interaction.

This can be done in several ways, for example, by changing the boundary condition. Such a choice implies a discussion of how much the boundary conditions influence the positions of the peaks of $\rho(\boldsymbol{k})$: for instance, it is not obvious that a boundary condition will not generate a state with a period different from the one that *a priori* has been selected for disproval (a possibility which would imply a reciprocal lattice of $K$'s different from the one considered to begin with). Therefore, here the choice will be to imagine that an external weak force with potential $\varepsilon W(\boldsymbol{q})$ acts forcing a symmetry breaking that favors the occupation of regions around the points of the ideal lattice (which would mark the average positions of the particles in the crystal state that is being sought). The proof (*Mermin's theorem*) that no equilibrium state with particles distribution "close" to $\overline{\mu}$, i.e., with peaks in place of the delta functions (see below), is essentially reproduced below.

Take $W(\boldsymbol{q}) = \sum_{\boldsymbol{n}a\in\Omega} \chi(\boldsymbol{q} - \boldsymbol{n}a)$, where $\chi(\boldsymbol{q}) \le 0$ is smooth and zero everywhere except in a small vicinity of the lattice points around which it decreases to some negative minimum keeping a rotation symmetry around them. The potential $W$ is invariant under translations by the lattice steps. By the choice of the boundary condition and $\varepsilon W$, the density $\widetilde{\rho}_\varepsilon(\boldsymbol{q})$ will be periodic with period $a$ so that $\rho_\varepsilon(\boldsymbol{k})$ will, possibly, not have a vanishing limit as $N \to \infty$ only if $\boldsymbol{k}$ is a reciprocal vector $\boldsymbol{K} = (2\pi/a)\boldsymbol{n}$. If the potential is $\varphi + \varepsilon W$ and if there exists a crystal state in which particles have higher probability of being near the lattice points $\boldsymbol{n}a$, it should be expected that for small $\varepsilon > 0$ the system will be found in a state with Fourier transform of the density, $\rho_\varepsilon(\boldsymbol{k})$, satisfying, for some vector $\boldsymbol{K} \ne \boldsymbol{0}$ in the reciprocal lattice,

$$\lim_{\varepsilon\to 0}\lim_{N\to\infty} |\rho_\varepsilon(\boldsymbol{K})| = r > 0 \qquad [30]$$

that is, the requirement is that uniformly in $\varepsilon \to 0$ the Fourier transform of the density has a peak at some $\boldsymbol{K} \ne \boldsymbol{0}$. Note that if $\boldsymbol{k}$ is not in the reciprocal lattice $\rho_\varepsilon(\boldsymbol{k}) \xrightarrow[N\to\infty]{} 0$, being bounded above by

$$\frac{1}{N} O\left(\max_{j=1,2} |e^{ik_j a} - 1|^{-2}\right)$$

because $(1/N)\widetilde{\rho}_\varepsilon$ is periodic and its integral over $\boldsymbol{q}$ is equal to 1. Hence, excluding the existence of a crystal will be identified with the impossibility of the [30]. Other criteria can be imagined, for example, considering crystals with a lattice different from simple cubic, which lead to the same result by following the same technique. Nevertheless, it is not mathematically excluded (but unlikely) that, with some weaker existence definition, a crystal state could be possible even in two dimensions.

The following inequalities hold under the present assumptions on the potential and in the canonical distribution with periodic boundary conditions and parameters $(\beta, \rho), \rho = a^{-3}$ in a box $\Omega$ with side multiple of $a$ (so that $N = (La^{-1})^d$) and potential of interaction $\varphi + \varepsilon W$. The further assumption that the lattice $\boldsymbol{n}a$ is not a close-packed lattice is (of course) necessary when the interaction potential has a hard core. Then, for suitable $B_0, B, B_1, B_2 > 0$, independent of $N$, and $\varepsilon$ and for $|\boldsymbol{\kappa}| < \pi/a$ and for all $\Omega$ (*if* $\boldsymbol{K} \ne \boldsymbol{0}$)

$$\frac{1}{N}\left\langle \left| \sum_{j=1}^{N} e^{-i(\boldsymbol{\kappa}+\boldsymbol{K})\cdot \boldsymbol{q}_j} \right|^2 \right\rangle \ge B\frac{(\rho_\varepsilon(\boldsymbol{K}) + \rho_\varepsilon(\boldsymbol{K} + 2\boldsymbol{\kappa}))^2}{B_1\boldsymbol{\kappa}^2 + \varepsilon B_2}$$

$$\frac{1}{N}\sum_{\boldsymbol{\kappa}} \gamma(\boldsymbol{\kappa})\, \frac{d\boldsymbol{\kappa}}{N} \left\langle \left| \sum_{j=1}^{N} e^{-i(\boldsymbol{\kappa}+\boldsymbol{K})\cdot \boldsymbol{q}_j} \right|^2 \right\rangle \le B_0 < \infty \qquad [31]$$

where the averages are in the canonical distribution $(\beta, \rho)$ with periodic boundary conditions and a symmetry-breaking potential $\varepsilon W(\boldsymbol{q}); \gamma(\boldsymbol{k}) \ge 0$ is an (arbitrary) smooth function vanishing for $2|\boldsymbol{\kappa}| \ge \delta$ with $\delta < 2\pi/a$ and $B_0$ depends on $\gamma$. See Appendix 3 for a derivation of [31].

Multiplying both sides of the first equation in [31] by $N^{-1}\gamma(\boldsymbol{\kappa})$ and summing over $\boldsymbol{\kappa}$, the crystallinity condition in the form [30] implies

$$B_0 \ge Br^2 a^d \int_{|\boldsymbol{\kappa}|<\delta} \frac{\gamma(\boldsymbol{\kappa})\, d\boldsymbol{\kappa}}{\boldsymbol{\kappa}^2 B_1 + \varepsilon B_2}$$

For $d = 1, 2$ the integral diverges, as $\varepsilon^{-1/2}$ or $\log \varepsilon^{-1}$, respectively, implying $|\rho_\varepsilon(\boldsymbol{K})| \xrightarrow[\varepsilon\to 0]{} r = 0$: the criterion of crystallinity, [30] cannot be satisfied if $d = 1, 2$.

The above inequality is an example of a general class of inequalities called *infrared inequalities* stemming from another inequality called *Bogoliubov's inequality* (see Appendix 3), which lead to the proof that certain kinds of ordered phases cannot exist if the dimension of the ambient space is $d = 2$ when a finite volume, under suitable boundary conditions (e.g., periodic), shows a continuous symmetry. The excluded phenomenon is, more precisely, the nonexistence of equilibrium states exhibiting, in the thermodynamic limit, a symmetry lower than the continuous symmetry holding in a finite volume.

In general, existence of thermodynamic equilibrium states with symmetry lower than the

symmetry enjoyed by the system in finite volume and under suitable boundary conditions is called a "spontaneous symmetry breaking." It is yet another manifestation of instability with respect to changes in boundary conditions, hence its occurrence reveals a phase transition. There is a large class of systems for which an infrared inequality implies absence of spontaneous symmetry breaking: in most of the one- or two-dimensional systems a continuous symmetry cannot be spontaneously broken.

The limitation to dimension $d \le 2$ is a strong limitation to the generality of the applicability of infrared theorems to exclude phase transitions. More precisely, systems can be divided into classes each of which has a "critical dimension" below which too much symmetry implies absence of phase transitions (or of certain kinds of phase transitions).

It should be stressed that, at the critical dimension, the symmetry breaking is usually so weakly forbidden that one might need astronomically large containers to destroy small effects (due to boundary conditions or to very small fields) which break the symmetry. For example, in the crystallization just discussed, the Fourier transform peaks are only bounded by $O(1/\sqrt{\log \varepsilon^{-1}})$. Hence, from a practical point of view, it might still be possible to have some kind of order even in large containers.

The reader is referred to Mermin (1968), Hohenberg (1969), and Ruelle (1969).

## High Temperature and Small Density

There is another class of systems in which no phase transitions take place. These are the systems with stable and tempered interactions $\varphi$ (e.g., those satisfying [14]) in the high-temperature and low-density region. The property is obtained by showing that the equation of state is analytic in the variables $(\beta, \rho)$ near the origin $(0, 0)$.

A simple algorithm (*Mayer's series*) yields the coefficients of the virial series

$$\beta p(\beta, \rho) = \rho + \sum_{k=2}^{\infty} c_k(\beta)\rho^k$$

It has the drawback that the $k$th order coefficient $c_k(\beta)$ is expressed as a sum of many terms (a number growing more than exponentially fast in the order $k$) and it is not so easy (but possible) to show combinatorially that their sum is bounded exponentially in $k$ if $\beta$ is small enough. A more efficient approach leads quickly to the desired solution. Denoting $\boldsymbol{\Phi}(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n) \stackrel{\text{def}}{=} \sum_{i<j} \varphi(\boldsymbol{q}_i - \boldsymbol{q}_j)$, consider the ("spatial or configurational") correlation functions defined, in the grand canonical distribution with parameters $\beta, \lambda$ (and empty boundary conditions), by

$$\rho_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n) \stackrel{\text{def}}{=} \frac{1}{Z^{gc}(\beta, \lambda, V)} \sum_{m=0}^{\infty} z^{n+m} \times \int_\Omega \mathrm{e}^{-\beta\Phi(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n, \boldsymbol{y}_1, \ldots, \boldsymbol{y}_m)} \frac{\mathrm{d}\boldsymbol{y}_1 \cdots \mathrm{d}\boldsymbol{y}_m}{m!} \quad [32]$$

This is the probability density for finding particles with any momentum in the volume element $\mathrm{d}\boldsymbol{q}_1 \cdots \mathrm{d}\boldsymbol{q}_n$ (irrespective of where other particles are), and $z = \mathrm{e}^{\beta\lambda}(\sqrt{2\pi m \beta^{-1} h^{-2}})^d$ accounts for the integration over the momenta variables and is called the activity: it has the dimension of a density (cf. [23]).

Assuming that the potential has a hard core (for simplicity) of radius $R$, the interaction energy $\Phi_{\boldsymbol{q}_1}(\boldsymbol{q}_2, \ldots, \boldsymbol{q}_n)$ of a particle at $\boldsymbol{q}_1$ with any number of other particles at $\boldsymbol{q}_2, \ldots, \boldsymbol{q}_m$ with $|\boldsymbol{q}_i - \boldsymbol{q}_j| > R$ is bounded below by $-B$ for some $B \ge 0$ (related but not equal to the $B$ in [14]). The functions $\rho_\Omega$ will be regarded as a sequence of functions "of one, two, ... particle positions": $\rho_\Omega = \{\rho_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n)\}_{n=1}^{\infty}$ vanishing for $\boldsymbol{q}_j \notin \Omega$. Then, one checks that

$$\rho_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n) = z\delta_{n,1}\chi_\Omega(\boldsymbol{q}_1) + K\rho_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n) \quad [33a]$$

with

$$K\rho_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n) \stackrel{\text{def}}{=} \mathrm{e}^{-\beta\Phi_{\boldsymbol{q}_1}(\boldsymbol{q}_2, \ldots, \boldsymbol{q}_n)} \Big(\rho_\Omega(\boldsymbol{q}_2, \ldots, \boldsymbol{q}_n)\delta_{n>1} + \sum_{s=1}^{\infty} \int_\Omega \frac{\mathrm{d}\boldsymbol{y}_1 \cdots \mathrm{d}\boldsymbol{y}_s}{s!} \prod_{k=1}^{s} (\mathrm{e}^{-\beta\varphi(\boldsymbol{q}_1 - \boldsymbol{y}_k)} - 1) \times \rho_\Omega(\boldsymbol{q}_2, \ldots, \boldsymbol{q}_n, \boldsymbol{y}_1, \ldots, \boldsymbol{y}_s)\Big) \quad [33b]$$

where $\delta_{n,1}, \delta_{n>1}$ are Kronecker deltas and $\chi_\Omega(\boldsymbol{q})$ is the indicator function of $\Omega$. Equation [33] is called the *Kirkwood–Salzburg equation* for the family of correlation functions in $\Omega$. The kernel $K$ of the equations is independent of $\Omega$, but the domain of integration is $\Omega$.

Calling $\alpha_\Omega$ the sequence of functions $\alpha_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n) \equiv 0$ if $n \neq 1$ and $\alpha_\Omega(\boldsymbol{q}) = z\chi_\Omega(\boldsymbol{q})$, a recursive expansion arises, namely

$$\rho_\Omega = z\alpha_\Omega + z^2 K\alpha_\Omega + z^3 K^2\alpha_\Omega + z^4 K^3 \alpha_\Omega + \cdots \quad [34]$$

It gives the correlation functions, provided the series converges. The inequality

$$|K^p \alpha_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n)| \le \mathrm{e}^{(2\beta B+1)p} \left( \int |\mathrm{e}^{-\beta\varphi(\boldsymbol{q})} - 1| \mathrm{d}\boldsymbol{q} \right)^p \stackrel{\text{def}}{=} \mathrm{e}^{(2\beta B+1)p} r(\beta)^{3p} \quad [35]$$

shows that the series [34], called Mayer's series, converges if $|z| < \mathrm{e}^{-(2\beta B+1)} r(\beta)^{-3}$. Convergence is uniform (as $\Omega \to \infty$) and $(K^p)\alpha_\Omega(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n)$ tends to a limit as $V \to \infty$ at fixed $\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n$ and the limit is simply $(K^p\alpha)(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n)$, if $\alpha(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n) \equiv 0$ for $n \neq 1$, and $\alpha(\boldsymbol{q}_1) \equiv 1$. This is because the kernel $K$ contains

the factors $(e^{-\beta\varphi(q_1-y)}-1)$ which decay rapidly or, if $\varphi$ has finite range, will eventually even vanish. It is also clear that $(K^p\alpha)(q_1,\ldots,q_n)$ is translation invariant.

Hence, if $|z|e^{2\beta B+1}r(\beta)^3<1$, the limits, as $\Omega\to\infty$, of the correlation functions exist and can be computed by a convergent power series in $z$; the correlation functions will be translation invariant (in the thermodynamic limit).

In particular, the one-point correlation function $\rho=\rho(q)$ is $\rho=z(1+O(zr(\beta)^3))$, which, to lowest order in $z$, just shows that activity and density essentially coincide when they are small enough. Furthermore, $\beta p_\Omega=(1/V)\log Z^{gc}(\beta,\lambda,V)$ is such that

$$z\partial_z\,\beta p_\Omega=\frac{1}{V}\int\rho_\Omega(q)\,dq$$

(from the definition of $\rho_\Omega$ in [32]). Therefore,

$$\begin{aligned}\beta p(\beta,z)&=\lim_{V\to\infty}\frac{1}{V}\log Z^{gc}(\beta,\lambda,V)\\&=\int_0^z\frac{dz'}{z'}\rho(\beta,z')\end{aligned}\qquad[36]$$

and, since the density $\rho$ is analytic in $z$ as well and $\rho\simeq z$ for $z$ small, the grand canonical pressure is analytic in the density and $\beta p=\rho(1+O(\rho^2))$, at small density. In other words, the equation of state is, to lowest order, essentially the equation of a perfect gas. All quantities that are conceivably of some interest turn out to be analytic functions of temperature and density. The system is essentially a free gas and it has no phase transitions in the sense of a discontinuity or of a singularity in the dependence of a thermodynamic function in terms of others. Furthermore, the system cannot show phase transitions in the sense of sensitive dependence on boundary conditions of fixed external particles. This also follows, with some extra work, from the Kirkwood–Salzburg equations.

The reader is referred to Ruelle (1969) and Gallavotti (1969) for more details.

## Lattice Models

The problem of proving the existence of phase transitions in models of homogeneous gases with pair interactions is still open. Therefore, it makes sense to study the problem of phase transitions in simpler models, tractable to some extent but nontrivial, and which are of practical interest in their own right.

The simplest models are the so-called lattice models in which particles are constrained to points of a lattice: they cannot move in the ordinary sense of the word (but, of course, they could jump) and therefore their configurations do not contain momentum variables.

The interaction energy is just the potential energy, and ensembles are defined as collections of probability distributions on the position coordinates of the particle configurations. Usually, the potential is a pair potential decaying fast at $\infty$ and, often, with a hard-core forbidding double or higher occupancy of the same lattice site. For instance, the *lattice gas* with potential $\varphi$, in a cubic box $\Omega$ with $|\Omega|=V=L^d$ sites of a square lattice with mesh $a>0$, is defined by the potential energy attributed to the configuration $X$ of occupied distinct sites, i.e., subsets $X\subset\Omega$:

$$H(X)=-\sum_{(x,y)\in X}\varphi(x-y)\qquad[37]$$

where the sum is over pairs of distinct points in $X$. The canonical ensemble and the grand canonical ensemble are the collections of distributions, parametrized by $(\beta,\rho),(\rho=N/V)$, or, respectively, by $(\beta,\lambda)$, attributing to $X$ the probability

$$p_{\beta,\rho}(X)=\frac{e^{-\beta H(X)}}{Z_p^c(\beta,N,\Omega)}\delta_{|X|,N}\qquad[38a]$$

or

$$p_{\beta,\lambda}(X)=\frac{e^{\beta\lambda|X|}e^{-\beta H(X)}}{Z_p^{gc}(\beta,\lambda,\Omega)}\qquad[38b]$$

where the denominators are normalization factors that can, respectively, be called, in analogy with the theory of continuous systems, canonical and grand canonical partition functions; the subscript $p$ stands for particles.

A lattice gas in which in each site there can be at most one particle can be regarded as a model for the distribution of a family of spins on a lattice. Such models are quite common and useful (e.g., they arise in studying systems with magnetic properties). Simply identify an "occupied" site with a "spin up" or + and an "empty" site with a "spin down" or − (say). If $\boldsymbol{\sigma}=\{\sigma_x\}_{x\in\Omega}$ is a spin configuration, the energy of the configuration "for potential $\varphi$ and magnetic field $h$" will be

$$H(\boldsymbol{\sigma})=-\sum_{(x,y)\in\Omega}\varphi(x-y)\sigma_x\sigma_y-h\sum_x\sigma_x\qquad[39]$$

with the sum running over pairs $(x,y)\in\Omega$ of distinct sites. If $\varphi(x-y)\equiv J_{xy}\geq 0$, the model is called a *ferromagnetic Ising model*. As in the case of continuous systems, it will be assumed to have a finite range for $\varphi$: that is, $\varphi(x)=0$ for $|x|>R$, for some $R$, unless explicitly stated otherwise.

The canonical and grand canonical ensembles in the box $\Omega$ with respective parameters $(\beta, m)$ or $(\beta, h)$ will be defined as the probability distributions on the spin configurations $\boldsymbol{\sigma} = \{\sigma_x\}_{x\in\Omega}$ with $\sum_{x\in\Omega}\sigma_x = M = mV$ or without constraint on $M$, respectively; hence,

$$p_{\beta,m}(\boldsymbol{\sigma}) = \frac{\exp\left(-\beta\sum_{(x,y)}\varphi(x-y)\sigma_x\sigma_y\right)}{Z_s^{\rm c}(\beta, M, \Omega)}$$
$$p_{\beta,h}(\boldsymbol{\sigma}) = \frac{\exp\left(-\beta h\sum\sigma_x - \beta\sum_{(x,y)}\varphi(x-y)\sigma_x\sigma_y\right)}{Z_s^{\rm gc}(\beta, h, \Omega)} \qquad [40]$$

where the denominators are normalization factors again called, respectively, the canonical and grand canonical partition functions. As in the study of the previous continuous systems, canonical and grand canonical ensembles with "external fixed particle configurations" can be defined together with the corresponding ensembles with "external fixed spin configurations"; the subscript $s$ stands for spins.

For each configuration $X \subset \Omega$ of a lattice gas, let $\{n_x\}$ be $n_x = 1$ if $x \in X$ and $n_x = 0$ if $x \notin X$. Then the transformation $\sigma_x = 2n_x - 1$ establishes a correspondence between lattice gas and spin distributions. In the correspondence, the potential $\varphi(x-y)$ of the lattice gas generates a potential $(1/4)\varphi(x-y)$ for the corresponding spin system and the chemical potential $\lambda$ for the lattice gas is associated with a magnetic field $h$ for the spin system with $h = (1/2)(\lambda + \sum_{x\neq 0}\varphi(x))$.

The correspondence between boundary conditions is natural: for instance, a boundary condition for the lattice gas in which all external sites are occupied becomes a boundary condition in which external sites contain a spin +. The close relation between lattice gas and spin systems permits switching from one to the other with little discussion.

In the case of spin systems, empty boundary conditions are often considered (no spins outside $\Omega$). In lattice gases and spin systems (as well as in continuum systems), often periodic and semiperiodic boundary conditions are considered (i.e., periodic in one or more directions and with empty or fixed external particles or spins in the others).

Thermodynamic limits for the partition functions

$$\begin{aligned}
-\beta f(\beta, v) &= \lim_{\substack{\Omega\to\infty \\ V/N=v}} \frac{1}{N}\log Z_p^{\rm c}(\beta, N, \Omega) \\
\beta p(\beta, \lambda) &= \lim_{\Omega\to\infty} \frac{1}{V}\log Z_p^{\rm gc}(\beta, \lambda, \Omega) \\
-\beta g(\beta, m) &= \lim_{\substack{\Omega\to\infty, \\ M/V\to m}} \frac{1}{V}\log Z_s^{\rm c}(\beta, M, \Omega) \\
\beta f(\beta, h) &= \lim_{\Omega\to\infty} \frac{1}{V}\log Z_s^{\rm gc}(\beta, \lambda, \Omega)
\end{aligned} \qquad [41]$$

can be shown to exist by a method similar to the one discussed in Appendix 2. They have convexity and continuity properties as in the cases of the continuum systems. In the case of a lattice gas, the $f, p$ functions are still interpreted as free energy and pressure, respectively. In the case of spin, $f(\beta, h)$ has the interpretation of magnetic free energy, while $g(\beta, m)$ does not have a special name in the thermodynamics of magnetic systems. As in the continuum systems, it is occasionally useful to define infinite-volume equilibrium states:

**Definition** An infinite-volume state with parameters $(\beta, h)$ or $(\beta, m)$ is a collection of average values $F \to \langle F\rangle$ obtained, respectively, as limits of finite-volume averages $\langle F\rangle_{\Omega_n}$ defined from canonical or grand canonical distributions in $\Omega_n$ with fixed parameters $(\beta, h)$ or $(\beta, m)$, or $(u, v)$ and with general boundary condition of fixed external spins or empty sites, on sequences $\Omega_n \to \infty$ for which such limits exist simultaneously for all local observables $F$.

This is taken verbatim from the definition in the section "Phase transitions and boundary conditions." In this way, it makes sense to define the spin correlation functions for $X = (\boldsymbol{\xi}_1, \ldots, \boldsymbol{\xi}_n)$ as $\langle\sigma_X\rangle$ if $\sigma_X = \prod_j \sigma_{\xi_j}$. For instance, we shall call $\rho(\boldsymbol{\xi}_1, \boldsymbol{\xi}_2) \stackrel{\rm def}{=} \langle\sigma_{\xi_1}\sigma_{\xi_2}\rangle$ and a pure phase can be defined as an infinite-volume state such that

$$\langle\sigma_X\sigma_{Y+\xi}\rangle - \langle\sigma_X\rangle\langle\sigma_{Y+\xi}\rangle \underset{\xi\to\infty}{\longrightarrow} 0 \qquad [42]$$

Again, for more details, we refer the reader to Ruelle (1969) and Gallavotti (1969).

## Thermodynamic Limits and Inequalities

An interesting property of lattice systems is that it is possible to study delicate questions like the existence of infinite-volume states in some (moderate) generality. A typical tool is the use of inequalities. As the simplest example of a vast class of inequalities, consider the ferromagnetic Ising model with some finite (but arbitrary) range interaction $J_{xy} \geq 0$ in a field $h_x \geq 0$: $J, h$ may even be not translationally invariant. Then the average of $\sigma_X \stackrel{\rm def}{=} \sigma_{x_1}\sigma_{x_2}\cdots\sigma_{x_n}$, $X = (x_1, \ldots, x_n)$, in a state with "empty boundary conditions" (i.e., no external spins) satisfies the inequalities

$$\langle\sigma_X\rangle,\ \partial_{h_x}\langle\sigma_X\rangle,\ \partial J_{xy}\langle\sigma_X\rangle \geq 0 \quad X = (x_1, \ldots, x_n)$$

More generally, let $H(\boldsymbol{\sigma})$ in [39] be replaced by $H(\boldsymbol{\sigma}) = -\sum_X J_X\sigma_X$ with $J_X \geq 0$ and $X$ can be any finite set; then, if $Y = (y_1, \ldots, y_n)$, $X = (x_1, \ldots, x_n)$, the following *Griffiths inequalities* hold:

$$\langle\sigma_X\rangle \geq 0, \quad \partial_{J_Y}\langle\sigma_X\rangle \equiv \langle\sigma_X\sigma_Y\rangle - \langle\sigma_X\rangle\langle\sigma_Y\rangle \geq 0 \quad [43]$$

The inequalities can be used to check, in ferromagnetic Ising models, [39], existence of infinite-volume states (cf. the sections "Phase transitions and boundary conditions" and "Lattice models") obtained by fixing the boundary condition $\mathcal{B}$ to be either "all external spins +" or "all external sites empty." If $\langle F\rangle_{\mathcal{B},\Omega}$ denotes the grand canonical average with boundary condition $\mathcal{B}$ and any fixed $\beta, h > 0$, this means that for all local observables $F(\boldsymbol{\sigma}_\Lambda)$ (i.e., for all $F$ depending on the spin configuration in any fixed region $\Lambda$) all the following limits exist:

$$\lim_{\Omega\to\infty} \langle F\rangle_{\mathcal{B},\Omega} = \langle F\rangle_{\mathcal{B}} \qquad [44]$$

The reason is that the inequalities [43] imply that all averages $\langle \sigma_X\rangle_{\mathcal{B},\Omega}$ are monotonic in $\Omega$ for all fixed $X \subset \Omega$: so the limit [44] exists for $F(\boldsymbol{\sigma}) = \sigma_X$. Hence, it exists for all $F$'s depending only on finitely many spins, because any local function $F$ "measurable in $\Lambda$" can be expressed (uniquely) as a linear combination of functions $\sigma_X$ with $X \subseteq \Lambda$.

Monotonicity with empty boundary conditions is seen by considering the sites outside $\Omega$ and in a region $\Omega'$ with side one unit larger than that of $\Omega$ and imagining that the couplings $J_X$ with $X \subset \Omega'$ but $X \not\subset \Omega$ vanish. Then, $\langle\sigma_X\rangle_{\Omega'} \geq \langle\sigma_X\rangle_{\Omega}$, because $\langle\sigma_X\rangle_{\Omega'}$ is an average computed with a distribution corresponding to an energy with the couplings $J_X$ with $X \not\subset \Omega$, but $X \subset \Omega'$, changed from 0 to $J_X \geq 0$.

Likewise, if the boundary condition is +, then enlarging the box from $\Omega$ to $\Omega'$ corresponds to decreasing an external field $h$ acting on the external spins from $+\infty$ (which would force all external spins to be +) to a finite value $h \geq 0$: so, increasing the box $\Omega$ causes $\langle\sigma_X\rangle_{+,\Omega}$ to decrease. Therefore, as $\Omega$ increases, Ising ferromagnets spin correlations increase if the boundary condition is empty and decrease if it is +.

The inequalities can be used in similar ways to prove that the infinite-volume states obtained from + or empty boundary conditions are translation invariant; and that in zero external field, $h = 0$, the + and − boundary conditions generate pure states if the interaction potential is only a pair ferromagnetic interaction.

There are many other important inequalities which can be used to prove several existence theorems along very simple paths. Unfortunately, their use is mostly restricted to lattice systems and requires very special assumptions on the energy (e.g., ferromagnetic interactions in the above example). The quoted examples were among the first discovered and provide a way to exhibit nontrivial thermodynamic limits and pure states.

For more details, see Ruelle (1969), Lebowitz (1974), Gallavotti (1999), Lieb and Thirring (2001), and Lieb (2002).

## Symmetry-Breaking Phase Transitions

The simplest phase transitions (see the section "Phase transitions and boundary conditions") are symmetry-breaking transitions in lattice systems: they take place when the energy of the system in a container $\Omega$ and with some special boundary condition (e.g., periodic, antiperiodic, or empty) is invariant with respect to the action of a group $\mathcal{G}$ on phase space. This means that on the points $x$ of phase space acts a group of transformations $\mathcal{G}$ so that with each $\gamma \in \mathcal{G}$ is associated a map $x \to x\gamma$ which transforms $x$ into $x\gamma$ respecting the composition law in $\mathcal{G}$, that is, $(x\gamma)\gamma' \equiv x(\gamma\gamma')$. If $F$ is an observable, the action of the group on phase space induces an action on the observable $F$ changing $F(x)$ into $F_\gamma(x) \stackrel{\text{def}}{=} F(x\gamma^{-1})$.

A symmetry-breaking transition occurs when, by fixing suitable boundary conditions and taking the thermodynamic limit, a state $F \to \langle F\rangle$ is obtained in which some local observable shows a nonsymmetric average $\langle F\rangle \neq \langle F_\gamma\rangle$ for some $\gamma$.

An example is provided by the "nearest-neighbor ferromagnetic Ising model" on a d-dimensional lattice with energy function given by [39] with $h = 0$ and $\varphi(x - y) \equiv 0$ unless $|x - y| = 1$, i.e., unless $x, y$ are nearest neighbors, in which case $\varphi(x - y) = J > 0$. With periodic or empty boundary conditions, it exhibits a discrete "up–down" symmetry $\boldsymbol{\sigma} \to -\boldsymbol{\sigma}$.

Instability with respect to boundary conditions can be revealed by considering the two boundary conditions, denoted + or −, in which the lattice sites outside the container $\Omega$ are either occupied by spins + or by spins −. Consider also, for later reference, (1) the boundary conditions in which the boundary spins in the upper half of the boundary are + and the ones in the lower part are −: call this the ±-boundary condition (see Figure 2); or (2) the boundary conditions in

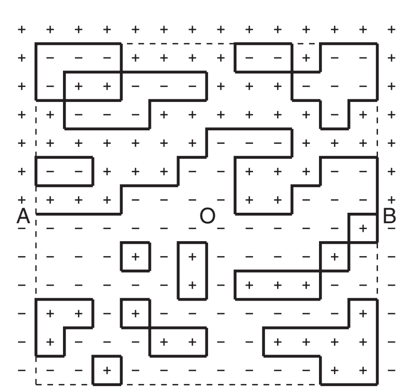

**Figure 2** The dashed line is the boundary of $\Omega$; the outer spins correspond to the $\pm$ boundary condition. The points $A$, $B$ are points where an open "line" $\lambda$ ends.

which some of the opposite sides of $\Omega$ are identified while + or − conditions are assigned on the remaining sides: call these "cylindrical or semiperiodic boundary conditions."

A new description of the spin configurations is useful: given $\boldsymbol{\sigma}$, draw a unit segment perpendicular to the center of each bond $b$ having opposite spins at its extremes. An example of this construction is provided by Figure 2 for the boundary condition $\pm$.

The set of segments can be grouped into lines separating regions where the spins are positive from regions where they are negative. If the boundary condition is + or −, the lines form "closed polygons", whereas, if the condition is $\pm$, there is also a single polygon $\lambda_1$ which is not closed (as in Figure 2). If the boundary condition is periodic or cylindrical, all polygons are closed but some may "go around" $\Omega$. The polygons are also called "contours" and the length of a polygon $\gamma$ will be denoted $|\gamma|$.

The correspondence $(\gamma_1, \gamma_2, \ldots, \gamma_n, \lambda_1) \longleftrightarrow \boldsymbol{\sigma}$, for the boundary condition $\pm$ or, for the boundary condition + (or −), $\boldsymbol{\sigma} \longleftrightarrow (\gamma_1, \ldots, \gamma_n)$ is one-to-one and, if $h = 0$, the energy $H_\Omega(\boldsymbol{\sigma})$ of a configuration is higher than $-J \times$(number of bonds in $\Omega$) by an amount $2J(|\lambda_1| + \sum_i |\gamma_i|)$ or, respectively, $2J\sum_i |\gamma_i|$. The grand canonical probability of each spin configuration is therefore proportional, if $h = 0$, respectively, to

$$e^{-2\beta J(|\lambda_1| + \sum_i |\gamma_i|)} \quad \text{or} \quad e^{-2\beta J \sum_i |\gamma_i|} \qquad [45]$$

and the "up–down" symmetry is clearly reflected by [45].

The average $\langle \sigma_x \rangle_{\Omega,+}$ of $\sigma_+$ with + boundary conditions is given by $\langle \sigma_x \rangle_{\Omega,+} = 1 - 2P_{\Omega,+}(-)$, where $P_{\Omega,+}(-)$ is the probability that the spin $\sigma_x$ is –1. If the site $x$ is occupied by a negative spin then the point $x$ is inside some contour $\gamma$ associated with the spin configuration $\boldsymbol{\sigma}$ under consideration. Hence, if $\rho(\gamma)$ is the probability that a given contour belongs to the set of contours describing a configuration $\boldsymbol{\sigma}$, it is $P_{\Omega,+}(-) \le \sum_{\gamma o x} \rho(\gamma)$ where $\gamma o x$ means that $\gamma$ "surrounds" $x$.

If $\Gamma = (\gamma_1, \ldots, \gamma_n)$ is a spin configuration and if the symbol $\Gamma\,\text{comp}\gamma$ means that the contour $\gamma$ is "disjoint" from $\gamma_1, \ldots, \gamma_n$ (i.e., $\{\gamma \cup \Gamma\}$ is a new spin configuration), then

$$\begin{aligned} \rho(\gamma) &= \frac{\sum_{\Gamma \ni \gamma} e^{-2\beta J \sum_{\gamma' \in \Gamma} |\gamma'|}}{\sum_{\Gamma} e^{-2\beta J \sum_{\gamma' \in \Gamma} |\gamma'|}} \\ &\equiv e^{-2\beta J |\gamma|} \frac{\sum_{\Gamma \text{comp} \gamma} e^{-2\beta J \sum_{\gamma' \in \Gamma} |\gamma'|}}{\sum_{\Gamma} e^{-2\beta J \sum_{\gamma' \in \Gamma} |\gamma'|}} \\ &\le e^{-2\beta J |\gamma|} \end{aligned} \qquad [46]$$

because the last ratio in [46] does not exceed 1. Note that there are $> 3^p$ different shapes of $\gamma$ with perimeter $p$ and at most $p^2$ congruent $\gamma$'s containing $x$; therefore, the probability that the spin at $x$ is − when the boundary condition is + satisfies the inequality

$$P_{\Omega,+}(-) \le \sum_{p=4}^{\infty} p^2 3^p e^{-2\beta J p} \underset{\beta \to \infty}{\longrightarrow} 0$$

This probability can be made arbitrarily small so that $\langle \sigma_x \rangle_{\Omega,+}$ is estimated by a quantity which is as close to 1 as desired provided $\beta$ is large enough and the closeness of $\langle \sigma_x \rangle_{\Omega,+}$ to 1 is estimated by a quantity which is both $x$ and $\Omega$ independent.

A similar argument for the (−)-boundary condition, or the remark that for $h = 0$ it is $\langle \sigma_x \rangle_{\Omega,-} = -\langle \sigma_x \rangle_{\Omega,+}$, leads to conclude that, at large $\beta$, $\langle \sigma_x \rangle_{\Omega,-} \neq \langle \sigma_x \rangle_{\Omega,+}$ and the difference between the two quantities is positive uniformly in $\Omega$. This is the proof (*Peierls' theorem*) of the fact that there is, if $\beta$ is large, a strong instability, of the magnetization with respect to the boundary conditions, i.e., the nearest-neighbor Ising model in dimension 2 (or greater, by an identical argument) has a phase transition. If the dimension is 1, the argument clearly fails and no phase transition occurs (see the section "Absence of phase transitions: $d = 1$").

For more details, see Gallavotti (1999).

## Finite-Volume Effects

The description in the last section of the phase transition in the nearest-neighbor Ising model can be made more precise both from physical and mathematical points of view giving insights into the nature of the phase transitions. Assume that the boundary condition is the (+)-boundary condition and describe a spin configuration $\boldsymbol{\sigma}$ by means of the associated closed disjoint polygons $(\gamma_1, \ldots, \gamma_n)$. Attribute to $\boldsymbol{\sigma} = (\gamma_1, \ldots, \gamma_n)$ a probability proportional to [45]. Then the following *Minlos–Sinai's theorem* holds:

**Theorem** *If $\beta$ is large enough there exist $C > 0$, $\rho(\gamma) > 0$ with $\rho(\gamma) \le e^{-2\beta J|\gamma|}$ and such that a spin configuration $\boldsymbol{\sigma}$ randomly chosen out of the grand canonical distribution with + boundary conditions and $h = 0$ will contain, with probability approaching 1 as $\Omega \to \infty$, a number $K_{(\gamma)}(\boldsymbol{\sigma})$ of contours congruent to $\gamma$ such that*

$$|K_{(\gamma)}(\boldsymbol{\sigma}) - \rho(\gamma)|\Omega|| \le C\sqrt{|\Omega|}\, e^{-\beta J|\gamma|} \qquad [47]$$

*and this relation holds simultaneously for all $\gamma$'s.*

Thus, there are very few contours (and the larger they are the smaller is, in absolute and relative value, their number): a typical spin configuration in the grand canonical ensemble with (+)-boundary conditions is such that the large majority of the spins is "positive" and, in the "sea" of positive spins, there are a few negative spins distributed in small and rare regions (their number, however, is still of order of $|\Omega|$).

Another consequence of the analysis in the last section concerns the the approximate equation of state near the phase transition region at low temperatures and finite $\Omega$. If $\Omega$ is finite, the graph of $h$ versus $m_\Omega(\beta, h)$ will have a rather different behavior depending on the possible boundary conditions. For example, if the boundary condition is $(+)$ or $(-)$, one gets, respectively, the results depicted in Figure 3a and 3b, where $m^*(\beta)$ denotes the spontaneous magnetization (i.e., $m^*(\beta) \stackrel{\text{def}}{=} \lim_{h\to 0^+} \lim_{\Omega\to\infty} m_\Omega(\beta, h)$).

With periodic or empty boundary conditions, the diagram changes as in Figure 4. The thermodynamic limit $m(\beta, h) = \lim_{\Omega\to\infty} m_\Omega(\beta, h)$ exists for all $h \neq 0$ and the resulting graph is in Figure 4b, which shows that at $h = 0$ the limit is discontinuous. It can be proved, if $\beta$ is large enough, that $\infty > \lim_{h\to 0^+} \partial_h m(\beta, h) = \chi(\beta) > 0$ (i.e., the angle between the vertical part of the graph and the rest is sharp).

Furthermore, it can be proved that $m(\beta, h)$ is analytic in $h$ for $h \neq 0$. If $\beta$ is small enough, analyticity holds at all $h$. For $\beta$ large, the function $f(\beta, h)$ has an essential singularity at $h = 0$: a result that can be interpreted as excluding a naive theory of metastability as a description of states governed by an equation of state obtained from an analytic continuation to negative values of $h$ of $f(\beta, h)$.

The above considerations and results further clarify the meaning of a phase transition for a finite system. For more details, we refer the reader to Gallavotti (1999) and Friedli and Pfister (2004).

## Beyond Low Temperatures (Ferromagnetic Ising Model)

A limitation of the results discussed above is the condition of low temperature ("$\beta$ large enough"). A natural problem is to go beyond the low-temperature region and to describe fully the phenomena in the region where boundary condition instability takes place and first develops. A number of interesting partial results are known, which considerably improve the picture emerging from the previous analysis. A striking list, but far from exhaustive, of such results follows and focuses on the properties of ferromagnetic Ising spin systems. The reason for restricting to such cases is that they are simple enough to allow a rather fine analysis, which sheds considerable light on the structure of statistical mechanics suggesting precise formulation

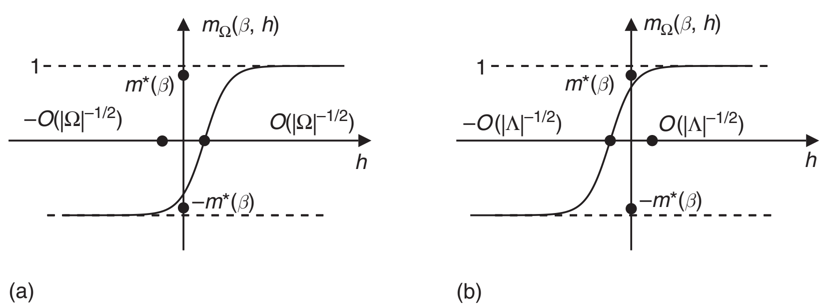

**Figure 3** The $h$ vs $m_\Omega(\beta, h)$ graphs for $\Omega$ finite and (a) + and (b) − conditions.

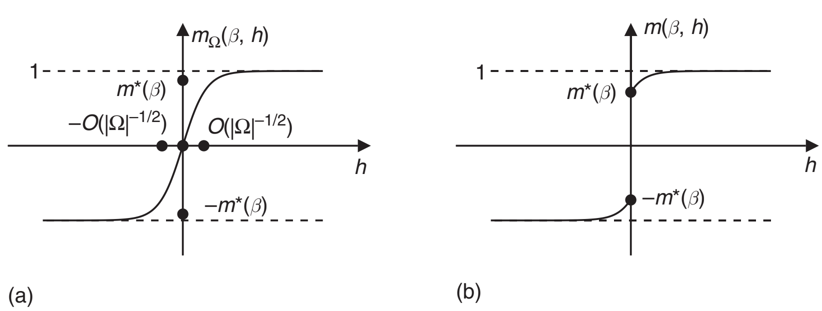

**Figure 4** (a) The $h$ vs $m_\Omega(\beta, h)$ graph for periodic or empty boundary conditions. (b) The discontinuity (at $h = 0$) of the thermodynamic limit.

of the problems that it would be desirable to understand in more general systems.

1. Let $z \stackrel{\text{def}}{=} e^{\beta h}$ and consider that the product of $z^V$ ($V$ is the number of sites $|\Omega|$ of $\Omega$) times the partition function with periodic or perfect-wall boundary conditions and with finite-range ferromagnetic interaction, not necessarily nearest-neighbor; a polynomial in $z$ (of degree $2V$) is thus obtained. Its zeros lie on the unit circle $|z| = 1$: this is *Lee–Yang's theorem*. It implies that the only singularities of $f(\beta, h)$ in the region $0 < \beta < \infty, -\infty < h < +\infty$ can be found at $h = 0$.

   A singularity can appear only if the point $z = 1$ is an accumulation point of the limiting distribution (as $\Omega \to \infty$) of the zeros on the unit circle: if the zeros are $z_1, \ldots, z_{2V}$ then

$$\frac{1}{V}\log z^V Z(\beta, h, \Omega, \text{periodic}) = 2\beta J + \beta h + \frac{1}{V}\sum_{i=1}^{2V}\log(z - z_i)$$

   and if

$$V^{-1} \times (\text{number of zeros of the form } z_j = e^{i\theta_j}, \theta \le \theta_j \le \theta + d\theta) \underset{\Omega\to\infty}{\longrightarrow} \frac{d\rho_\beta(\theta)}{2\pi}$$

   it is

$$\beta f(\beta, h) = 2\beta J + \frac{1}{2\pi}\int_{-\pi}^{\pi}\log(z - e^{i\theta})\, d\rho_\beta(\theta) \qquad [48]$$

   The existence of the measure $d\rho_\beta(\theta)$ follows from the existence of the thermodynamic limit: but $d\rho_\beta(\theta)$ is not necessarily $d\theta$-continuous, i.e., not necessarily proportional to $d\theta$.
2. It can be shown that, with not necessarily a nearest-neighbor interaction, the zeros of the partition function do not move too much under small perturbations of the potential even if one perturbs the energy (at perfect-wall or periodic boundary conditions) into

$$\begin{aligned} H'_\Omega(\boldsymbol{\sigma}) &= H_\Omega(\boldsymbol{\sigma}) + (\delta H_\Omega)(\boldsymbol{\sigma}) \\ (\delta H_\Omega)(\boldsymbol{\sigma}) &= \sum_{X \subset \Omega} J'(X)\,\sigma_X \end{aligned} \qquad [49]$$

   where $J'(X)$ is very general and defined on subsets $X = (x_1, \ldots, x_k) \subset \Omega$ such that the quantity $||J'|| = \sup_{y\in Z^d}\sum_{y\in X}|J'(X)|$ is small enough. More precisely, with a ferromagnetic pair potential $J$ fixed, suppose that one knows that, when $J' = 0$, the partition function zeros in the variable $z = e^{\beta h}$ lie in a certain closed set $N$ (of the unit circle) in the $z$-plane. Then, if $J' \neq 0$, they lie in a closed set $N^1$, $\Omega$-independent and contained in a neighborhood of $N$ of width shrinking to 0 when $||J'|| \to 0$. This allows to establish various relations between analyticity properties and boundary condition instability as described in (3) below.
3. In the ferromagnetic Ising model, with not necessarily a nearest-neighbor interaction, one says that there is a gap around 0 if $d\rho_\beta(\theta) = 0$ near $\theta = 0$. It can be shown that if $\beta$ is small enough there is a gap for all $h$ of width *uniform* in $h$.
4. Another question is whether the boundary condition instability is always revealed by the one-spin correlation function (i.e., by the magnetization) or whether it might be shown only by some correlation functions of higher order. It can be proved that no boundary condition instability occurs for $h \neq 0$; at $h = 0$ it is possible only if

$$\lim_{h\to 0^-} m(\beta, h) \neq \lim_{h\to 0^+} m(\beta, h) \qquad [50]$$

5. A consequence of the Griffiths' inequalities (cf. the section "Thermodynamic limits and inequalities") is that if [50] is true for a given $\beta_0$ then it is true for all $\beta > \beta_0$. Therefore, item (4) leads to a natural definition of the critical temperature $T_c$ as the least upper bound of the $T$'s such that [50] holds ($k_B T = \beta^{-1}$).
6. If $d = 2$ the free energy of the nearest-neighbor ferromagnetic Ising model has a singularity at $\beta_c$ and the value of $\beta_c$ is known exactly from the exact solutions of the model: $m(\beta, 0^+) \stackrel{\text{def}}{=} m^*(\beta) \equiv (1 - \sinh^4 2\beta J)^{1/8}$. The location and nature of the singularities of $f(\beta, 0)$ as a function of $\beta$ remains an open question for $d = 3$. In particular, the question whether there is a singularity of $f(\beta, 0)$ at $\beta = \beta_c$ is open.
7. For $\beta < \beta_c$ there is instability with respect to boundary conditions (see (6) above) and a natural question is: how many "pure" phases can exist in the ferromagnetic Ising model? (cf. the section "Phase transitions and boundary conditions," eqn [22]). Intuition suggests that there should be only two phases: the positively magnetized and the negatively magnetized ones.

   One has to distinguish between translation-invariant pure phases and non-translation-invariant ones. It can be proved that, in the case of the two-dimensional nearest-neighbor ferromagnetic Ising models, all infinite-volume states (cf. the section "Lattice models") are translationally invariant. Furthermore, they can be obtained by

considering just the two boundary conditions + and −: the latter states are also pure states for models with non-nearest-neighbor ferromagnetic interaction. The solution of this problem has led to the introduction of many new ideas and techniques in statistical mechanics and probability theory.

8. In any dimension $d \geq 2$, for $\beta$ large enough, it can be proved that the nearest-neighbor Ising model has only two translation-invariant phases. If the dimension is $\geq 3$ and $\beta$ is large, the + and − phases exhaust the set of translation-invariant pure phases but there exist non-translation-invariant phases. For $\beta$ close to $\beta_c$, however, the question is much more difficult.

For more details, see Onsager (1944), Lee and Yang (1952), Ruelle (1971), Sinai (1991), Gallavotti (1999), Aizenman (1980), Higuchi (1981), and Friedli and Pfister (2004).

## Geometry of Phase Coexistence

Intuition about the phenomena connected with the classical phase transitions is usually based on the properties of the liquid–gas phase transition; this transition is usually experimentally investigated in situations in which the total number of particles is fixed (canonical ensemble) and in presence of an external field (gravity).

The importance of such experimental conditions is obvious; the external field produces a nontranslationally invariant situation and the corresponding separation of the two phases. The fact that the number of particles is fixed determines, on the other hand, the fraction of volume occupied by each of the two phases.

Once more, consider the nearest-neighbor ferromagnetic Ising model: the results available for it can be used to obtain a clear picture of the solution to problems that one would like to solve but which in most other models are intractable with present-day techniques.

It will be convenient to discuss phase coexistence in the canonical ensemble distributions on configurations of fixed total magnetization $M = mV$ (see the section "Lattice models"; [40]). Let $\beta$ be large enough to be in the two-phase region and, for a fixed $\alpha \in (0, 1)$, let

$$m = \alpha\, m^*(\beta) + (1-\alpha)\,(-m^*(\beta)) \\ = (1-2\alpha)\, m^*(\beta) \qquad [51]$$

that is, $m$ is in the vertical part of the diagram $m = m(\beta, h)$ at $\beta$ fixed (see Figure 4).

Fixing $m$ as in [51] does not yet determine the separation of the phases in two different regions; for this effect, it will be necessary to introduce some external cause favoring the occupation of a part of the volume by a single phase. Such an asymmetry can be obtained in at least two ways: through a weak uniform external field (in complete analogy with the gravitational field in the liquid–vapor transition) or through an asymmetric field acting only on boundary spins. The latter should have the same qualitative effect as the former, because in a phase transition region a boundary perturbation produces volume effects (see sections "Phase transitions and inequalities" and "Symmetry-breaking phase transitions"). From a mathematical point of view, it is simpler to use a boundary asymmetry to produce phase separations and the simplest geometry is obtained by considering $\pm$-cylindrical or $++$-cylindrical boundary conditions: this means $++$ or $\pm$ boundary conditions periodic in one direction (e.g., in Figure 2 imagine the right and left boundary identified after removing the boundary spins on them).

Spins adjacent to the bases of $\Omega$ act as symmetry-breaking external fields. The $++$-cylindrical boundary condition should favor the formation inside $\Omega$ of the positively magnetized phase; therefore, it will be natural to consider, in the canonical distribution, this boundary condition only when the total magnetization is fixed to be the spontaneous magnetization $m^*(\beta)$.

On the other hand, the $\pm$-boundary condition favors the separation of phases (positively magnetized phase near the top of $\Omega$ and negatively magnetized phase near the bottom). Therefore, it will be natural to consider the latter boundary condition in the case of a canonical distribution with magnetization $m = (1-2\alpha)m^*(\beta)$ with $0 < \alpha < 1$ ([51]). In the latter case, the positive phase can be expected to adhere to the top of $\Omega$ and to extend, in some sense to be discussed, up to a distance $O(L)$ from it; and then to change into the negatively magnetized pure phase.

To make the phenomenological description precise, consider the spin configurations $\boldsymbol{\sigma}$ through the associated sets of disjoint polygons (cf. the section "Symmetry-breaking phase transitions"). Fix the boundary conditions to be $++$ or $\pm$-cylindrical boundary conditions and note that polygons associated with a spin configuration $\boldsymbol{\sigma}$ are all closed and of two types: the ones of the first type, denoted $\gamma_1, \ldots, \gamma_n$, are polygons which do not encircle $\Omega$; the second type of polygons, denoted by the symbols $\lambda_\alpha$, are the ones which wind up, at least once, around $\Omega$.

So, a spin configuration $\boldsymbol{\sigma}$ will be described by a set of polygons; the statistical weight of a configuration $\boldsymbol{\sigma} = (\gamma_1, \ldots, \gamma_n, \lambda_1, \ldots, \lambda_h)$ is (cf. [45]):

$$e^{-2\beta J\left(\sum_i |\gamma_i| + \sum_j |\lambda_j|\right)} \qquad [52]$$

The reason why the contours $\lambda$ that go around the cylinder $\Omega$ are denoted by $\lambda$ (rather than by $\gamma$) is that they "look like" open contours (see the section "Symmetry-breaking phase transitions") if one forgets that the opposite sides of $\Omega$ have to be identified. In the case of the $\pm$-boundary conditions then the number of polygons of $\lambda$-type must be odd (hence $\neq 0$), while for the $++$-boundary condition the number of $\lambda$-type polygons must be even (hence it could be 0).

For more details, the reader is referred to Sinai (1991) and Gallavotti (1999).

## Separation and Coexistence of Phases

In the context of the geometric description of the spin configuration in the last section, consider the canonical distributions with $++$-cylindrical or the $\pm$-cylindrical boundary conditions and zero field: they will be denoted briefly as $\mu_{\beta,++}$, $\mu_{\beta,\pm}$, respectively. The following theorem (*Minlos–Sinai's theorem*) provided the foundations of the microscopic theory of coexistence: it is formulated in dimension $d=2$ but, modulo obvious changes, it holds for $d \geq 2$.

**Theorem** *For* $0 < \alpha < 1$ *fixed, let* $m = (1-2\alpha)\, m^*(\beta)$; *then for* $\beta$ *large enough a spin configuration* $\boldsymbol{\sigma} = (\gamma_1, \ldots, \gamma_n, \lambda_1, \ldots, \lambda_{2h+1})$ *randomly chosen with the distribution* $\mu_{\beta,\pm}$ *enjoys the properties (i)–(iv) below with a* $\mu_{\beta,\pm}$*-probability approaching* 1 *as* $\Omega \to \infty$:

(i) $\boldsymbol{\sigma}$ *contains only one contour of* $\lambda$*-type and*

$$||\lambda| - (1+\varepsilon(\beta))L| < o(L) \qquad [53]$$

*where* $\varepsilon(\beta) > 0$ *is a suitable (*$\alpha$*-independent) function of* $\beta$ *tending to zero exponentially fast as* $\beta \to \infty$.

(ii) *If* $\Omega_\lambda^+, \Omega_\lambda^-$ *denote respectively, the regions above and below* $\lambda$, *and* $|\Omega| \equiv V, |\Omega^+|, |\Omega^-|$ *are, respectively, the volumes of* $\Omega$, $\Omega^+$, $\Omega^-$ *then*

$$||\Omega_\lambda^+| - \alpha V| < \kappa(\beta)\, V^{3/4}$$
$$|\Omega_\lambda^-| - (1-\alpha)V| < \kappa(\beta)\, V^{3/4} \qquad [54]$$

*where* $\kappa(\beta) \xrightarrow[\beta\to\infty]{}$ *exponentially fast; the exponent* 3/4, *here and below, is not optimal.*

(iii) *If* $M_\lambda^+ = \sum_{x\in\Omega_\lambda^+} \sigma_x$ and $M_\lambda^- = \sum_{x\in\Omega_\lambda^-} \sigma_x$, *then*

$$|M_\lambda^+ - \alpha\, m^*(\beta)\, V| < \kappa(\beta)\, V^{3/4}$$
$$M_\lambda^- - (1-\alpha)\, m^*(\beta)\, V| < \kappa(\beta) V^{3/4} \qquad [55]$$

(iv) *If* $K_\gamma^\lambda(\boldsymbol{\sigma})$ *denotes the number of contours congruent to a given* $\gamma$ *and lying in* $\Omega_\lambda^+$ *then, simultaneously for all the shapes of* $\gamma$:

$$|K_\gamma^\lambda(\boldsymbol{\sigma}) - \rho(\gamma)\,\alpha\, V| \leq Ce^{-\beta J|\gamma|}V^{1/2}, \quad C>0 \qquad [56]$$

*where* $\rho(\gamma) \leq e^{-2\beta J|\gamma|}$ *is the same quantity as already mentioned in the text of the theorem of "Finite-volume effects". A similar result holds for the contours below* $\lambda$ (cf. *the comments on* [47]).

The above theorem not only provides a detailed and rather satisfactory description of the phase separation phenomenon, but it also furnishes a precise microscopic definition of the line of separation between the two phases, which should be naturally identified with the (random) line $\lambda$.

A similar result holds in the canonical distribution $\mu_{\beta,++,m^*(\beta)}$ where (i) is replaced by: no $\lambda$-type polygon is present, while (ii), (iii) become superfluous, and (iv) is modified in the obvious way. In other words, a typical configuration for the distribution the $\mu_{\beta,++,m^*(\beta)}$ has the same appearance as a typical configuration of the corresponding grand canonical ensemble with $(+)$-boundary condition (whose properties are described by the theorem given in the section "Beyond low temperatures (ferromagnetic Ising model")).

For more details, see Sinai (1991) and Gallavotti (1999).

## Phase Separation Line and Surface Tension

Continuing to refer to the nearest-neighbor Ising ferromagnet, the theorem of the last section means that, if $\beta$ is large enough, then the microscopic line $\lambda$, separating the two phases, is almost straight (since $\varepsilon(\beta)$ is small). The deviations of $\lambda$ from a straight line are more conveniently studied in the grand canonical distributions $\mu_\pm^0$ with boundary condition set to +1 in the upper half of $\partial\Omega$, vertical sites included, and to –1 in the lower half: this is illustrated in Figure 2 (see the section "Symmetry-breaking phase transitions"). The results can be converted into very similar results for grand canonical distributions with $\pm$-cylindrical boundary conditions of the last section.

Define $\lambda$ to be *rigid* if the probability that $\lambda$ passes through the center of the box $\Omega$ (i.e., 0) does not tend to 0 as $\Omega \to \infty$; otherwise, it is *not rigid*.

The notion of rigidity distinguishes between the possibilities for the line $\lambda$ to be "straight." The "excess" length $\varepsilon(\beta)L$ (see [53]) can be obtained in two ways: either the line $\lambda$ is essentially straight (in the geometric sense) with a few "bumps" distributed with a density of order $\varepsilon(\beta)$ or, otherwise, it is only locally straight and with an important part of the excess length being gained through a small bending on a large length scale. In three dimensions a similar phenomenon is possible. Rigidity of $\lambda$, or its failure, can in principle be investigated by optical means;

there can be interference of coherent light scattered by macroscopically separated surface elements of $\lambda$ only if $\lambda$ is rigid in the above sense.

It has been rigorously proved that, the line $\lambda$ is *not rigid* in dimension 2. And, at least at low temperature, the fluctuation of the middle point is of the order $O(\sqrt{L})$. In dimension 3 however, it has been shown that the surface $\lambda$ is *rigid* at low enough temperature.

A deeper analysis is needed to study the shape of the separation surface under other conditions, for example, with + boundary conditions in a canonical distribution with magnetization intermediate between $\pm m^*(\beta)$. It involves, as a prerequisite, the definition and many properties of the surface tension between the two phases. Here only the definition of surface tension in the case of $\pm$-boundary conditions in the two-dimensional case will be mentioned. If $Z^{++}(\Omega, m^*(\beta))$ and $Z^{+-}(\Omega, m)$ are, respectively, the canonical partition functions for the ++- and $\pm$-cylindrical boundary conditions the tension $\tau(\beta)$ is defined as

$$\beta\tau(\beta) = -\lim_{\Omega\to\infty} \frac{1}{L} \log \frac{Z^{+-}(\Omega, m)}{Z^{++}(\Omega, m^*(\beta))}$$

The limit can be shown to be $\alpha$-independent for $\beta$ large enough: the definition and its justification is based on the microscopic geometric description in the section "Geometry of phase co-existence." The definition can be naturally extended to higher dimension (and to more general non-nearest-neighbor models). If $d = 2$, the tension $\tau$ can be exactly computed at all temperatures below criticality and is $\beta\tau(\beta) = 2\beta J + \log \tanh \beta J$.

More remarkably, the definition can be extended to define the surface tension $\tau(\beta, \boldsymbol{n})$ in the "direction $\boldsymbol{n}$," that is, when the boundary conditions are such that the line of separation is in the average orthogonal to the unit vector $\boldsymbol{n}$. In this way, if $d = 2$ and $\alpha \in (0, 1)$ is fixed, it can be proved that at low enough temperature the canonical distribution with + boundary conditions and intermediate magnetization $m = (1 - 2\alpha)m^*(\beta)$ has typical configurations containing a spin − region of area $\sim\alpha V$; furthermore, if the container is rescaled to size $L = 1$, the region will have a limiting shape filling an area $\alpha$ bounded by a smooth curve whose form is determined by the classical macroscopic *Wulff's theory* of the shape of crystals in terms of the surface tension $\tau(\boldsymbol{n})$.

An interesting question remains open in the three-dimensional case: it is conceivable that the surface, although rigid at low temperature, might become "loose" at a temperature $\widetilde{T}_c$ smaller than the critical temperature $T_c$ (the latter being defined as the highest temperature below which there are at least two pure phases). The temperature $\widetilde{T}_c$, whose existence is rather well established in numerical experiments, would be called the "roughening transition" temperature. The rigidity of $\lambda$ is connected with the existence of translationally non-invariant equilibrium states. The latter exist in dimension $d = 3$, but not in dimension $d = 2$, where the discussed nonrigidity of $\lambda$, established all the way to $T_c$, provides the intuitive reason for the absence of non-translation-invariant states. It has been shown that in $d = 3$ the roughening temperature $\widetilde{T}_c(\beta)$ necessarily cannot be smaller than the critical temperature of the two-dimensional Ising model with the same coupling.

Note that existence of translationally noninvariant equilibrium states is not necessary for the description of coexistence phenomena. The theory of the nearest-neighbor two-dimensional Ising model is a clear proof of this statement.

The reader is referred to Onsager (1944), van Beyeren (1975), Sinai (1991), Miracle-Solé (1995), Pfister and Velenik (1999), and Gallavotti (1999) for more details.

## Critical Points

Correlation functions for a system with short-range interactions and in an equilibrium state (which is a pure phase) have cluster properties (see [22]): their physical meaning is that in a pure phase there is independence between fluctuations occurring in widely separated regions. The simplest cluster property concerns the "pair correlation function," that is, the probability density $\rho(\boldsymbol{q}_1, \boldsymbol{q}_2)$ of finding particles at points $\boldsymbol{q}_1, \boldsymbol{q}_2$ independently of where the other particles may happen to be (see [23]). In the case of spin systems, the pair correlation $\rho(\boldsymbol{q}_1, \boldsymbol{q}_2) = \langle \sigma_{q_1} \sigma_{q_2} \rangle$ will be considered. The pair correlation of a translation-invariant equilibrium state has a cluster property ([22], [42]), if

$$|\rho(\boldsymbol{q}_1, \boldsymbol{q}_2) - \rho^2| \xrightarrow[|q_1 - q_2| \to \infty]{} 0 \qquad [57]$$

where $\rho$ is the probability density for finding a particle at $\boldsymbol{q}$ (i.e., the physical density of the state) or $\rho = \langle \sigma_q \rangle$ is the average of the value of the spin at $\boldsymbol{q}$ (i.e., the magnetization of the state).

A general definition of critical point is a point $c$ in the space of the parameters characterizing equilibrium states, for example, $\beta, \lambda$ in grand canonical distributions, $\beta$, $v$ in canonical distributions, or $\beta$, $h$ in the case of lattice spin systems in a grand canonical

distribution. In systems with short-range interaction (i.e., with $\varphi(\boldsymbol{r})$ vanishing for $|\boldsymbol{r}|$ large enough) the point $c$ is a critical point if the pair correlation tends to 0 (see [57]), slower than exponential (e.g., as a power of the distance $|\boldsymbol{r}| = |\boldsymbol{q}_1 - \boldsymbol{q}_2|$).

A typical example is the two-dimensional Ising model on a square lattice and with nearest-neighbor ferromagnetic interaction of size $J$. It has a single critical point at $\beta = \beta_c$, $h = 0$ with $\sinh 2\beta_c J = 1$. The cluster property is that $\langle \sigma_x \sigma_y \rangle - \langle \sigma_x \rangle \langle \sigma_y \rangle \xrightarrow[|x-y|\to\infty]{} 0$ as

$$A_+(\beta)\frac{e^{-\kappa(\beta)|x-y|}}{\sqrt{|x-y|}}, \qquad A_-(\beta)\frac{e^{-\kappa(\beta)|x-y|}}{|x-y|^2}$$
$$A_c\frac{1}{|x-y|^{1/4}}, \qquad [58]$$

for $\beta < \beta_c$, $\beta > \beta_c$, or $\beta = \beta_c$, respectively, where $A_\pm(\beta)$, $A_c$, $\kappa(\beta) > 0$. The properties [58] stem from the exact solution of the model.

At the critical point, several interesting phenomena occur: the lack of exponential decay indicates lack of a length scale over which really distinct phenomena can take place, and properties of the system observed at different length scales are likely to be simply related by suitable scaling transformations. Many efforts have been dedicated at finding ways of understanding quantitatively the scaling properties pertaining to different observables. The result has been the development of the *renormalization group* approach to critical phenomena (cf. the section "Renormalization group"). The picture that emerges is that the closer the critical point is the larger becomes the maximal scale of length below which scaling properties are observed. For instance, in a lattice spin system in zero field the magnetization $M|\Lambda|^{-a}$ in a box $\Lambda \subset \Omega$ should have essentially the same distribution for all $\Lambda$'s with side $< l_0(\beta)$ and $l_0(\beta) \to \infty$ as $\beta \to \beta_c$, provided $a$ is suitably chosen. The number $a$ is called a *critical exponent*.

There are several other "critical exponents" that can be defined near a critical point. They can be associated with singularities of the thermodynamic function or with the behavior of the correlation functions involving joint densities at two or more than two points. As an example, consider a lattice spin system: then the "$2n$–spins correlation" $\langle \sigma_0 \sigma_{\xi_1} \ldots \sigma_{\xi_{2n-1}} \rangle_c$ could behave proportionally to $\chi_{2n}(0, \xi_1, \ldots, \xi_{2n-1}), n = 1, 2, 3, \ldots$, for a suitable family of homogeneous functions $\chi_n$, of some degree $\omega_{2n}$, of the coordinates $(\xi_1, \ldots, \xi_{2n-1})$ at east when the reciprocal distances are large but $< l_0(\beta)$ and

$$l_0(\beta) = \text{const.}(\beta - \beta_c)^{-\nu} \xrightarrow[\beta\to\beta_0]{} \infty$$

This means that if $\xi_i$ are regarded as points in $\mathbb{R}^d$ there are functions $\chi_{2n}$ such that

$$\chi_{2n}\left(0, \frac{\xi_1}{\lambda}, \ldots, \frac{\xi_{2n-1}}{\lambda}\right) = \lambda^{\omega_{2n}} \chi_{2n}(0, \xi_1, \ldots, \xi_{2n-1})$$
$$0 < \lambda \in \mathbb{R} \qquad [59]$$

and $\langle \sigma_0 \sigma_{\xi_1} \ldots \sigma_{\xi_{2n-1}} \rangle \propto \chi_{2n}(0, \xi_1, \ldots, \xi_{2n-1})$ if $1 \ll |x_i - x_j| \ll l_0(\beta)$. The numbers $\omega_{2n}$ define a sequence of critical exponents.

Other critical exponents can be associated with approaching the critical point along other directions (e.g., along $h \to 0$ at $\beta = \beta_c$). In this case, the length up to which there are scaling phenomena is $l_0(h) = \ell_o h^{-\bar{\nu}}$. Further, the magnetization $m(h)$ tends to 0 as $h \to 0$ at fixed $\beta = \beta_c$ as $m(h) = m_0 h^{1/\delta}$ for $\delta > 0$.

None of the feautres of critical exponents is known rigorously, including their existence. An exception is the case of the two–dimensional nearest-neighbor Ising ferromagnet where some exponents are known exactly (e.g., $\omega_2 = 1/4$, $\omega_{2n} = n\omega_2$, or $\nu = 1$, while $\delta$, $\bar{\nu}$ are not rigorously known). Nevertheless, for Ising ferromagnets (not even nearest-neighbor but, as always here, finite-range) in all dimensions, all of the exponents mentioned are conjectured to be the same as those of the nearest-neighbor Ising ferromagnet. A further exception is the derivation of rigorous relations between critical exponents and, in some cases, even their values under the assumption that they exist.

**Remark** Naively it could be expected that in a pure state in zero field with $\langle \sigma_x \rangle = 0$ the quantity $s = |\Lambda|^{-1/2} \sum_{x\in\Lambda} \sigma_x$, if $\Lambda$ is a cubic box of side $\ell$, should have a probability distribution which is Gaussian, with dispersion $\lim_{\Lambda\to\infty}\langle s^2 \rangle$. This is "usually true," but not always. Properties [58] show that in the $d = 2$ ferromagnetic nearest-neighbor Ising model, $\langle s^2 \rangle$ diverges proportionally to $\ell^{2-\frac{1}{4}}$ so that the variable $s$ cannot have the above Gaussian distribution. The variable $S = |\Lambda|^{-7/8} \sum_{x\in\Lambda} \sigma_x$ will have a finite dispersion: however, there is no reason that it should be Gaussian. This makes clear the great interest of a fluctuation theory and its relevance for the critical point studies (see the next two sections).

For more details, the reader is referred to Onsager (1944), Domb and Green (1972), McCoy and Wu (1973), and Aizenman (1982).

## Fluctuations

As it appears from the discussion in the last section, fluctuations of observables around their averages have interesting properties particularly at critical points. Of particular interest are observables that

are averages, over large volumes $\Lambda$, of local functions $F(x)$ on phase space: this is so because macroscopic observables often have this form. For instance, given a region $\Lambda$ inside the system container $\Omega$, $\Lambda \subset \Omega$, consider a configuration $x = (\boldsymbol{P}, \boldsymbol{Q})$ and the number of particles $N_\Lambda = \sum_{q \in \Lambda} 1$ in $\Lambda$, or the potential energy $\boldsymbol{\Phi}_\Lambda = \sum_{(q,q') \in \Lambda} \varphi(\boldsymbol{q} - \boldsymbol{q}')$ or the kinetic energy $K_\Lambda = \sum_{q \in \Lambda} (1/2m)\boldsymbol{p}^2$. In the case of lattice spin systems, consider a configuration $\boldsymbol{\sigma}$ and, for instance, the magnetization $M_\Lambda = \sum_{i \in \Lambda} \sigma_i$ in $\Lambda$. Label the above four examples by $\alpha = 1, \ldots, 4$.

Let $\mu_\alpha$ be the probability distribution describing the equilibrium state in which the quantities $X_\Lambda$ are considered; let $x_\Lambda = \langle X_\Lambda / |\Lambda| \rangle_{\mu_\alpha}$ and $p \stackrel{\text{def}}{=} (X_\Lambda - x_\Lambda)/|\Lambda|$. Then typical properties of fluctuations that should be investigated are ($\alpha = 1, \ldots, 4$):

1. for all $\delta > 0$ it is $\lim_{\Lambda \to \infty} \mu_\alpha(|p| > \delta) = 0$ (*law of large numbers*);
2. there is $D_\alpha > 0$ such that

$$\mu(p\sqrt{|\Lambda|} \in [a,b]) \underset{\Lambda \to \infty}{\longrightarrow} \int_a^b \frac{\mathrm{d}z}{\sqrt{2\pi D_\alpha}} \mathrm{e}^{-z^2/2D_\alpha}$$

   (*central limit law*); and
3. there is an interval $I_\alpha = (p^*_{\alpha,-}, p^*_{\alpha,+})$ and a concave function $F_\alpha(p)$, $p \in I$, such that if $[a,b] \subset I$ then

$$\frac{1}{|\Lambda|} \log \mu(p \in [a,b]) \underset{\Lambda \to \infty}{\longrightarrow} \max_{p \in [a,b]} F_\alpha(p)$$

   (*large deviations law*).

The law of large numbers provides the certainty of the macroscopic values; the central limit law controls the small fluctuations (of order $\sqrt{|\Lambda|}$) of $X_\Lambda$ around its average; and the large deviations law concerns the fluctuations of order $|\Lambda|$.

The relations (1)–(3) above are not always true: they can be proved under further general assumptions if the potential $\varphi$ satisfies [14] in the case of particle systems or if $\sum_q |\varphi(q)| < \infty$ in the case of lattice spin systems. The function $F_\alpha(p)$ is defined in terms of the thermodynamic limits of suitable thermodynamic functions associated with the equilibrium state $\mu_\alpha$. The further assumption is, essentially in all cases, that a suitable thermodynamic function in terms of which $F_\alpha(p)$ will be expressed is smooth and has a nonvanishing second derivative.

For the purpose of a simple concrete example, consider a lattice spin system of Ising type with energy $-\sum_{x,y \in \Omega} \varphi(x-y)\sigma_x\sigma_y - \sum_x h\sigma_x$ and the fluctuations of the magnetization $M_\Lambda = \sum_{x \in \Lambda} \sigma_x$, $\Lambda \subset \Omega$, in the grand canonical equilibrium states $\mu_{h,\beta}$.

Let the free energy be $\beta f(\beta, h)$ (see [41]), let $m = m(h) \stackrel{\text{def}}{=} \langle M_\Lambda / |\Lambda| \rangle$ and let $h(m)$ be the inverse function of $m(h)$. If $p = M_\Lambda / |\Lambda|$ the function $F(p)$ is given by

$$F(p) = \beta(f(\beta, h(p)) - f(\beta, h) - \partial_h f(\beta, h)(h(p) - h)) \quad [60]$$

then a quite general result is:

**Theorem** *The relations* (1)–(3) *hold if the potential satisfies* $\sum_x |\varphi(x)| < \infty$ *and if* $F(p)$ [60] *is smooth and* $F''(p) \neq 0$ *in open intervals around those in which* $p$ *is considered, that is, around* $p = 0$ *for the law of large numbers and for the central limit law or in an open interval containing* $a, b$ *for the case of the large deviations law.*

In the cases envisaged, the theory of equivalence of ensembles implies that the function $F$ can also be computed via thermodynamic functions naturally associated with other equilibrium ensembles. For instance, instead of the grand canonical $f(\beta, h)$, one could consider the canonical $\beta g(\beta, m)$ (see [41]), then

$$F(p) = -\beta(g(\beta, p) - g(\beta, m) - \partial_m g(\beta, m)(p - m)) \quad [61]$$

It has to be remarked that there should be a strong relation between the central limit law and the law of large deviations. Setting aside stating the conditions for a precise mathematical theorem, the statement can be efficiently illustrated in the case of a ferromagnetic lattice spin system and with $\Lambda \equiv \Omega$, by showing that the law of large deviations in small intervals, around the average $m(h_0)$, at a value $h_0$ of the external field, is implied by the validity of the central limit law for all values of $h$ near $h_0$ and vice versa (here $\beta$ is fixed). Taking $h_0 = 0$ (for simplicity), the heuristic reasons are the following. Let $\mu_{h,\Omega}$ be the grand canonical distribution in external field $h$. Then:

1. The probability $\mu_{h,\Omega}(p \in dp)$ is proportional, by definition, to $\mu_{0,\Omega}(p \in \mathrm{d}p)\mathrm{e}^{-\beta h p |\Omega|}$. Hence, if the central limit law holds for all $h$ near $h_0 = 0$, there will exist two functions $m(h)$ and $D(h) > 0$, defined for $h$ near $h_0 = 0$, with $m(0) = 0$ and

$$\mu_0(p \in \mathrm{d}p)\mathrm{e}^{-\beta h p^{|\Omega|}} = \text{const.} \exp\left(-|\Omega| \frac{(p - m(h))^2}{2D(h)} + o(\Omega)\right) \mathrm{d}p \quad [62]$$

2. There is a function $\zeta(m)$ such that $\partial_m \zeta(m(h)) = \beta h$ and $\partial_m^2 \zeta(m(h)) = D(h)^{-1}$. (This is obtained by noting that, given $D(h)$, the differential equation $\partial_m \beta h = D(h)^{-1}$ with the initial value $h(0) = 0$ determines the function $h(m)$; therefore, $\zeta(m)$ is determined by a second integration, from $\partial_m \zeta(m) = \beta h(m)$.

It then follows, heuristically, that the probability of $p$ in zero field has the form const. $e^{\zeta(p)|\Omega|}\,dp$ so that the probability that $p \in [a,b]$ will be const $\exp(|\Omega| \max_{p\in[a,b]} \zeta(p))$.

Conversely, the large deviations law for $p$ at $h=0$ implies the validity of the central limit law for the fluctuations of $p$ in all small enough fields $h$: this simply arises from the function $F(p)$ having a negative second derivative.

This means that there is a "duality" between central limit law and large deviation law or that the law of large deviations is a "global version" of the central limit law, in the sense that:

1. if the central limit law holds for h in an interval around $h_0$ then the fluctuations of the magnetization at field $h_0$ satisfy a large deviation law in a small enough interval $J$ around $m(h_0)$; and
2. if a large deviation law is satisfied in an interval around $h_0$ then the central limit law holds for the fluctuations of magnetization around its average in all fields h with $h - h_0$ small enough.

Going beyond the heuristic level in establishing the duality amounts to giving a precise meaning to "small enough" and to discuss which properties of $m(h)$ and $D(h)$, or $F(p)$ are needed to derive properties (1), (2).

For purposes of illustration consider the Ising model with ferromagnetic short range interaction $\varphi$: then the central limit law holds for all $h$ if $\beta$ is small enough and, under the same condition on $\beta$, the large deviations law holds for all $h$ and all intervals $[a,b] \subset (-1,1)$. If $\beta$ is not small then the condition $h \neq 0$ has to be added. Hence, the conditions are fairly weak and the apparent exceptions concern the value $h=0$ and $\beta$ not small where the statements may become invalid because of possible phase transitions.

In presence of phase transitions, the law of large numbers, the central limit law, and law of large deviations should be reformulated. Basically, one has to add the requirement that fluctuations are considered in pure phases and change, in a natural way, the formulation of the laws. For instance, the large fluctuations of magnetization in a pure phase of the Ising model in zero field and large $\beta$ (i.e., in a state obtained as limit of finite-volume states with + or − boundary conditions) in intervals $[a,b]$ which do not contain the average magnetization $m^*$ are not necessarily exponentially small with the size of $|\Lambda|$: if $[a,b] \subset [-m^*, m^*]$ they are exponentially small but only with the size of the surface of $\Lambda$ (i.e., with $|\Lambda|^{(d-1)/d}$) while they are exponentially small with the volume if $[a,b] \cap [-m^*, m^*] = \emptyset$.

The discussion of the last section shows that at the critical point the nature of the large fluctuations is also expected to change: no central limit law is expected to hold in general because of the example of [58] with the divergence of the average of the normal second moment of the magnetization in a box as the side tends to $\infty$.

For more details the reader is referred to Olla (1987).

## Renormalization Group

The theory of fluctuations just discussed concerns only fluctuations of a single quantity. The problem of joint fluctuations of several quantities is also interesting and in fact led to really new developments in the 1970s. It is necessary to restrict attention to rather special cases in order to illustrate some ideas and the philosophy behind the approach. Consider, therefore, the equilibrium distribution $\mu_0$ associated with one of the classical equilibrium ensembles. To fix the ideas we consider the equilibrium distribution of an Ising energy function $\beta H_0$, having included the temperature factor in the energy: the inclusion is done because the discussion will deal with the properties of $\mu_0$ as a function of $\beta$. It will also be assumed that the average of each spin is zero ("no magnetic field," see [39] with $h=0$). Keeping in mind a concrete case, imagine that $\beta H_0$ is the energy function of the nearest-neighbor Ising ferromagnet in zero field.

Imagine that the volume $\Omega$ of the container has periodic boundary conditions and is very large, ideally infinite. Define the family of blocks $k\boldsymbol{\xi}$, parametrized by $\boldsymbol{\xi} \in \mathbb{Z}^d$ and with $k$ an integer, consisting of the lattice sites $\boldsymbol{x} = \{k\xi_i \le x_i < (k+1)\xi_i\}$. This is a lattice of cubic blocks with side size $k$ that will be called the "$k$-rescaled lattice."

Given $\alpha$, the quantities $m_{\boldsymbol{\xi}} = k^{-\alpha d} \sum_{\boldsymbol{x}\in k\boldsymbol{\xi}} \sigma_{\boldsymbol{x}}$ are called the block spins and define the map $R^*_{\alpha,k}\mu_0 = \mu_k$ transforming the initial distribution on the original spins into the distribution of the block spins. Note that if the initial spins have only two values $\sigma_{\boldsymbol{x}} = \pm 1$, the block spins take values between $-k^d/k^{\alpha d}$ and $k^d/k^{\alpha d}$ at steps of size $2/k^{\alpha d}$. Furthermore, the map $R^*_{\alpha,k}$ makes sense independently of how many values the initial spins can assume, and even if they assume a continuum of values $S_{\boldsymbol{x}} \in \mathbb{R}$.

Taking $\alpha = 1$ means, for $k$ large, looking at the probability distribution of the joint large fluctuations in the blocks $k\boldsymbol{\xi}$. Taking $\alpha = 1/2$ corresponds to studying a joint central limit property for the block variables.

Considering a one-parameter family of initial distributions $\mu_0$ parametrized by a parameter $\beta$

(that will be identified with the inverse temperature), typically there will be a unique value $\alpha(\beta)$ of $\alpha$ such that the joint fluctuations of the block variables admit a limiting distribution,

$$\text{prob}_k(m_\xi \in [a_\xi, b_\xi], \boldsymbol{\sigma} \in \Lambda) \underset{k\to\infty}{\longrightarrow} \int_{\{a_\xi\}}^{\{b_\xi\}} g_\Lambda((S_\xi)_{\xi\in\Lambda}) \prod_{\xi\in\Lambda} \mathrm{d}S_\xi \qquad [63]$$

for some distribution $g_\Lambda(z)$ on $\mathbb{R}^\Lambda$.

If $\alpha > \alpha(\beta)$, the limit will then be $\prod_{\xi\in\Lambda}\delta(S_\xi)\,\mathrm{d}S_\xi$, or if $\alpha < \alpha(\beta)$ the limit will not exist (because the block variables will be too large, with a dispersion diverging as $k \to \infty$).

It is convenient to choose as sequence of $k \to \infty$ the sequence $k = 2^n$ with $n = 0, 1, \ldots$ because in this way it is $R^*_{\alpha,k} \equiv R^{*n}_{\alpha,1}$ and the limits $k \to \infty$ along the sequence $k = 2^n$ can be regarded as limits on a sequence of iterations of a map $R^*_{\alpha,1}$ acting on the probability distributions of generic spins $S_x$ on the lattice $\mathbb{Z}^d$ (the sequence $3^n$ would be equally suited).

It is even more convenient to consider probability distributions that are expressed in terms of energy functions $H$ which generate, in the thermodynamic limit, a distribution $\mu$: then $R^*_{\alpha,1}$ defines an action $R_\alpha$ on the energy functions so that $R_\alpha H = H'$ if $H$ generates $\mu$, $H'$ generates $\mu'$ and $R^*_{\alpha,1}\mu = \mu'$. Of course, the energy function will be more general than [39] and at least a form like $\delta U$ in [49] has to be admitted.

In other words, $R_\alpha$ gives the result of the action of $R^*_{\alpha,1}$ expressed as a map acting on the energy functions. Its iterates also define a semigroup which is called the block spin renormalization group.

While the map $R^*_{\alpha,1}$ is certainly well defined as a map of probability distributions into probability distributions, it is by no means clear that $R_\alpha$ is well defined as a map on the energy functions. Because, if $\mu$ is given by an energy function, it is not clear that $R^*_{\alpha,1}\mu$ is such.

A remarkable theorem can be (easily) proved when $R^*_{\alpha,1}$ and its iterates act on initial $\mu_0$'s which are equilibrium states of a spin system with short-range interactions and at high temperature ($\beta$ small). In this case, if $\alpha = 1/2$, the sequence of distributions $R^{*n}_{1/2,1}\mu_0(\beta)$ admits a limit which is given by a product of independent Gaussians:

$$\text{prob}_k(m_\xi \in [a_\xi, b_\xi], \boldsymbol{\sigma} \in \Lambda) \underset{k\to\infty}{\longrightarrow} \int_{\{a_\xi\}}^{\{b_\xi\}} \prod_{\xi\in\Lambda} \exp\left(-\frac{1}{2D(\beta)} S_\xi^2\right) \prod_{\xi\in\Lambda} \frac{\mathrm{d}S_\xi}{\sqrt{2\pi D(\beta)}} \qquad [64]$$

Note that this theorem is stated without even mentioning the renormalization maps $R^n_{1/2}$: it can nevertheless be interpreted as stating that

$$R^n_{1/2}\beta H_0 \underset{n\to\infty}{\longrightarrow} \sum_{\xi\in\mathbb{Z}^d} \frac{1}{2D(\beta)} S_\xi^2 \qquad [65]$$

but the interpretation is not rigorous because [64] does not state require that $R^n_{1/2}H_0(\beta)$ makes sense for $n \geq 1$. It states that at high temperature block spins have normal independent fluctuations: it is therefore an extension of the central limit law.

There are a few cases in which the map $R_\alpha$ can be rigorously shown to be well defined at least when acting on special equilibrium states like the high-temperature lattice spin systems: but these are exceptional cases of relatively little interest.

Nevertheless, there is a vast literature dealing with approximate representations of the map $R_\alpha$. The reason is that, assuming not only its existence but also that it has the properties that one would normally expect to hold for a map acting on a finite dimensional space, it follows that a number of consequences can be drawn; quite nontrivial ones as they led to the first theory of the critical point that goes beyond the van der Waals theory discribed in the section "van der Waals theory."

The argument proceeds essentially as follows. At the critical point, the fluctuations are expected to be anomalous (cf. the last remark in the section "Critical points") in the sense that $\langle(\sum_{x\in\Lambda}\sigma_\xi/\sqrt{|\Lambda|})^2\rangle$ will tend to $\infty$, because $\alpha = 1/2$ does not correspond to the right fluctuation scale of $\sum_{\xi\in\Lambda}\sigma_\xi$, signaling that $R^{*n}_{1/2,1}\mu_0(\beta_c)$ will not have a limit but, possibly, there is $\alpha_c > 1/2$ such that $R^{*n}_{\alpha_c,1}\mu_0(\beta_c)$ converges to a limit in the sense of [63]. In the case of the critical nearest-neighbor Ising ferromagnetic $\alpha_c = 7/8$ (see ending remark in the section "Critical points"). Therefore, if the map $R^*_{\alpha_c,1}$ is considered as acting on $\mu_0(\beta)$, it will happen that for all $\beta < \beta_c$, $R^{*n}_{\alpha_c,1}\mu_0(\beta_c)$ will converge to a trivial limit $\prod_{\xi\in\Lambda}\delta(S_\xi)\,\mathrm{d}S_\xi$ because the value $\alpha_c$ is greater than 1/2 while normal fluctuations are expected.

If the map $R_{\alpha_c}$ can be considered as a map on the energy functions, this says that $\prod_{\xi\in\Lambda}\delta(S_\xi)\,\mathrm{d}S_\xi$ is a "(trivial) fixed point of the renormalization group" which "attracts" the energy functions $\beta H_0$ corresponding to the high-temperature phases.

The existence of the critical $\beta_c$ can be associated with the existence of a *nontrivial fixed point* $H^*$ for $R_{\alpha_c}$ which is hyperbolic with just one Lyapunov exponent $\lambda > 1$; hence, it has a stable manifold of codimension 1. Call $\mu^*$ the probability distribution corresponding to $H^*$.

The migration towards the trivial fixed point for $\beta < \beta_c$ can be explained simply by the fact that for

such values of $\beta$ the initial energy function $\beta H_0$ is outside the stable manifold of the nontrivial fixed point and under application of the renormalization transformation $R^n_{\alpha_c}$, $\beta H_0$ migrates toward the trivial fixed point, which is attractive in all directions.

By increasing $\beta$, it may happen that, for $\beta = \beta_c$, $\beta H_0$ crosses the stable manifold of the nontrivial fixed point $H^*$ for $R_{\alpha_c}$. Then $R^n_{\alpha_c}\beta_c H_0$ will no longer tend to the trivial fixed point but it will tend to $H^*$: this means that the block spin variables will exhibit a completely different fluctuation behavior. If $\beta$ is close to $\beta_c$, the iterations of $R_{\alpha_c}$ will bring $R^n_{\alpha_c}\beta H_0$ close to $H^*$, only to be eventually repelled along the unstable direction reaching a distance from it increasing as $\lambda^n|\beta - \beta_c|$.

This means that up to a scale length $O(2^{n(\beta)})$ lattice units with $\lambda^{n(\beta)}|\beta - \beta_c| = 1$ (i.e., up to a scale $O(|\beta - \beta_c|^{-\log_2 \lambda})$), the fluctuations will be close to those of the fixed point distribution $\mu^*$, but beyond that scale they will come close to those of the trivial fixed point: to see them the block spins would have to be normalized with index $\alpha = 1/2$ and they would appear as uncorrelated Gaussian fluctuations (cf. [64], [65]).

The next question concerns finding the nontrivial fixed points, which means finding the energy functions $H^*$ and the corresponding $\alpha_c$ which are fixed points of $R_{\alpha_c}$. If the above picture is correct, the distributions $\mu^*$ corresponding to the $H^*$ would describe the critical fluctuations and, if there was only one choice, or a limited number of choices, of $\alpha_c$ and $H^*$ this would open the way to a universality theory of the critical point hinted already by the "primitive" results of van der Waals' theory.

The initial hope was, perhaps, that there would be a very small number of critical values $\alpha_c$ and $H^*$ possible: but it rapidly faded away leaving, however, the possibility that the critical fluctuations could be classified into universality classes. Each class would contain many energy functions which, upon iterated actions of $R_{\alpha_c}$, would evolve under the control of the trivial fixed point (always existing) for $\beta$ small while, for $\beta = \beta_c$, they would be controlled, instead, by a nontrivial fixed point $H^*$ for $R_{\alpha_c}$ with the same $\alpha_c$ and the same $H^*$. For $\beta < \beta_c$, a "resolution" of the approach to the trivial fixed point would be seen by considering the map $R_{1/2}$ rather than $R_{\alpha_c}$ whose iterates would, however, lead to a Gaussian distribution like [64] (and to a limit energy function like [65]).

The picture is highly hypothetical: but it is the first suggestion of a mechanism leading to critical points with the character of universality and with exponents different from those of the van der Waals theory or, for ferromagnets on a lattice, from those of its lattice version (the *Curie–Weiss theory*). Furthermore, accepting the approximations (e.g., the Wilson–Fisher $\varepsilon$-expansion) that allow one to pass from the well-defined $R^*_{\alpha,1}$ to the action of $R_\alpha$ on the energy functions, it is possible to obtain quite unambiguously values for $\alpha_c$ and expressions for $H^*$ which are associated with the action of $R_{\alpha_c}$ on various classes of models.

For instance, it can lead to conclude that the critical behavior of all ferromagnetic finite-range lattice spin systems (with energy functions given by [39]) have critical points controlled by the same $\alpha_c$ and the same nontrivial fixed point: this property is far from being mathematically proved, but it is considered a major success of the theory. One has to compare it with van der Waals' critical point theory: *for the first time*, an approximation scheme has led, even though under approximations not fully controllable, to computable critical exponents which are not equal to those of the van der Waals theory.

The renormalization group approach to critical phenomena has many variants, depending on which kind of fluctuations are considered and on the models to which it is applied. In statistical mechanics, there are a few mathematically complete applications: certain results in higher dimensions, theory of dipole gas in $d = 2$, hierarchical models, some problems in condensed matter and in statistical mechanics of lattice spins, and a few others. Its main mathematical successes have occured in various related fields where not only the philosophy described above can be applied but it leads to renormalization transformations that can be defined precisely and studied in detail: for example, constructive field theory, KAM theory of quasiperiodic motions, and various problems in dynamical systems.

However, the applications always concern special cases and in each of them the general picture of the trivial–nontrivial fixed point dichotomy appears realized but without being accompanied, except in rare cases (like the hierarchical models or the universality theory of maps of the interval), by the full description of stable manifold, unstable direction, and action of the renormalization transformation on objects other than the one of immediate interest (a generality which looks often an intractable problem, but which also turns out not to be necessary).

In the renormalization group context, mathematical physics has played an important role also by providing clear evidence that universality classes could not be too few: this was shown by the numerous exact solutions after Onsager's solution of the nearest-neighbor Ising ferromagnet: there are in fact several lattice models in $d = 2$ that exhibit critical points with some critical exponents exactly computable and that depend continuously on the models parameters.

For more details, we refer the reader to McCoy and Wu (1973), Baxter (1982), Bleher and Sinai (1975), Wilson and Fisher (1972), Gawedzky and Kupiainen (1983, 1985), Benfatto and Gallavotti (1995), and Mastropietro (2004).

## Quantum Statistics

Statistical mechanics is extended to assemblies of quantum particles rather straightforwardly. In the case of $N$ identical particles, the observables are operators $O$ on the Hilbert space

$$\mathcal{H}_N = L_2(\Omega)^N_\alpha \quad \text{or} \quad \mathcal{H}_N = (L_2(\Omega) \otimes \mathcal{C}^2)^N_\alpha$$

where $\alpha = +, -$, of the symmetric ($\alpha = +$, bosonic particles) or antisymmetric ($\alpha = -$, fermionic particles) functions $\psi(\boldsymbol{Q})$, $\boldsymbol{Q} = (\boldsymbol{q}_1, \ldots, \boldsymbol{q}_N)$, of the position coordinates of the particles or of the position and spin coordinates $\psi(\boldsymbol{Q}, \boldsymbol{\sigma})$, $\boldsymbol{\sigma} = (\sigma_1, \ldots, \sigma_N)$, normalized so that

$$\int |\psi(\boldsymbol{Q})|^2 \, \mathrm{d}\boldsymbol{Q} = 1 \quad \text{or} \quad \sum_{\boldsymbol{\sigma}} \int |\psi(\boldsymbol{Q}, \boldsymbol{\sigma})|^2 \, \mathrm{d}\boldsymbol{Q} = 1$$

here only $\sigma_j = \pm 1$ is considered. As in classical mechanics, a state is defined by the average values $\langle O \rangle$ that it attributes to the observables.

Microcanonical, canonical, and grand canonical ensembles can be defined quite easily. For instance, consider a system described by the Hamiltonian ($\hbar$ = Planck's constant)

$$H_N = -\frac{\hbar^2}{2m} \sum_{j=1}^{N} \Delta_{q_j} + \sum_{j<j'} \varphi(\boldsymbol{q}_j - \boldsymbol{q}_{j'}) + \sum_j w(\boldsymbol{q}_j) \stackrel{\text{def}}{=} K + \boldsymbol{\Phi} \qquad [66]$$

where periodic boundary conditions are imagined on $\Omega$ and $w(\boldsymbol{q})$ is periodic, smooth potential (the side of $\Omega$ is supposed to be a multiple of the periodic potential period if $w \neq 0$). Then a canonical equilibrium state with inverse temperature $\beta$ and specific volume $v = V/N$ attributes to the observable $O$ the average value

$$\langle O \rangle \stackrel{\text{def}}{=} \frac{\operatorname{tr} \mathrm{e}^{-\beta H_N} O}{\operatorname{tr} \mathrm{e}^{-\beta H_N}} \qquad [67]$$

Similar definitions can be given for the grand canonical equilibrium states.

Remarkably, the ensembles are orthodic and a "heat theorem" (see the section "Heat theorem and ergodic hypothesis") can be proved. However, "equipartition" does not hold: that is, $\langle K \rangle \neq (d/2)N\beta^{-1}$, although $\beta^{-1}$ is still the integrating factor of $\mathrm{d}U + p\,\mathrm{d}V$ in the heat theorem; hence, $\beta^{-1}$ continues to be proportional to temperature.

Lack of equipartition is important, as it solves paradoxes that arise in classical statistical mechanics applied to systems with infinitely many degrees of freedom, like crystals (modeled by lattices of coupled oscillators) or fields (e.g., the electromagnetic field important in the study of black body radiation). However, although this has been the first surprise of quantum statistics (and in fact responsible for the very discovery of quanta), it is by no means the last.

At low temperatures, new unexpected (i.e., with no analogs in classical statistical mechanics) phenomena occur: Bose–Einstein condensation (superfluidity), Fermi surface instability (superconductivity), and appearance of off-diagonal long-range order (ODLRO) will be selected to illustrate the deeply different kinds of problems of quantum statistical mechanics. Largely not yet understood, such phenomena pose very interesting problems not only from the physical point of view but also from the mathematical point of view and may pose challenges even at the level of a definition. However, it should be kept in mind that in the interesting cases (i.e., three-dimensional systems and even most two- and one-dimensional systems) there is no proof that the objects defined below really exist for the systems like [66] (see, however, the final comment for an important exception).

### Bose–Einstein Condensation

In a canonical state with parameters $\beta, v$, a definition of the occurrence of Bose condensation is in terms of the eigenvalues $\nu_j(\Omega, N)$ of the kernel $\rho(\boldsymbol{q}, \boldsymbol{q}')$ on $L_2(\Omega)$, called the *one-particle reduced density matrix*, defined by

$$N \sum_{n=1}^{\infty} \frac{\mathrm{e}^{-\beta E_n(\Omega,N)}}{\operatorname{tr} \mathrm{e}^{-\beta H_N}} \int \overline{\psi}_n(\boldsymbol{q}, \boldsymbol{q}_1, \ldots, \boldsymbol{q}_{N-1}) \times \psi_n(\boldsymbol{q}', \boldsymbol{q}_1, \ldots, \boldsymbol{q}_{N-1}) \, \mathrm{d}\boldsymbol{q}_1 \ldots \mathrm{d}\boldsymbol{q}_{N-1} \qquad [68]$$

where $E_n(\Omega, N)$ are the eigenvalues of $H_N$ and $\psi_n(\boldsymbol{q}_1, \ldots, \boldsymbol{q}_N)$ are the corresponding eigenfunctions. If $\nu_j$ are ordered by increasing value, the state with parameters $\beta, v$ is said to contain a *Bose–Einstein condensate* if $\nu_1(\Omega, N) \geq bN > 0$ for all large $\Omega$ at $v = V/N, \beta$ fixed. This receives the interpretation that there are more than $bN$ particles with equal momentum. The free Bose gas exhibits a Bose condensation phenomenon at fixed density and small temperature.

### Fermi Surface

The wave functions $\psi_n(\boldsymbol{q}_1, \sigma_1, \ldots, \boldsymbol{q}_N, \sigma_N) \equiv \psi_n(\boldsymbol{Q}, \boldsymbol{\sigma})$ are now antisymmetric in the permutations of the pairs $(\boldsymbol{q}_i, \sigma_i)$. Let $\psi(\boldsymbol{Q}, \boldsymbol{\sigma}; N, n)$ denote the $n$th

eigenfunction of the $N$-particle energy $H_N$ in [66] with eigenvalue $E(N,n)$ (labeled by $n=0,1,\ldots$ and nondecreasingly ordered). Setting $\boldsymbol{Q}''=(\boldsymbol{q}''_1,\ldots,\boldsymbol{q}''_{N-p})$, $\boldsymbol{\sigma}''=(\sigma''_1,\ldots,\sigma''_{N-p})$, introduce the kernels $\rho_p^{H_N}(\boldsymbol{Q},\boldsymbol{\sigma};\boldsymbol{Q}',\boldsymbol{\sigma}')$ by

$$\rho_p(\boldsymbol{Q},\boldsymbol{\sigma};\boldsymbol{Q}',\boldsymbol{\sigma}') \stackrel{\text{def}}{=} p!\binom{N}{p}\int\sum_{\boldsymbol{\sigma}''}\mathrm{d}^{N-p}\boldsymbol{Q}''\sum_{n=0}^{\infty}\frac{\mathrm{e}^{-\beta E(N,n)}}{\operatorname{tr}\mathrm{e}^{-\beta H_N}} \times\overline{\psi}(\boldsymbol{Q},\boldsymbol{\sigma};\boldsymbol{Q}'',\boldsymbol{\sigma}'';N,n)\psi(\boldsymbol{Q}',\boldsymbol{\sigma}';\boldsymbol{Q}'',\boldsymbol{\sigma}'';N,n) \quad [69]$$

which are called *p-particle reduced density matrices* (extending the corresponding one-particle reduced density matrix [68]). Denote $\rho(\boldsymbol{q}_1-\boldsymbol{q}_2)\stackrel{\text{def}}{=}\sum_\sigma\rho_1(\boldsymbol{q}_1,\sigma,\boldsymbol{q}_2,\sigma)$. It is also useful to consider spinless fermionic systems: the corresponding definitions are obtained simply by suppressing the spin labels and will not be repeated.

Let $r_1(\boldsymbol{k})$ be the Fourier transform of $\rho_1(\boldsymbol{q}-\boldsymbol{q}')$: the Fermi surface can be defined as the locus of the $\boldsymbol{k}$'s in the neighborhood of which $\partial_{\boldsymbol{k}} r_1(\boldsymbol{k})$ is unbounded as $\Omega\to\infty$, $\beta\to\infty$. The limit as $\beta\to\infty$ is important because the notion of a Fermi surface is, possibly, precise only at zero temperature, that is at $\beta=\infty$.

So far, existence of Fermi surface (i.e., the smoothness of $r_1(\boldsymbol{k})$ except on a smooth surface in $\boldsymbol{k}$-space) has been proved in free Fermi systems ($\varphi=0$) and

1. certain exactly soluble one-dimensional spinless systems and
2. in rather general one-dimensional spinless systems or systems with spin and repulsive pair interaction, possibly in an external periodic potential.

The spinning case in a periodic potential and dimension $d\ge 2$ is the most interesting case to study for its relevance in the theory of conduction in crystals. Essentially no mathematical results are available as the above-mentioned ones do not concern any case in dimension >1: this is a rather deceiving aspect of the theory and a challenge.

In dimension 2 or higher, for fermionic systems with Hamiltonian [66], not only there are no results available, even without spin, but it is not even clear that a Fermi surface can exist in presence of interesting interactions.

### Cooper Pairs

The superconductivity theory has been phenomenologically related to the existence of Cooper pairs. Consider the Hamiltonian [66] and define (cf. [69])

$$\rho(\boldsymbol{x}-\boldsymbol{y},\sigma;\boldsymbol{x}'-\boldsymbol{y}',\sigma';\boldsymbol{x}-\boldsymbol{x}') \stackrel{\text{def}}{=} \rho_2(\boldsymbol{x},\sigma,\boldsymbol{y},-\sigma;\boldsymbol{x}',\sigma',\boldsymbol{y}',-\sigma')$$

The system is said to contain *Cooper pairs* with spins $\sigma,-\sigma$ ($\sigma=+$ or $\sigma=-$) if there exist functions $g^\alpha(\boldsymbol{q},\sigma)\neq 0$ with

$$\int\overline{g^\alpha}(\boldsymbol{q},\sigma)g^{\alpha'}(\boldsymbol{q},\sigma)\,\mathrm{d}\boldsymbol{q}=0\quad\text{if }\alpha\neq\alpha'$$

such that

$$\lim_{V\to\infty}\rho(\boldsymbol{x}-\boldsymbol{y},\sigma,\boldsymbol{x}'-\boldsymbol{y}',\sigma',\boldsymbol{x}-\boldsymbol{x}') \xrightarrow[\boldsymbol{x}-\boldsymbol{x}'\to\infty]{} \sum_\alpha g^\alpha(\boldsymbol{x}-\boldsymbol{y},\sigma)\overline{g^\alpha}(\boldsymbol{x}'-\boldsymbol{y}',\sigma') \quad [70]$$

In this case, $g^\alpha(\boldsymbol{x}-\boldsymbol{y},\sigma)$ with largest $L_2$ norm can be called, after normalize, the wave function of the paired state of lowest energy: this is the analog of the plane wave for a free particle (and, like it, it is manifestly not normalizable, i.e., it is not square integrable as a function of $\boldsymbol{x},\boldsymbol{y}$). If the system contains Cooper pairs and the nonleading terms in the limit [70] vanish quickly enough the two-particle reduced density matrix [70] regarded as a kernel operator has an eigenvalue of order $V$ as $V\to\infty$: that is, the state of lowest energy is "macroscopically occupied," quite like the free Bose condensation in the ground state.

Cooper pairs instability might destroy the Fermi surface in the sense that $r_1(\boldsymbol{k})$ becomes analytic in $\boldsymbol{k}$; but it is also possible that, even in the presence of them, there remains a surface which is the locus of the singularities of the function $r_1(\boldsymbol{k})$. In the first case, there should remain a trace of it as a very steep gradient of $r_1(\boldsymbol{k})$ of the order of an exponential in the inverse of the coupling strength; this is what happens in the *BCS model* for superconductivity. The model is, however, a mean-field model and this particular regularity aspect might be one of its peculiarities. In any event, a smooth singularity surface is very likely to exist for some interesting density matrix (e.g., in the BCS model with "gap parameter $\gamma$" the wave function

$$g(\boldsymbol{x}-\boldsymbol{y},\sigma)\equiv\frac{1}{(2\pi)^d}\int_{\varepsilon(\boldsymbol{k})>0}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})}\frac{\gamma}{\sqrt{\varepsilon(\boldsymbol{k})^2+\gamma^2}}\mathrm{d}\boldsymbol{k}$$

of the lowest energy level of the Cooper pairs is singular on a surface coinciding with the Fermi surface of the free system).

### ODLRO

Consider the $k$-fermion reduced density matrix $\rho_k(\boldsymbol{Q},\boldsymbol{\sigma};\boldsymbol{Q}',\boldsymbol{\sigma}')$ as kernel operators $O_k$ on $L_2((\Omega\times C^2)^k)_-$. Suppose $k$ is even, then if $O_k$ has a (generalized) eigenvalue of order $N^{k/2}$ as $N\to\infty, N/V=\rho$, the system is said to exhibit *off-diagonal long-range* order of order $k$. For $k$ odd, ODLRO is defined to exist if $O_k$ has an eigenvalue of order $N^{(k-1)/2}$ and $k\ge 3$ (if $k=1$ the largest eigenvalue of $O_1$ is necessarily $\le 1$).

For bosons, consider the reduced density matrix $\rho_k(Q;Q')$ regarding it as a kernel operator $O_k$ on $L_2(\Omega)_+^k$ and define ODLRO of order $k$ to be present if $O(k)$ has a (generalized) eigenvalue of order $N^k$ as $N \to \infty, N/V = \rho$.

ODLRO can be regarded as a unification of the notions of Bose condensation and of the existence of Cooper pairs, because Bose condensation could be said to correspond to the kernel operator $\rho_1(q_1 - q_2)$ in [68] having a (generalized) eigenvalue of order $N$, and to be a case of ODLRO of order 1. If the state is pure in the sense that it has a cluster property (see the sections "Phase transitions and boundary conditions" and "Lattice models"), then the existence of ODLRO, Bose condensation, and Cooper pairs implies that the system shows a spontaneously broken symmetry: conservation of particle number and clustering imply that the off-diagonal elements of (all) reduced density matrices vanish at infinite separation in states obtained as limits of states with periodic boundary conditions and Hamiltonian [66], and this is incompatible with ODLRO.

The free Fermi gas has no ODLRO, the BCS model of superconductivity has Cooper pairs and ODLRO with $k = 2$, but no Fermi surface in the above sense (possibly too strict). Fermionic systems cannot have ODLRO of order 1 (because the reduced density matrix of order 1 is bounded by 1).

The contribution of mathematical physics has been particularly effective in providing exactly soluble models: however, the soluble models deal with one-dimensional systems and it can be shown that in dimensions 1, 2 no ODLRO can take place. A major advance is the recent proof of ODLRO and Bose condensation in the case of a lattice version of [66] at a special density value (and $d \geq 3$).

In no case, for the Hamiltonian [66] with $\varphi \neq 0$, existence of Cooper pairs has been proved nor existence of a Fermi surface for $d > 1$. Nevertheless, both Bose condensation and Cooper pairs formation can be proved to occur rigorously in certain limiting situations. There are also a variety of phenomena (e.g., simple spectral properties of the Hamiltonians) which are believed to occur once some of the above-mentioned ones do occur and several of them can be proved to exist in concrete models.

If $d = 1, 2$, ODLRO can be proved to be impossible at $T > 0$ through the use of Bogoliubov's inequality (used in the "no $d = 2$ crystal theorem," see the section "Continuous symmetries: 'no $d = 2$ crystal' theorem").

For more details, the reader is referred to Penrose and Onsager (1956), Yang (1962), Ruelle (1969), Hohenberg (1967), Gallavotti (1999), and Aizenman *et al.* (2004).

## Appendix 1: The Physical Meaning of the Stability Conditions

It is useful to see what would happen if the conditions of stability and temperedness (see [14]) are violated. The analysis also illustrates some of the typical methods of statistical mechanics.

### Coalescence Catastrophe due to Short-Distance Attraction

The simplest violation of the first condition in [14] occurs when the potential $\varphi$ is smooth and negative at the origin.

Let $\delta > 0$ be so small that the potential at distances $\leq 2\delta$ is $\leq -b < 0$. Consider the canonical distribution with parameters $\beta, N$ in a (cubic) box $\Omega$ of volume $V$. The probability $P_{\text{collapse}}$ that all the $N$ particles are located in a little sphere of radius $\delta$ around the center of the box (or around any prefixed point of the box) is estimated from below by remarking that

$$\Phi \leq -b\binom{N}{2} \sim -\frac{b}{2}N^2$$

so that

$$P_{\text{collapse}} = \frac{\int_c \frac{\mathrm{d}p\,\mathrm{d}q}{h^{3N}N!}\mathrm{e}^{-\beta(K(p)+\Phi(q))}}{\int \frac{\mathrm{d}p\,\mathrm{d}q}{h^{3N}N!}\mathrm{e}^{-\beta(K(p)+\Phi(q))}} \geq \frac{\left(\frac{4\pi\sqrt{2m\beta^{-1}}^3}{3h^3}\right)^N \frac{\delta^{3N}}{N!}\mathrm{e}^{\beta b(1/2)N(N-1)}}{\int \frac{\mathrm{d}q}{h^{3N}N!}\mathrm{e}^{-\beta\Phi(q)}} \qquad [71]$$

The phase space is extremely small: nevertheless, such configurations are far more probable than the configurations which "look macroscopically correct," that is, configurations with particles more or less spaced by the average particle distance expected in a macroscopically homogeneous configuration, namely $(N/V)^{-1/3} = \rho^{-1/3}$. Their energy $\Phi(q)$ is of the order of $uN$ for some $u$, so that their probability will be bounded above by

$$P_{\text{regular}} \leq \frac{\int \frac{\mathrm{d}p\,\mathrm{d}q}{h^{3N}N!}\mathrm{e}^{-\beta(K(p)+uN)}}{\int \frac{\mathrm{d}p\,\mathrm{d}q}{h^{3N}N!}\mathrm{e}^{-\beta(K(p)+\Phi(q))}} = \frac{\frac{V^N\sqrt{2m\beta^{-1}}^3}{h^{3N}N!}\mathrm{e}^{-\beta uN}}{\int \frac{\mathrm{d}q}{h^{3N}N!}\mathrm{e}^{-\beta\Phi(q)}} \qquad [72]$$

However, no matter how small $\delta$ is, the ratio $P_{\text{regular}}/P_{\text{collapse}}$ will approach 0 as $V \to \infty$, $N/V \to v^{-1}$; this occurs extremely rapidly because $e^{\beta b N^2/2}$ eventually dominates over $V^N \sim e^{N \log N}$.

Thus, it is far more probable to find the system in a microscopic volume of size $\delta$ rather than in a configuration in which the energy has some macroscopic value proportional to $N$. This catastrophe can be called an ultraviolet catastrophe (as it is due to the behavior at very short distances) and it causes the collapse of the particles into configurations concentrated in regions as small as we please as $V \to \infty$.

#### Coalescence Catastrophe due to Long-Range Attraction

It occurs when the potential is too attractive near $\infty$. For simplicity, suppose that the potential has a hard core, i.e., it is $+\infty$ for $r < r_0$, so that the above-discussed coalescence cannot occur and the system density bounded above by a certain quantity $\rho_{\text{cp}} < \infty$ (*close-packing density*).

The catastrophe occurs if $\varphi(\boldsymbol{q}) \sim -g|\boldsymbol{q}|^{-3+\varepsilon}$, $g, \varepsilon > 0$, for $|\boldsymbol{q}|$ large. For instance, this is the case for matter interacting gravitationally; if $k$ is the gravitational constant, $m$ is the particle mass, then $g = km^2$ and $\varepsilon = 2$.

The probability $P_{\text{regular}}$ of "regular configurations," where particles are at distances of order $\rho^{-1/3}$ from their close neighbors, is compared with the probability $P_{\text{collapse}}$ of "catastrophic configurations," with the particles at distances $r_0$ from their close neighbors to form a configuration of density $\rho_{\text{cp}}/(1+\delta)^3$ almost in close packing (so that $r_0$ is equal to the hard-core radius times $1+\delta$). In the latter case, the system does not fill the available volume and leaves empty a region whose volume is a fraction $\sim((\rho_{\text{cp}} - \rho)/\rho_{\text{cp}})V$ of $V$. Further, it can be checked that the ratio $P_{\text{regular}}/P_{\text{collapse}}$ tends to 0 at a rate $O(\exp(g\frac{1}{2}N(\rho_{\text{cp}}(1+\delta)^{-3} - \rho)))$ if $\delta$ is small enough (and $\rho < \rho_{\text{cp}}$).

A system which is too attractive at infinity will not occupy the available volume but will stay confined in a close-packed configuration even in empty space.

This is important in the theory of stars: stars cannot be expected to obey "regular thermodynamics" and in particular will not "evaporate" because their particles interact via the gravitational force at large distances. Stars do not occupy the whole volume given to them (i.e., the universe); they do not collapse to a point only because the interaction has a strongly repulsive core (even when they are burnt out and the radiation pressure is no longer able to keep them at a reasonable size).

#### Evaporation Catastrophe

This is another *infrared catastrophe*, that is, a catastrophe due to the long-range structure of the interactions in the above subsection; it occurs when the potential is too repulsive at $\infty$, that is,

$$\varphi(\boldsymbol{q}) \sim +g|\boldsymbol{q}|^{-3+\varepsilon} \quad \text{as} \quad \boldsymbol{q} \to \infty$$

so that the temperedness condition is again violated.

In addition, in this case, the system does not occupy the whole volume: it will generate a layer of particles sticking, in close-packed configuration, to the walls of the container. Therefore, if the density is lower than the close-packing density, $\rho < \rho_{\text{cp}}$, the system will leave a region around the center of the container $\Omega$ empty; and the volume of the empty region will still be of the order of the total volume of the box (i.e., its diameter will be a fraction of the box side $L$). The proof is completely analogous to the one of the previous case; except that now the configuration with lowest energy will be the one sticking to the wall and close packed there, rather than the one close packed at the center.

Also this catastrophe is important as it is realized in systems of charged particles bearing the same charge: the charges adhere to the boundary in close-packing configuration, and dispose themselves so that the electrostatic potential energy is minimal. Therefore, charges deposited on a metal will not occupy the whole volume: they will rather form a surface layer minimizing the potential energy (i.e., so that the Coulomb potential in the interior is constant). In general, charges in excess of neutrality do not behave thermodynamically: for instance, besides not occupying the whole volume given to them, they will not contribute normally to the specific heat.

Neutral systems of charges behave thermodynamically if they have hard cores, so that the ultraviolet catastrophe cannot occur or if they obey quantum-mechanical laws and consist of fermionic particles (plus possibly bosonic particles with charges of only one sign).

For more details, we refer the reader to Lieb and Lebowitz (1972) and Lieb and Thirring (2001).

## Appendix 2: The Subadditivity Method

A simple consequence of the assumptions is that the exponential in (5.2) can be bounded above by $e^{\beta BN} \exp(-\frac{\beta}{2m}\sum_{i=1}^{N} \boldsymbol{P}_i^2)$ so that

$$1 \le Z_{\text{gc}}(\beta, \lambda, V) \le \exp\left(V e^{\beta\lambda} e^{\beta B} \sqrt{2m\beta^{-1}}^{\,d}\right)$$
$$\Rightarrow 0 \le \frac{1}{V} \log Z_{\text{gc}}(\beta, \lambda, V) \le e^{\beta\lambda} e^{\beta B} \sqrt{2m\beta^{-1}}^{\,d} \quad [73]$$

Consider, for simplicity, the case of a hard-core interaction with finite range (cf. [14]). Consider a

sequence of boxes $\Omega_n$ with sides $2^n L_0$, where $L_0 > 0$ is arbitrarily fixed to be $>2R$. The partition function $Z_{gc}(\beta, z)$ relative to the volume $\Omega_n$ is

$$Z_n = \sum_{N=0}^{\infty} \frac{z^N}{N!} \int_{\Omega_n} \mathrm{d}Q \mathrm{e}^{-\beta\Phi(Q)}$$

because the integral over the $P$ variables can be explicitly performed and included in $z^N$ if $z$ is defined as $z = \mathrm{e}^{\beta\lambda}(2m\beta^{-1})^{d/2}$.

Then the box $\Omega_n$ contains $2^d$ boxes $\Omega_{n-1}$ for $n \geq 1$ and

$$1 \leq Z_n \leq Z_{n-1}^{2^d} \exp\left(\beta B 2d (L_{n-1}/R)^{d-1} 2^{2d}\right) \qquad [74]$$

because the corridor of width $2R$ around the boundaries of the $2^d$ cubes $\Omega_{n-1}$ filling $\Omega_n$ has volume $2RL_{n-1}2^d$ and contains at most $(L_{n-1}/R)^{d-1}2^d$ particles, each of which interacts with at most $2^d$ other particles. Therefore,

$$\begin{aligned}\beta p_n &\stackrel{\text{def}}{=} L_n^d \log Z_n \\ &\leq L_{n-1}^d \log Z_{n-1} + \beta B \gamma_d 2^{-n}(L_0/R)^{d-1}\end{aligned}$$

for some $\gamma_d > 0$. Hence, $0 \leq \beta p_n \leq \beta p_{n-1} + \Gamma_d 2^{-n}$ for some $\Gamma_d > 0$ and $p_n$ is bounded above and below uniformly in $n$. So, the limit [13] exists on the sequence $L_n = L_0 2^n$ and defines a function $\beta p_\infty(\beta, \lambda)$.

A box of arbitrary size $L$ can be filled with about $(L/L_{\bar{n}})^d$ boxes of side $L_{\bar{n}}$ with $\bar{n}$ so large that, prefixed $\delta > 0$, $|p_\infty - p_n| < \delta$ for all $n \geq \bar{n}$. Likewise, a box of size $L_n$ can be filled by about $(L_n/L)^d$ boxes of size $L$ if $n$ is large. The latter remarks lead us to conclude, by standard inequalities, that the limit in [13] exists and coincides with $p_\infty$.

The subadditivity method just demonstrated for finite-range potentials with hard core can be extended to the potentials satisfying just stability and temperedness (cf. the section "Thermodynamic limit").

For more details, the reader is referred to Ruelle (1969) and Gallavotti (1999).

## Appendix 3: An Infrared Inequality

The infrared inequalities stem from *Bogoliubov's inequality*. Consider as an example the problem of crystallization discussed in the section "Continuous symmetries: 'no $d=2$ crystal' theorem". Let $\langle \cdot \rangle$ denote average over a canonical equilibrium state with Hamiltonian

$$H = \sum_{j=1}^{N} \frac{p_j^2}{2} + U(Q) + \varepsilon W(Q)$$

with given temperature and density parameters $\beta, \rho, \rho = a^{-3}$. Let $\{X, Y\} = \sum_j (\partial_{p_j} X \, \partial_{q_j} Y - \partial_{q_j} X \, \partial_{p_j} Y)$ be the Poisson bracket. Integration by parts, with periodic boundary conditions, yields

$$\begin{aligned}\langle A^* \{C, H\}\rangle &\equiv -\frac{\int A^* \{C, \mathrm{e}^{-\beta H}\} \mathrm{d}P \mathrm{d}Q}{\beta Z_c(\beta, \rho, N)} \\ &\equiv -\beta^{-1} \langle \{A^*, C\}\rangle \end{aligned} \qquad [75]$$

as a general identity. The latter identity implies, for $A = \{C, H\}$, that

$$\langle \{H, C\}^* \{H, C\}\rangle = -\beta^{-1} \langle \{C, \{H, C^*\}\}\rangle \qquad [76]$$

Hence, the Schwartz inequality $\langle A^* A\rangle \langle \{H, C\}^* \{H, C\}\rangle \geq |\langle \{A^*, C\}\rangle|^2$ combined with the two relations in [75], [76] yields Bogoliubov's inequality:

$$\langle A^* A\rangle \geq \beta^{-1} \frac{|\langle \{A^*, C\}\rangle|^2}{\langle \{C, \{C^*, H\}\}\rangle} \qquad [77]$$

Let $g$, $h$ be arbitrary complex (differentiable) functions and $\partial_j = \partial_{q_j}$

$$A(Q) \stackrel{\text{def}}{=} \sum_{j=1}^{N} g(q_j), \qquad C(P, Q) \stackrel{\text{def}}{=} \sum_{j=1}^{N} p_j h(q_j) \qquad [78]$$

Then $H = \sum \frac{1}{2} p_j^2 + \Phi(q_1, \ldots, q_N)$, if

$$\Phi(q_1, \ldots, q_N) = \frac{1}{2} \sum_{j \neq j'} \varphi(|q_j - q_{j'}|) + \varepsilon \sum_j W(q_j)$$

so that, via algebra,

$$\{C, H\} \equiv \sum_j (h_j \partial_j \Phi - p_j (p_j \cdot \partial_j) h_j)$$

with $h_j \stackrel{\text{def}}{=} h(q_j)$. If $h$ is real valued, $\langle \{C, \{C^*, H\}\}\rangle$ becomes, again via algebra,

$$\left\langle \sum_{jj'} h_j h_{j'} \partial_j \cdot \partial_{j'} \Phi(Q) \right\rangle + \left\langle \varepsilon \sum_j h_j^2 \Delta W(q_j) + \frac{4}{\beta} \sum_j (\partial_j h_j)^2 \right\rangle$$

(integrals on $p_j$ just replace $p_j^2$ by $2\beta^{-1}$ and $\langle (p_j)_i (p_j)_{i'}\rangle = \beta^{-1} \delta_{i,i'}$). Therefore, the average $\langle \{C, \{C^*, H\}\}\rangle$ becomes

$$\left\langle \frac{1}{2} \sum_{jj'} (h_j - h_{j'})^2 \Delta\varphi(|q_j - q_{j'}|) + \varepsilon \sum_j h_j^2 \Delta W(q_j) + 4\beta^{-1} \sum_j (\partial_j h_j)^2 \right\rangle \qquad [79]$$

Choose $g(q) \equiv e^{-i(\kappa + K)\cdot q}$, $h(q) = \cos q \cdot \kappa$ and bound $(h_j - h_{j'})^2$ by $\kappa^2 (q_j - q_{j'})^2$, $(\partial_j h_j)^2$ by $\kappa^2$ and

$h_j^2$ by 1. Hence [79] is bounded above by $ND(\boldsymbol{\kappa})$ with

$$D(\boldsymbol{\kappa}) \stackrel{\text{def}}{=} \left\langle \boldsymbol{\kappa}^2 \left( 4\beta^{-1} + \frac{1}{2N} \sum_{j \neq j'} (\boldsymbol{q}_j - \boldsymbol{q}_{j'})^2 |\Delta\varphi(\boldsymbol{q}_j - \boldsymbol{q}_{j'})| \right) + \varepsilon \frac{1}{N} \sum_j |\Delta W(\boldsymbol{q}_j)| \right\rangle \qquad [80]$$

This can be used to estimate the denominator in [77]. For the LHS remark that

$$\langle A^*, A \rangle = |\sum_{j=1}^{N} \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot(\boldsymbol{\kappa}+\boldsymbol{K})}|^2$$

and

$$|\langle\{A^*, \mathbf{C}\}\rangle|^2 = \left|\left\langle \sum_j h_j \partial g_j \right\rangle\right|^2 = |\boldsymbol{K} + \boldsymbol{\kappa}|^2 N^2 (\rho_\varepsilon(\boldsymbol{K}) + \rho_\varepsilon(\boldsymbol{K} + 2\boldsymbol{\kappa}))^2$$

hence [77] becomes, after multiplying both sides by the auxiliary function $\gamma(\boldsymbol{\kappa})$ (assumed even and vanishing for $|\boldsymbol{\kappa}| > \pi/a$) and summing over $\boldsymbol{\kappa}$,

$$D_1 \stackrel{\text{def}}{=} \frac{1}{N} \sum_{\boldsymbol{\kappa}} \gamma(\boldsymbol{\kappa}) \left\langle \frac{1}{N} |\sum_{j=1}^{N} \mathrm{e}^{-\mathrm{i}(\boldsymbol{K}+\boldsymbol{\kappa})\cdot \boldsymbol{q}_j}|^2 \right\rangle \geq \frac{1}{N} \sum_{\boldsymbol{\kappa}} \gamma(\boldsymbol{\kappa}) \times \frac{|\boldsymbol{K}|^2}{4\beta} \frac{(\rho_\varepsilon(\boldsymbol{K}) + \rho_\varepsilon(\boldsymbol{K} + 2\boldsymbol{\kappa}))^2}{D(\boldsymbol{\kappa})} \qquad [81]$$

To apply [77] the averages in [80], [81] have to be bounded above: this is a technical point that is discussed here, as it illustrates a general method of using the results on the thermodynamic limits and their convexity properties to obtain estimates.

Note that $\langle (1/N) \sum_{\boldsymbol{k}} \gamma(\boldsymbol{k}) \mathrm{d}^d \boldsymbol{k} | \sum_{j=1}^{N} \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot \boldsymbol{q}_j}|^2 \rangle$ is identically $\widetilde{\varphi}(0) + (2/N) \langle \sum_{j<j'} \widetilde{\varphi}(\boldsymbol{q}_j - \boldsymbol{q}_{j'}) \rangle$ with $\widetilde{\varphi}(\boldsymbol{q}) \stackrel{\text{def}}{=} (1/N) \sum_{\boldsymbol{\kappa}} \gamma(\boldsymbol{\kappa}) \mathrm{e}^{\mathrm{i}\boldsymbol{\kappa}\cdot \boldsymbol{q}}$.

Let $\varphi_{\lambda,\zeta}(\boldsymbol{q}) \stackrel{\text{def}}{=} \varphi(\boldsymbol{q}) + \lambda \boldsymbol{q}^2 |\Delta\varphi(\boldsymbol{q})| + \eta \widetilde{\varphi}(\boldsymbol{q})$ and let $F_V(\lambda, \eta, \zeta) \stackrel{\text{def}}{=} (1/N) \log Z^{\mathrm{c}}(\lambda, \eta, \zeta)$ with $Z^{\mathrm{c}}$ the partition function in the volume $\Omega$ computed with energy $U' = \sum_{jj'} \varphi_{\lambda,\zeta}(\boldsymbol{q}_j - \boldsymbol{q}_{j'}) + \varepsilon \sum_j W(\boldsymbol{q}_j) + \eta\varepsilon \sum |\Delta W(\boldsymbol{q}_j)|$. Then $F_V(\lambda, \eta, \zeta)$ is convex in $\lambda, \eta$ and it is uniformly bounded above and below if $|\eta|, |\varepsilon|, |\zeta| \leq 1$ (say) and $|\lambda| \leq \lambda_0$: here $\lambda_0 > 0$ exists if $\boldsymbol{r}^2 |\Delta\varphi(\boldsymbol{r})|$ satisfies the assumption set at the beginning of the section "Continuous symmetries: 'no $d = 2$ crystal' theorem" and the density is smaller than a close packing (this is because the potential $U'$ will still satisfy conditions similar to [14] uniformly in $|\varepsilon|, |\eta| < 1$ and $|\lambda|$ small enough).

Convexity and boundedness above and below in an interval imply bounds on the derivatives in the interior points, in this case on the derivatives of $F_V$ with respect to $\lambda, \eta, \zeta$ at 0. The latter are identical to the averages in [80], [81]. In this way, the constants $B_1, B_2, B_0$ such that $D(\boldsymbol{\kappa}) \leq \boldsymbol{\kappa}^2 B_1 + \varepsilon B_2$ and $B_0 > D_1$ are found.

# Introductory Article: Functional Analysis

**S Paycha**, Université Blaise Pascal, Aubière, France

## Introduction

Functional analysis is concerned with the study of functions and function spaces, combining techniques borrowed from classical analysis with algebraic techniques. Modern functional analysis developed around the problem of solving equations with solutions given by functions. After the differential and partial differential equations, which were studied in the eighteenth century, came the integral equations and other types of functional equations investigated in the nineteenth century, at the end of which arose the need to develop a new analysis, with functions of an infinite number of variables instead of the usual functions. In 1887, Volterra, inspired by the calculus of variations, suggested a new infinitesimal calculus where usual functions are replaced by functionals, that is, by maps from a function space to $\mathbb{R}$ or $\mathbb{C}$, but he and his followers were still missing some algebraic and topological tools to be developed later. Modern analysis was born with the development of an "algebra of the infinite" closely related to classical linear algebra which by 1890 had (up to the concept of duality, which was developed later) settled on firm ground. Strongly inspired by algebraic methods, Fredholm's work at the turn of the nineteenth century, in which emerged the concept of kernel of an operator, became a founding stone for the modern theory of integral equations. Hilbert developed further Fredholm's methods for symmetric kernels, exploiting analogies with the theory of real quadratic forms and thereby making clear the importance of the notion of square-integrable functions. With Hilbert's *Grundzüge einer allgemeinen Theorie der Integralgleichung*, a further step was made from the "algebra of the infinite" to the "geometry of the infinite." The contribution of Fréchet, who introduced the abstract notion of a space endowed with a distance, made it possible to transfer Euclidean geometry to the framework of what have since then been called Hilbert spaces, a basic concept in mathematics and quantum physics.

The usefulness of functional analysis in the study of quantum systems became clear in the 1950s when Kato proved the self-adjointness of atomic Hamiltonians, and Garding and Wightman formulated axioms for quantum field theory. Ever since functional analysis lies at the very heart of many approaches to quantum field theory. Applications of functional analysis stretch out to many branches of mathematics, among which are numerical

analysis, global analysis, the theory of pseudodifferential operators, differential geometry, operator algebras, noncommutative geometry, etc.

## Topological Vector Spaces

Most topological spaces one comes across in practice are metric spaces. A metric on a topological space $E$ is a map $d: E \times E \to [0, +\infty[$ which is symmetric, such that $d(u,v) = 0 \Leftrightarrow u = v$ and which verifies the triangle inequality $d(u,w) \leq d(u,v) + d(v,w)$ for all vectors $u, v, w$. A topological space $E$ is metrizable if there is a metric $d$ on $E$ compatible with the topology on $E$, in which case the balls with radius $1/n$ centered at any point $x \in E$ form a local base at $x$ – that is, a collection of neighborhoods of $x$ such that every neighborhood of $x$ contains a member of this collection. A sequence $(u_n)$ in $E$ then converges to $u \in E$ if and only if $d(u_n, u)$ converges to 0.

The Banach fixed-point theorem on a complete metric space $(E, d)$ is a useful tool in nonlinear functional analysis: it states that *a (strict) contraction on* $E$*, that is, a map* $T: E \to E$ *such that* $d(Tu, Tv) \leq k(u,v)$ *for all* $u \neq v \in E$ *and fixed* $0 < k < 1$*, has a unique fixed point* $T u_0 = u_0$. In particular, it provides local existence and uniqueness of solutions of differential equations $\mathrm{d}y/\mathrm{d}t = F(y,t)$ with initial condition $y(0) = y_0$, where $F$ is Lipschitz continuous.

Linear functional analysis starts from topological vector spaces, that is, vector spaces equipped with a topology for which the operations are continuous. A topological vector space equipped with a local base whose members are convex is said to be locally convex. Examples of locally convex spaces are normed linear spaces, namely vector spaces equipped with a norm, a concept that first arose in the work of Fréchet. A seminorm on a vector space $V$ is a map $\rho: V \to [0, \infty[$ which obeys the triangle identity $\rho(u+v) \leq \rho(u) + \rho(v)$ for any vectors $u, v$ and such that $\rho(\lambda u) = |\lambda| \rho(u)$ for any scalar $\lambda$ and any vector $u$; if $\rho(u) = 0 \Rightarrow u = 0$, it is a norm, often denoted by $\|\cdot\|$. A norm on a vector space $E$ gives rise to a translation-invariant distance function $d(u,v) = \|u - v\|$ making it a metric space.

Historically, one of the first examples of normed spaces is the space $C([0,1])$ investigated by Riesz of (real- or complex-valued) continuous functions on the interval $[0,1]$ equipped with the supremium norm $\|f\|_\infty := \sup_{x \in [0,1]} |f(x)|$. In the 1920s, the general definition of Banach space arose in connection with the works of Hahn and Banach. A normed linear space is a Banach space if it is complete as a metric space for the induced metric, $C([0,1])$ being a prototype of a Banach space. More generally, for any non-negative integer $k$, the space $C^k([0,1])$ of functions on $[0,1]$ of class $C^k$ equipped with the norm $\|f\|_k = \sum_{i=0}^k \|f^{(i)}\|_\infty$ expressed in terms of a finite number of seminorms $\|f^{(i)}\|_\infty = \sup_{x \in [0,1]} |f^{(i)}(x)|, i = 0, \ldots, k$, is also a Banach space.

The space $C^\infty([0,1])$ of smooth functions on the interval $[0,1]$ is not anymore a Banach space since its topology is described by a countable family of seminorms $\|f\|_k$ with $k$ varying in the positive integers. The metric

$$d(f,g) = \sum_{k=1}^{\infty} 2^{-k} \frac{\|f - g\|_k}{1 + \|f - g\|_k}$$

turns it into a Fréchet space, that is, a locally convex complete metric space. The space $\mathcal{S}(\mathbb{R}^n)$ of rapidly decreasing functions, which are smooth functions $f$ on $\mathbb{R}^n$ for which

$$\|f\|_{\alpha,\beta} := \sup_{x \in \mathbb{R}^n} |x^\alpha D_x^\beta f(x)|$$

is finite for any multiindices $\alpha$ and $\beta$, is also a Fréchet space with the topology given by the seminorms $\|\cdot\|_{\alpha,\beta}$. Further examples of Fréchet spaces are the space $C_0^\infty(K)$ of smooth functions with support in a fixed compact subset $K \subset \mathbb{R}^n$ equipped with the countable family of seminorms

$$\|D^\alpha f\|_{\infty, K} = \sup_{x \in K} |D_x^\alpha f(x)|, \quad \alpha \in \mathbb{N}_0^n$$

and the space $C^\infty(M, E)$ of smooth sections of a vector bundle $E$ over a closed manifold $M$ equipped with a similar countable family of seminorms. Given an open subset $\Omega = \cup_{p \in \mathbb{N}} K_p$ with $K_p, p \in \mathbb{N}$ compact subsets of $\mathbb{R}^n$, the space $\mathcal{D}(\Omega) = \cup_{p \in \mathbb{N}} C_0^\infty(K_p)$ equipped with the inductive limit topology – for which a sequence $(f_n)$ in $\mathcal{D}(\Omega)$ converges to $f \in \mathcal{D}(\Omega)$ if each $f_n$ has support in some fixed compact subset $K$ and $(D^\alpha f_n)$ converges uniformly to $D^\alpha f$ on $K$ for each mutilindex $\alpha$ – is a locally convex space.

Among Banach spaces are Hilbert spaces which have properties very similar to those of finite-dimensional spaces and are historically the first type of infinite-dimensional space to appear with the works of Hilbert at the beginning of the twentieth century. A Hilbert space is a Banach space equipped with a norm $\|\cdot\|$ that derives from an inner product, that is, $\|u\|^2 = \langle u, u \rangle$ with $\langle \cdot, \cdot \rangle$ a positive-definite bilinear (or sesquilinear according to whether the base space is real or complex) form. Hilbert spaces are fundamental building blocks in quantum mechanics; using (closed) tensor products, from a Hilbert space $H$ one builds the Fock space $\mathcal{F}(H) = \sum_{k=0}^\infty \otimes^k H$ and from there the bosonic Fock space $\mathcal{F}(H) = \sum_{k=0}^\infty \otimes_s^k H$ (where $\otimes_s$ stands for the (closed) symmetrized tensor product) as well

as the fermionic Fock space $\mathcal{F}(H)=\sum_{k=0}^{\infty}\Lambda^k H$ (where $\Lambda^k$ stands for the antisymmetrized (closed) tensor product).

A prototype of Hilbert space is the space $l_2(\mathbb{Z})$ of complex-valued sequences $(u_n)_{n\in\mathbb{Z}}$ such that $\sum_{n\in\mathbb{Z}}|u_n|^2$ is finite, which is already implicit in Hilbert's Grundzügen. Shortly afterwords, Riesz and Fischer, with the help of the integration tool introduced by Lebesgue, showed that the space $L^2(]0,1[)$ (first introduced by Riesz) of square-summable functions on the interval $]0,1[$, that is, functions $f$ such that

$$\|f\|_{L^2}=\left(\int_0^1|f(x)|^2\,\mathrm{d}x\right)^{1/2}$$

is finite, provides an example of Hilbert space. These were then further generalized to spaces $L^p(]0,1[)$ of $p$-summable $(1\le p<\infty)$ functionals on $]0,1[$ (i.e., functions $f$ such that

$$\|f\|_{L^p}=\left(\int_0^1|f(x)|^p\,\mathrm{d}x\right)^{1/p}$$

is finite), which are not Hilbert unless $p=2$ but which provide further examples of Banach spaces, the space $L^\infty(]0,1[)$ of functions on $]0,1[$ bounded almost everywhere with respect to the Lebesgue measure, offering yet another example of Banach space.

In 1936, Sobolev gave a generalization of the notion of function and their derivatives through integration by parts, which led to the so-called Sobolev spaces $W^{k,p}(]0,1[)$ of functions $f\in L^p(]0,1[)$ with derivatives up to order $k$ lying in $L^p(]0,1[)$, obtained as the closure of $C^\infty(]0,1[)$ for the norm

$$f\mapsto\|f\|_{W^{k,p}}=\left(\sum_{j=1}^{k}\|\partial^j f\|_{L^p}^p\right)^{1/p}$$

(for $p=2, W^{k,p}(]0,1[)$ is a Hilbert space often denoted by $H^k(]0,1[)$. They differ from the Sobolev spaces $W_0^{k,p}(]0,1[)$, which correspond to the closure of the set $\mathcal{D}(]0,1[)$ for the norm $f\mapsto\|f\|_{W^{k,p}}$; for example, an element $u\in W^{1,p}(]0,1[)$ lies in $W_0^{1,p}(]0,1[)$ if and only if it vanishes at 0 and 1, that is, if and only if it satisfies Dirichlet-type boundary conditions on the boundary of the interval. Similarly, one defines Sobolev spaces $W_0^{k,p}(\mathbb{R})=W^{k,p}(\mathbb{R})$ on $\mathbb{R}$, Sobolev spaces $W^{k,p}(\Omega)$ and $W_0^{k,p}(\Omega)$ on open subsets $\Omega\subset\mathbb{R}^n$ and using a partition of unity on a closed manifold $M$, Sobolev spaces $H^k(M,E)=W^{k,2}(M,E)$ of sections of vector bundles $E$ over $M$. Using the Fourier transform (discussed later), one can drop the assumption that $k$ be an integer and extend the notion of Sobolev space to define $W^{s,p}(\Omega)$ and $H^s(M,E)$ with $s$ any real number.

Sobolev spaces arise in many areas of mathematics; one central example in probability theory is the Cameron–Martin space $H^1([0,t])$ embedded in the Wiener space $C([0,t])$. This embedding is a particular case of more general Sobolev embedding theorems, which embed (possibly continuously, sometimes even compactly (the notion of compact operator is discussed in a later section)) $W^{k,p}$-Sobolev spaces in $L^q$-spaces with $q>p$ such as the continuous inclusion $W^{k,p}(\mathbb{R}^n)\subset L^q(\mathbb{R}^n)$ with $1/q=1/p-k/n$, or in $C^l$-spaces with $l\le k$ such as, for a bounded open and regular enough subset $\Omega$ of $\mathbb{R}^n$ and for any $s\ge l+n/p$ with $p>n$, the continuous inclusion $W^{s,p}(\Omega)\subset C^l(\bar\Omega)$ (the set of functions in $C^l(\Omega)$ such that $D^\alpha u$ can be continuously extended to the closure $\bar\Omega$ for all $|\alpha|\le l$). Sobolev embeddings have important applications for the regularity of solutions of partial differential equations, when showing that weak solutions one constructs are in fact smooth. In particular, on an $n$-dimensional closed manifold $M$ for $s>l+n/2$, the Sobolev space $H^s(M,E)$ can be continuously embedded in the space $C^l(M,E)$ of sections of $E$ of class $C^l$, which in particular implies that the solutions of a hypoelliptic partial differential equation $Au=v$ with $v\in L^2(M,E)$ are smooth, as for example in the case of solutions of the Seiberg–Witten equations.

## Duality

The concept of duality (in a topological sense) was initiated at the beginning of the twentieth century by Hadamard, who was looking for continuous linear functionals on the Banach space $C(I)$ of continuous functions on a compact interval $I$ equipped with a uniform topology. It is implicit in Hilbert's theory and plays a central part in Riesz' work, who managed to express such continuous functionals as Stieltjes integrals, one of the starting points for the modern theory of integration.

The topological dual of a topological vector space $E$ is the space $E^*$ of continuous linear forms on $E$ which, when $E$ is a normed space, can be equipped with the dual norm $\|L\|_{E^*}=\sup_{u\in E,\,\|u\|\le 1}|L(u)|$.

Dual spaces often provide a receptacle for singular objects; any of the functions $f\in L^p(\mathbb{R}^n)(p\ge 1)$ and the delta-function at point $x\in\mathbb{R}^n$, $\delta_x:f\mapsto f(x)$, all lie in the space $\mathcal{S}'(\mathbb{R}^n)$ dual to $\mathcal{S}(\mathbb{R}^n)$ of tempered distributions on $\mathbb{R}^n$, which is itself contained in the space $\mathcal{D}'(\mathbb{R}^n)$ of distributions dual to $\mathcal{D}(\mathbb{R}^n)$. Furthermore, the topological dual $E^*$ of a nuclear space $E$ contains the support of a probability

measure with characteristic function (see the next section) given by a continuous positive-definite function on $E$. Among nuclear spaces are projective limits $E = \cap_{p\in\mathbb{N}} H_p$ (a sequence $(u_n) \in E$ converges to $u \in E$ whenever it converges to $u$ in each $H_p$) of countably many nested Hilbert spaces $\cdots \subset H_p \subset H_{p-1} \subset \cdots \subset H_0$ such that the embedding $H_p \subset H_{p-1}$ is a trace-class operator (see the section "Operator algebras"). If $H_p$ is the closure of $E$ for the norm $\|\cdot\|_p$, the topological dual $E'$ of $E$ for the norm $\|\cdot\|_0$ is an inductive limit $E' = \cup_{p\in\mathbb{N}_0} H_{-p}$, where $H_{-p}$ are the dual (with respect to $\|\cdot\|_0$) Hilbert spaces with norm $\|\cdot\|_{-p}$ (a sequence $(u_n) \in E'$ converges to $u \in E'$ whenever it lies in some $H_{-p}$ and converges to $u$ for the topology of $H_{-p}$) and we have

$$\begin{aligned} E &\subset \cdots \subset H_p \subset H_{p-1} \subset \cdots \subset H_0 \\ &= H_0' \subset H_{-1} \subset \cdots \subset H_{-p} \subset \cdots \subset E' \end{aligned}$$

As a result of the theory of elliptic operators on a closed manifold, the Fréchet space $C^\infty(M, E)$ of smooth sections of a vector bundle over a closed manifold $M$ is nuclear as the inductive limit of countably many Sobolev spaces $H^p(M, E)$ with $L^2$-dual given by the projective limit of countably many Sobolev spaces $H^{-p}(M, E)$.

The existence of nontrivial continuous linear forms on a normed linear space $E$ is ensured by the Hahn–Banach theorem, which asserts that *for any closed linear subspace $F$ of $E$, there is a nonvanishing continuous linear form that vanishes on $F$*. When the space is a Hilbert space $(H, \langle\cdot,\cdot\rangle_H)$, it follows from the Riesz–Fréchet theorem that any continuous linear form $L$ on $H$ is represented in a unique way by a vector $v \in H$ such that $L(u) = \langle v, u\rangle_H$ for all $u \in H$, thus relating the dual pairing on the left with the Hilbert inner product on the right and identifying the topological dual $H^*$ with $H$.

The strong topology induced by the norm $\|\cdot\|$ on a normed vector space $E$ – that is, the topology in which a sequence $(u_n)$ converges to $u$ whenever $\|u_n - u\| \to 0$ – is too refined to have compact sets when $E$ is infinite dimensional since the compactness of the unit ball in $E$ for the strong topology characterizes finite-dimensional spaces. Since compact sets are useful for existence theorems, one is inclined to weaken the topology: the weak topology on $E$ – which coincides with the strong topology when $E$ is finite dimensional and for which a sequence $(u_n)$ converges to $u$ if and only if $L(u_n) \to L(u)\ \forall L \in E^*$ – has compact unit ball if and only if $E$ is reflexive or, in other words, if $E$ can be canonically identified with its double dual $(E^*)^*$. For $1 < p < \infty$, given an open subset $\Omega \subset \mathbb{R}^n$, the topological dual of $L^p(\Omega)$ can be identified via the Riesz representation with $L^{p^*}(\Omega)$ with $p^*$ conjugate to $p$, that is, $1/p + 1/p^* = 1$ and $L^p(\Omega)$ is reflexive, whereas the topological duals of $W^{s,p}(\Omega)$ and $W_0^{s,p}(\Omega)$ both coincide with $W_0^{-s,p^*}(\Omega)$ so that only $W_0^{s,p}(\Omega)$ is reflexive. Neither $L^1(\Omega)$ nor its topological dual $L^\infty(\Omega)$ is reflexive since $L^1(\Omega)$ is strictly contained in the topological dual of $L^\infty(\Omega)$ for there are continuous linear forms $L$ on $L^\infty(\Omega)$ that are not of the form

$$L(u) = \int_\Omega uv\ \forall u \in L^\infty(\Omega) \quad \text{with } v \in L^1(\Omega)$$

Similarly, the topological dual $E^*$ of a normed linear space $E$ can be equipped with the topology induced by the dual norm $\|\cdot\|_{E^*}$ and the the weak $*$-topology, namely the weakest one for which the maps $L \mapsto L(u), u \in E$, are continuous, and the unit ball in $E^*$ is indeed compact for this topology (Banach–Alaoglu theorem).

Duality does not always preserve separability – a topological vector space is separable if it has a countable dense subspace – since $L^\infty(\Omega)$, which is not separable, is the topological dual of $L^1(\Omega)$, which is separable. However, as a consequence of the Hahn–Banach theorem, if the topological dual of a Banach space is separable then so is the original space and one has equivalence when adding the reflexivity assumption; a Banach space is reflexive and separable whenever its topological dual is. For $1 \le p < \infty, L^p(\Omega)$ and $W_0^{s,p}(\Omega)$ are separable and moreover reflexive if $p \neq 1$.

## Fourier Transform

In the middle of the eighteenth century, oscillations of a vibrating string were interpreted by Bernouilli as a limit case for the oscillation of $n$-point masses when $n$ tends the infinity, and Bernouilli introduced the novel idea of the superposition principle by which the general oscillation of the string should decompose in a superposition of "proper oscillations." This point of view triggered off a discussion as to whether or not an arbitrary function can be expanded as a trigonometric series. Other examples of expansions in "orthogonal functions" (this terminology actually only appears with Hilbert) had been found in the mean time in relation to oscillation problems and investigations on heat theory, but it was only in the nineteenth century, with the works of Fourier and Dirichlet, that the superposition problem was solved.

Separable Hilbert spaces can be equipped with a countable orthonormal system $\{e_n\}_{n\in\mathbb{Z}}$ ($\langle e_n, e_m\rangle_H = \delta_{mn}$ with $\langle\cdot,\cdot\rangle_H$ the scalar product on $H$) which is

complete, that is, any vector $u \in H$ can be expanded in this system in a unique way $u = \sum_{n\in\mathbb{Z}} \hat{u}_n e_n$ with Fourier coefficients $\hat{u}_n = \langle u, e_n\rangle$. The latter obey Parseval's relation $\sum_{n\in\mathbb{Z}} |\hat{u}_n|^2 = \|u\|^2$ (where $\|\cdot\|$ is the norm associated with $\langle\cdot,\cdot\rangle$), and the Fourier transform $u \mapsto (\hat{u}(n))_{n\in\mathbb{Z}}$ gives rise to an isometric isomorphism between the separable Hilbert space $H$ and the Hilbert space $l^2(\mathbb{Z})$ of square-summable sequences of complex numbers. In particular, the space $L^2(S^1)$ of $L^2$-functions on the unit circle $S^1 = \mathbb{R}/\mathbb{Z}$ with its usual Haar measure $\mathrm{d}t$ is separable with complete orthonormal system $t \mapsto e_n(t) = \mathrm{e}^{2\mathrm{i}\pi nt}, n \in \mathbb{Z}$ and the Fourier transform

$$u \mapsto \left( t \mapsto \hat{u}(n) = \int_0^1 \mathrm{e}^{-2\mathrm{i}\pi nt} u(t)\,\mathrm{d}t \right)_{n\in\mathbb{Z}}$$

identifies it with the space $l^2(\mathbb{Z})$. Under this identification, the Hilbert subspace $l^2(\mathbb{N})$ obtained as the range in $l^2(\mathbb{Z})$ of the projection $p_+ : (u)_{n\in\mathbb{Z}} \mapsto (u_n)_{n\in\mathbb{N}}$ corresponds to the Hardy space $\mathcal{H}^2(S^1)$.

The Fourier transform extends to the space $\mathcal{S}(\mathbb{R}^n)$, sending a function $f \in \mathcal{S}(\mathbb{R}^n)$ to the map

$$\xi \mapsto \hat{f}(\xi) = \frac{1}{\sqrt{(2\pi)^n}} \int_{\mathbb{R}^n} \mathrm{e}^{-\mathrm{i}\xi\cdot x} f(x)\,\mathrm{d}x$$

and maps $\mathcal{S}(\mathbb{R}^n)$ onto itself linearly and continuously with continuous inverse $f \mapsto \hat{f}(-\xi)$. When $n = 1$, the Poisson formula relates $f \in \mathcal{S}(\mathbb{R})$ with its Fourier transform $\hat{f}$ by $\sum_{n=-\infty}^{\infty} f(2\pi n) = \sum_{n=-\infty}^{\infty} \hat{f}(n)$.

Since Fourier transformation turns (up to a constant multiplicative factor) differentiation $D_\xi^\alpha$ for a multiindex $\alpha = (\alpha_1, \ldots, \alpha_n)$ into multiplication by $\xi^\alpha = \xi_1^{\alpha_1} \cdots \xi_n^{\alpha_n}$, it can be used to define $W^{s,p}$-Sobolev spaces with $s$ a real number as the space of $L^p$-functions with finite Sobolev norms $\|u\|_{W^{s,p}} = (\int |(1+|\xi|)^s \hat{u}(\xi)|^p)^{1/p}$ (which coincide with the ones defined previously when $s = k$ is a non-negative integer).

Fourier transforms are also used to describe a linear pseudodifferential operator $A$ (see next two sections where the notions of bounded and unbounded linear operator are discussed) of order $a$ acting on smooth functions on an open subset $U$ of $\mathbb{R}^n$ in terms of its symbol $\sigma_A$ – a smooth map $\sigma$ on $U \times \mathbb{R}^n$ with compact support in $x$ such that for any multi-indices $\alpha, \beta \in \mathbb{N}_0^n$, there is a constant $C_{\alpha,\beta}$ with

$$|D_x^\alpha D_\xi^\beta \sigma(x,\xi) \le C_{\alpha,\beta}(1+|\xi|)^{a-|\beta|}$$

for any $\xi \in \mathbb{R}^n$ – by

$$(Af)(x) = \frac{1}{\sqrt{(2\pi)^n}} \int_{\mathbb{R}^n} \mathrm{e}^{-\mathrm{i}x\cdot\xi} \sigma_A(x,\xi) \hat{f}(\xi)\,\mathrm{d}\xi$$

Fourier transform maps a Gaussian function $x \mapsto \mathrm{e}^{-(1/2)\lambda|x|^2}$ on $\mathbb{R}^n$, where $\lambda$ is a nonzero scalar, to another Gaussian function $\xi \mapsto \mathrm{e}^{-(1/2)\lambda^{-1}|\xi|^2}$ (up to a nonzero multiplicative factor), a starting point for $T$-duality in string theory. More generally, the characteristic function

$$\hat{\mu}(\xi) := \int_H \mathrm{e}^{\mathrm{i}\langle x,\xi\rangle_H} \mu(\mathrm{d}x)$$

of a Gaussian probability measure $\mu$ with covariance $C$ on a Hilbert space $H$ is the function $\xi \mapsto \mathrm{e}^{-(1/2)\langle \xi, C\xi\rangle_H}$. Such probability measures typically arise in Euclidean quantum field theory; in axiomatic quantum field theory, the analyticity properties of $n$-point functions can be derived from the Wightman axioms using Fourier transforms. Thus, Fourier transformation underlies many different aspects of quantum field theory.

## Fredholm operators

A complex-valued continuous function $K$ on $[0,1] \times [0,1]$ gives rise to an integral operator

$$A : f \to \int_0^1 K(x,y) f(y)\,\mathrm{d}y$$

on complex-valued continuous functions on $[0,1]$ (equipped with the supremum norm $\|\cdot\|_\infty$) with the following upper bound property:

$$\|Af\|_\infty \le \mathrm{Sup}_{[0,1]\times[0,1]} |K(x,y)|\, \|f\|_\infty$$

In other words, $A$ is a bounded linear operator with norm bounded from above by $\sup_{[0,1]\times[0,1]} |K(x,y)|$; a linear operator $A : E \to F$ from a normed linear space $(E, \|\cdot\|_E)$ to a normed linear space $(F, \|\cdot\|_F)$ is bounded (or continuous) if and only if its (operator) norm $|||A||| := \sup_{\|u\|_E \le 1} \|Au\|_F$ is bounded.

An integral operator

$$A : f \to \int_0^1 K(x,y) f(y)\,\mathrm{d}y$$

defined by a continuous kernel $K$ is, moreover, compact; a compact operator is a bounded operator of normed spaces that maps bounded sets to a precompact sets, that is, to sets whose closure is compact. Other examples of compact operators on normed spaces are finite-rank operators, operators with finite-dimensional range. In fact, any compact operator on a separable Hilbert space can be approximated in the topology induced by the operator norm $|||\cdot|||$ by a sequence of finite-rank operators.

Inspired by the work of Volterra, who, in the case of the integral operator defined above, produced

continuous solutions $\phi = (I - A)^{-1} f$ of the equation $f = (I - A)\phi$ for $f \in C([0,1])$, Fredholm in 1900 (*Sur une classe d'*équations *fonctionnelles*) studied the equation $f = (I - \lambda A)\phi$, introducing a complex parameter $\lambda$. He proved what is since then called the Fredholm alternative, which states that either the equation $f = (I - \lambda A)\phi$ has a unique solution for every $f \in C([0,1])$ or the corresponding homogeneous equation $(I - \lambda A)\phi = 0$ has nontrivial solutions. In modern language, it means that the resolvent $R(A,\mu) = (A - \mu I)^{-1}$ of a compact linear operator $A$ is surjective if and only if it is injective. The Fredholm alternative is a powerful tool to solve partial differential equations among which the Dirichlet problem, the solutions of which are harmonic functions $u$ (i.e., $\Delta u = 0$, where $\Delta = -\sum_{i=1}^{n} \partial^2 u/\partial x_i^2$) on some domain $\Omega \in \mathbb{R}^n$ with Dirichlet boundary conditions $u_{|\partial\Omega} = f$, where $f$ is a continuous function on the boundary $\partial\Omega$. The Dirichlet problem has geometric applications, in particular to the nonlinear Plateau problem, which minimizes the area of a surface in $\mathbb{R}^d$ with given boundary curves and which reduces to a (linear) Dirichlet problem.

The operator $B = I - A$ built from the compact operator $A$ is a particular Fredholm operator, namely a bounded linear operator $B : E \to F$ which is invertible "up to compact operators," that is, such that there is a bounded linear operator $C : F \to E$ with both $BC - I_F$ and $CB - I_E$ compact. A Fredholm operator $B$ has a finite-dimensional kernel Ker $B$ and when $(E, \langle\cdot,\cdot\rangle_E)$ and $(F, \langle\cdot,\cdot\rangle_F)$ are Hilbert spaces its cokernel Ker $B^*$, where $B^*$ is the adjoint of $B$ defined by

$$\langle B u, v\rangle_F = \langle u, B^* v\rangle_E \quad \forall u \in E,\ \forall v \in F$$

is also finite dimensional, so that it has a well-defined index $\mathrm{ind}(B) = \dim(\mathrm{Ker}\, B) - \dim(\mathrm{Ker}\, B^*)$, a starting point for index theory. Töplitz operators $T_\phi$, where $\phi$ is a continuous function on the unit circle $S^1$, provide first examples of Fredholm operators; they act on the Hardy space $\mathcal{H}^2(S^1)$ by

$$T_{e_{-n}}\left(\sum_{m\geq 0} a_m e_m\right) = \sum_{m \geq 0} a_{m+n} e_m$$

under the identification $\mathcal{H}^2(S^1) \simeq l^2(\mathbb{N}) \subset l^2(\mathbb{Z})$, with $l^2(\mathbb{Z})$ equipped with the canonical complete orthonormal basis $(e_n, n \in \mathbb{Z})$. The Fredholm index $\mathrm{ind}(T_{e_{-n}})$ is exactly the integer $n$ so that the index of its adjoint is $-n$, as a consequence of which the index map from Fredholm operators to integers is onto.

## One-Parameter (Semi) groups

Unlike in the finite-dimensional situation, a linear operator $A : E \to F$ between two normed linear spaces $(E, \|\cdot\|_E)$ and $(F, \|\cdot\|_F)$ is not expected to be bounded. Unbounded operators arise in partial differential equations that involve differential operators such as the Laplacian $\Delta$ on an open subset $\Omega \subset \mathbb{R}^n$. The following equations provide fundamental examples of partial differential equations which arose over time from the study of various problems in mathematical physics with the works of Poisson, Fourier, and Cauchy:

$$\begin{aligned} \Delta u &= 0 \quad \text{Laplace equation} \\ \frac{\partial^2 t}{\partial t^2} + \Delta u &= 0 \quad \text{wave equation} \\ \frac{\partial u}{\partial t} + \Delta u &= 0 \quad \text{heat equation} \end{aligned}$$

and later the Schrödinger equation in quantum mechanics:

$$\mathrm{i}\frac{\partial u}{\partial t} = \Delta u$$

where $t$ is a time parameter.

An unbounded linear operator on an infinite-dimensional normed space is usually defined on a domain $D(A)$ which is strictly contained in $E$. The Laplacian $\Delta$ is defined on the dense domain $D(A) = H^2(\mathbb{R}^n)$ in $L^2(\mathbb{R}^n)$; it defines a bounded operator from $H^2(\mathbb{R}^n)$ to $L^2(\mathbb{R}^n)$ but does not extend to a bounded operator on $L^2(\mathbb{R}^n)$. Like this operator, most unbounded operators $A : E \to F$ one comes across have dense domain $D(A)$ in $E$ and are closed, that is, their graph $\{(u, Au), u \in D(A)\}$ is closed as a subset of the normed linear space $E \times F$. When not actually closed, they can be closable, that is, they can have a closed extension called the closure of the operator. By the closed-graph theorem, when $E$ and $F$ are Banach spaces, a linear operator $A : E \to F$ is continuous whenever its graph is closed, as a consequence of which a closed linear operator $A : E \to F$ defined on a dense domain is bounded provided its domain coincides with the whole space.

For a closed operator $A : E \to F$ with dense domain $D(A)$, when $E$ and $F$ are Hilbert spaces equipped with inner products $\langle\cdot,\cdot\rangle_E$ and $\langle\cdot,\cdot\rangle_F$, the adjoint $A^*$ of $A$ is defined on its domain $D(A^*)$ by

$$\langle Au, v\rangle_F = \langle u, A^* v\rangle_E \quad \forall (u,v) \in D(A) \times D(A^*)$$

A self-adjoint operator $A$ with domain $D(A)$ is one for which $D(A) = D(A^*)$ and $A = A^*$; the Laplacian $\Delta$ on $\mathbb{R}^n$ is self-adjoint on the Sobolev space $H^2(\mathbb{R}^n)$ but it is only essentially self-adjoint on the dense domain $\mathcal{D}(\mathbb{R}^n)$, the latter meaning that its closure is self-adjoint.

Unbounded self-adjoint operators can arise as generators of one-parameter semigroups of bounded

operators. A one-parameter family of bounded operators $T_t, t \geq 0$ ($T_t, t \in \mathbb{R}$) on a Hilbert space $H$ is a semigroup (resp. group) if $T_s T_t = T_{t+s}$ $\forall t, s \geq 0$ (resp. $\forall t, s \in \mathbb{R}$) and it is strongly continuous (or simply continuous) if $\lim_{t \to t_0} T_t u = T_{t_0} u$ at any $t_0 \geq 0$ (resp. $t_0 \in \mathbb{R}$) and for any $u \in H$.

Stones' theorem sets up a one-to-one correspondence between continuous one-parameter unitary ($U_t^* U_t = U_t U_t^* = I$) groups $U_t, t \in \mathbb{R}$ on a Hilbert space such that $U_0 = \mathrm{Id}$ and self-adjoint operators $A$ obtained as infinitesimal generators, that is, as the strong limit

$$Au = \lim_{t \to 0} \frac{U_t u - u}{t}, \quad u \in H$$

of $U_t, t \in \mathbb{R}$, which in a compact form reads $U_t = \mathrm{e}^{\mathrm{i}tA}$. An important example in quantum mechanics is $U_t = \mathrm{e}^{\mathrm{i}tH} U_0, t \in \mathbb{R}$ with $H$ a self-adjoint Hamiltonian, which solves the Schrödinger equation $\mathrm{d}/\mathrm{d}tu = \mathrm{i}Hu$. The Lie–Trotter formula, which has important applications for Feynman path integrals, expresses the unitary semigroup generated by $A + B$, where $A$, $B$, and $A + B$ are self-adjoint on their respective domains as a strong limit

$$\mathrm{e}^{\mathrm{i}t(A+B)} = \lim_{t \to \infty} \left( \mathrm{e}^{\frac{\mathrm{i}tA}{n}} \mathrm{e}^{\frac{\mathrm{i}tB}{n}} \right)^n$$

On the other hand, positive operators on a Hilbert space $(H, \langle \cdot, \cdot \rangle_H)$ – that is, $A$ self-adjoint and such that $\langle Au, u \rangle_H \geq 0 \quad \forall u \in D(A)$ – generate one-parameter semigroups $T_t = \mathrm{e}^{-tA}, t \geq 0$. Hille and Yosida proved that on a Hilbert space, strongly continuous contraction (i.e., $|||T_t||| \leq 1 \quad \forall t > 0$) semigroups such that $T_0 = \mathrm{Id}$ are in one-to-one correspondence with densely defined positive operators $A : D(A) \subset H \to H$ that are maximal (i.e., $I + A$ is onto), obtained as (minus the) infinitesimal generators

$$-Au = \lim_{t \to 0} \frac{T_t u - u}{t}, \quad u \in H$$

of the corresponding semigroups. Similarly, a positive densely defined self-adjoint operator $A$ on a Hilbert space $H$ gives rise to a densely defined closed symmetric sesquilinear form $(u, v) \mapsto \langle \sqrt{A} u, \sqrt{A} v \rangle_H$ (see next section for a definition of $\sqrt{A}$; $\langle \cdot, \cdot \rangle_H$ is the scalar product on $H$) and this map yields a one-to-one correspondence between operators and sesquilinear forms on $H$ with the aforementioned properties, one of the starting points for the theory of Dirichlet forms. To a probability measure $\mu$ on a separable Banach space $E$, one can associate a densely defined closed symmetric sesquilinear form (it is in fact a Dirichlet form) on a Hilbert space $H$ such that $E^* \subset H^* = H \subset E$, which in the particular case of the standard Wiener measure $\mu$ on the Wiener space $E = C([0, t])$ and with Hilbert space given by the Cameron–Martin space $H = H^1([0, t])$, is the bilinear form

$$(u, v) \mapsto \int \langle \bar{\nabla} u, \bar{\nabla} v \rangle_H$$

with $\bar{\nabla}$ the (closed) gradient of Malliavin calculus.

The operator $-\Delta$, where $\Delta$ is the Laplacian on $\mathbb{R}^n$, generates the heat-operator semigroup $\mathrm{e}^{-\Delta t}, t \geq 0$. It has a smooth kernel $K_t \in C^\infty(\mathbb{R}^n \times \mathbb{R}^n)$ defined by

$$(\mathrm{e}^{-\Delta t} f)(x) = \int_{\mathbb{R}^n} K_t(x, y) f(y) \mathrm{d}y \quad \forall f \in C_0^\infty(\mathbb{R}^n)$$

and defines a smoothing operator, an operator that maps Sobolev function to smooth function. In general, a pseudodifferential operators $A$ on an open subset $U$ of $\mathbb{R}^n$ with symbol $\sigma_A$ only has a distribution kernel

$$K_A(x, y) = \int_{\mathbb{R}^n} \mathrm{e}^{\mathrm{i}\langle x - y, \xi \rangle} \sigma(\xi) \mathrm{d}\xi$$

The kernel of the inverse Laplacian $(\Delta + m^2)^{-1}$ on $\mathbb{R}^n$ (the non-negative real number $m^2$ stands for the mass) called Green's function on $\mathbb{R}^n$, plays an essential role in the theory of Feynman graphs.

## Spectral Theory

Spectral theory is the study of the distribution of the values of the complex parameter $\lambda$ for which, given a linear operator $A$ on a normed space $E$, the operator $A - \lambda I$ has an inverse and of the properties of this inverse when it exists, the resolvent $R(A, \lambda) = (A - \lambda I)^{-1}$ of $A$. The resolvent $\rho(A)$ of $A$ is the set of complex numbers $\lambda$ for which $A - \lambda I$ is invertible with densely defined bounded inverse. The spectrum $\mathrm{Sp}(A)$ of $A$ is the complement in $\mathbb{C}$ of the resolvent; it consists of a union of three disjoint sets: the set of all complex numbers $\lambda$ for which $A - \lambda I$ is not injective, called the point spectrum – such a $\lambda$ is an eigenvalue of $A$ with associated eigenfunction any $u \in D(A)$ such that $Au = \lambda u$; the set of points $\lambda$ for which $A - \lambda I$ has a densely defined unbounded inverse $R(A, \lambda)$ called the continuous spectrum; and the set of points $\lambda$ for which $A - \lambda I$ has a well-defined unbounded but not densely defined inverse $R(A, \lambda)$ called the residual spectrum.

A bounded operator has bounded spectrum and a self-adjoint operator $A$ acting on a Hilbert space has real spectrum and no residual spectrum since the range of $A - \lambda I$ is dense. As a consequence of the

Fredholm alternative, the spectrum of a compact operator consists only of point spectrum; it is countable with accumulation point at 0. A Hamiltonian of a quantum mechanichal system can have both point and continuous spectra, but its point spectrum is of special interest because the corresponding eigenfunctions are stationary states of the system. As was first pointed out by Kac ("Can you hear the shape of a drum?"), the spectrum of an operator acting on functions can reflect the geometry of the space these functions are defined on, a starting point for many interesting and far-reaching questions in differential geometry.

A self-adjoint linear operator on a Hilbert space can be described in terms of a family of projections $E_\lambda$, $\lambda \in \mathbb{R}$ via the spectral representation

$$A = \int_{\mathrm{Sp}(A)} \lambda \mathrm{d}E_\lambda$$

Given a Borel real-valued function $f$ on $\mathbb{R}$, the operator

$$f(A) = \int_{\mathrm{Sp}(A)} f(\lambda) \mathrm{d}E_\lambda$$

yields another self-adjoint operator. A positive operator $A$ on a dense domain $D(A)$ of some Hilbert space $(H, \langle \cdot, \cdot \rangle_H)$ has non-negative spectrum and for any positive real number $t$, the map $\lambda \mapsto \mathrm{e}^{-t\lambda}$ gives the associated bounded heat-operator

$$\mathrm{e}^{-tA} = \int_{\mathrm{Sp}(A)} \mathrm{e}^{-t\lambda} \mathrm{d}E_\lambda$$

while the map $\lambda \mapsto \sqrt{\lambda}$ gives rise to a positive operator $\sqrt{A}$ such that $\sqrt{A}^2 = A$.

The resolvent can also be used to define new operators

$$f(A) = \frac{1}{2\mathrm{i}\pi} \int_C f(\lambda) R(A, \lambda) \mathrm{d}\lambda$$

from a linear operator via a Cauchy-type integral along a countour $C$ around the spectrum; this way one defines complex powers $A^{-z}$ of (essentially self-adjoint) positive elliptic pseudodiffferential operators which enter the definition of the zeta-function, $z \mapsto \zeta(A, z)$, of the operator $A$. The $\zeta$-function is a useful tool to extend the ordinary determinant to $\zeta$-determinants of self-adjoint elliptic operators, thereby providing an ansatz to give a meaning to partition functions in the path integral approach to quantum field theory.

## Operator Algebras

Bounded linear operators on a Hilbert space $H$ form an algebra $\mathcal{L}(H)$ closed for the operator norm with involution given by the adjoint operation $A \mapsto A^*$; it is a $C^*$-algebra, that is, an algebra over $\mathbb{C}$ with a norm $\|\cdot\|$ and an involution $*$ such that $A$ is closed for this norm and such that $\|ab\| \leq \|a\|\|b\|$ and $\|a^* a\| = \|a\|^2$ for all $a, b \in A$ and by the Gelfand–Naimark theorem, every $C^*$-algebra is isomorphic to a sub-$C^*$-algebra of some $\mathcal{L}(H)$. The notion of spectrum extends from bounded operators to $C^*$-algebras; the spectrum $\mathrm{sp}(a)$ of an element $a$ in a $C^*$-algebra $A$ is a (compact) set of complex numbers such that $a - \lambda \cdot 1$ is not invertible. The notion of self-adjointness also extends $(a = a^*)$, and just as a self-adjoint operator $B \in \mathcal{L}(H)$ is non-negative (in which case its spectrum lies in $\mathbb{R}^+$) if and only if $B = A^* A$ for some bounded operator $A$, an element $b \in A$ is said to be non-negative if and only if $b = a^* a$ for some $a \in A$, in which case $\mathrm{sp}(a) \subset \mathbb{R}_0^+$.

The algebra $C(X)$ of continuous functions $f : X \to \mathbb{C}$ vanishing at infinity on some locally compact Hausdorff space $X$ equipped with the supremum norm and the conjugation $f \mapsto \bar{f}$ is also a $C^*$-algebra and a prototype for abelian $C^*$-algebras, since Gelfand showed that every abelian $C^*$-algebra is isometrically isomorphic to $C(X)$, with $X$ compact if the algebra is unital. To a $C^*$-algebra $A$, one can associate an abelian group $K_0(A)$ which is dual to the Grothendieck group $K^0(X)$ of isomorphism classes of vector bundles over a compact Hausdorff space $X$.

Compact operators on a Hilbert space $H$ form the only proper two-sided ideal $\mathcal{K}(H)$ of the $C^*$-algebra $\mathcal{L}(H)$ which is closed for the operator norm topology on $\mathcal{L}(H)$. The quotient $\mathcal{L}(H)/\mathcal{K}(H)$ is called the Calkin space, after Calkin, who classified all two-sided ideals in $\mathcal{L}(H)$ for a separable Hilbert space $H$; one can set up a one-to-one correspondence between such ideals and certain sequence spaces. Corresponding to the Banach space $l^1(\mathbb{Z})$ of complex-valued sequences $(u_n)$ such that $\sum_{n \in \mathbb{N}} |u_n| < \infty$, is the $*$-ideal $\mathcal{I}_1(H)$ of trace-class operators. The trace $\mathrm{tr}(A) = \sum_{n \in \mathbb{Z}} \langle A\, e_n, e_n \rangle_H$ of a negative operator $A \in \mathcal{L}(H)$ lies in $[0, +\infty]$ and is independent of the choice of the complete orthonormal basis $\{e_n, n \in \mathbb{Z}\}$ of $H$ equipped with the inner product $\langle \cdot, \cdot \rangle_H$. $\mathcal{I}_1(H)$ is the Banach space of bounded linear operators on $H$ such that $\|A\|_1 = \mathrm{tr}(|A|)$ is bounded. Given an (esssentially self-adjoint) positive differential operator $D$ of order $d$ acting on smooth functions on a closed $n$-dimensional Riemannian manifold $M$, its complex power $D^{-z}$ is a trace class on the space of $L^2$-functions on $M$ provided $\mathrm{Re}(z) > n/d$ and the corresponding trace $\mathrm{tr}(D^{-z})$ extends to a meromorphic function on the whole plane, the $\zeta$-function $\zeta(D, z)$ which is holomorphic at 0.

More generally, Banach spaces $l^p(\mathbb{Z})$, $1 \leq p < \infty$, of complex-valued sequences $(u_n)_{n\in\mathbb{Z}}$ such that $\sum_{n\in\mathbb{Z}} |u_n|^p < \infty$ relate to Schatten ideals $\mathcal{I}_p(H)$, $1 \leq p < \infty$, where $\mathcal{I}_p(H)$ is the Banach space of bounded linear operators on $H$ such that $\|A\|_p = (\mathrm{tr}(|A|^p))^{1/p}$ is bounded. Just as all $l^p$-sequences converge to 0, the Schatten ideals $\mathcal{I}_p(H)$ all lie in $\mathcal{K}(H)$ and we have $\cdots \subset \mathcal{I}_{p+1}(H) \subset \mathcal{I}_p(H) \subset \cdots \subset \mathcal{K}(H)$.

Compact operators and Schatten ideals are useful to extend index theory to a noncommutative context; a Fredholm module $(H, F)$ over an involutive algebra $A$ is given by an involutive representation $\pi$ of $A$ in a Hilbert space $H$ and a self-adjoint bounded linear operator $F$ on $H$ such that $F^2 = \mathrm{Id}_H$ and the operator brackets $[F, \pi(a)]$ are compact for all $a \in A$. To a $p$-summable Fredholm module $(H, F)$, that is, $[F, \pi(a)] \in \mathcal{I}_p(H)$ for all $a \in A$, one associates a representative $\tau$ of the Chern character $\mathrm{ch}^*(H, F)$ given by a cyclic cocycle on $A$, which pairs up with $K$-theory to build an integer-valued index map $\tau$ on $K$-theory.

Schatten ideals are also useful to investigate the geometry of infinite-dimensional spaces such as loop groups, for which the Hilbert–Schmidt operators (operators in $\mathcal{I}_2(H)$ are also called Hilbert–Schmidt operators) are particularly useful. A Hölder-type inequality shows that the product of two Hilbert–Schmidt operators is trace-class. Moreover, for any two Hilbert–Schmidt operators $A$ and $B$, the "cyclicity property" that $\mathrm{tr}(AB) = \mathrm{tr}(BA)$ holds, and the sesquilinear form $(A, B) \mapsto \mathrm{tr}(AB^*)$ makes $\mathcal{L}_2(H)$ a Hilbert space.

# Introductory Article: Minkowski Spacetime and Special Relativity

**G L Naber**, Drexel University, Philadelphia, PA, USA

## Introduction

Minkowski spacetime is generally regarded as the appropriate mathematical context within which to formulate those laws of physics that do not refer specifically to gravitational phenomena. Here we shall describe this context in rigorous terms, postulate what experience has shown to be its correct physical interpretation, and illustrate by means of examples its appropriateness for the formulation of physical laws.

## Minkowski Spacetime and the Lorentz Group

Minkowski spacetime $\mathcal{M}$ is a four-dimensional real vector space on which is defined a bilinear form $\boldsymbol{g} : \mathcal{M} \times \mathcal{M} \to \mathbb{R}$ that is symmetric ($\boldsymbol{g}(v, w) = \boldsymbol{g}(w, v)$ for all $v, w \in \mathcal{M}$) and nondegenerate ($\boldsymbol{g}(v, w) = 0$ for all $w \in \mathcal{M}$ implies $v = 0$). Further, $\boldsymbol{g}$ has index 1, that is, there exists a basis $\{e_1, e_2, e_3, e_4\}$ for $\mathcal{M}$ with

$$\boldsymbol{g}(e_a, e_b) = \eta_{ab} = \begin{cases} 1 & \text{if } a = b = 1, 2, 3 \\ -1 & \text{if } a = b = 4 \\ 0 & \text{if } a \neq b \end{cases}$$

$\boldsymbol{g}$ is called a Lorentz inner product for $\mathcal{M}$ and any basis of the type just described is an orthonormal basis for $\mathcal{M}$. We shall often write $v \cdot w$ for the value $\boldsymbol{g}(v, w)$ of $\boldsymbol{g}$ on $(v, w) \in \mathcal{M} \times \mathcal{M}$. A vector $v \in \mathcal{M}$ is said to be spacelike, timelike, or null if $v \cdot v$ is positive, negative, or zero, respectively, and the set $C_N$ of all null vectors is called the null cone in $\mathcal{M}$. If $\{e_1, e_2, e_3, e_4\}$ is an orthonormal basis and if we write $v = v^1 e_1 + v^2 e_2 + v^3 e_3 + v^4 e_4 = v^a e_a$ (using the Einstein summation convention, according to which a repeated index, one subscript and one superscript, is summed over its possible values) and $w = w^b e_b$, then

$$\begin{aligned} v \cdot w &= v^1 w^1 + v^2 w^2 + v^3 w^3 - v^4 w^4 \\ &= \eta_{ab} v^a w^b \end{aligned}$$

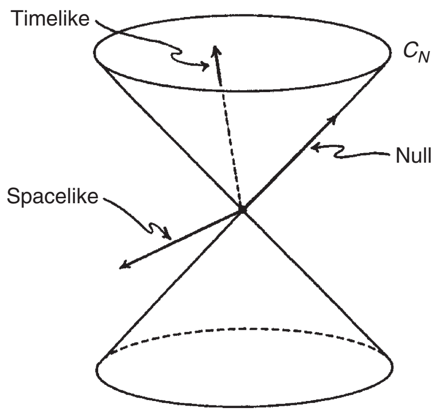

**Figure 1** Spacelike, timelike and null vectors.

In particular, $v$ is null if and only if

$$(v^4)^2 = (v^1)^2 + (v^2)^2 + (v^3)^2$$

(hence the name null "cone" for $C_N$). Timelike vectors are "inside" the null cone and spacelike vectors are "outside" (see Figure 1).

We select some orientation for the vector space $\mathcal{M}$ and will henceforth consider only oriented, orthonormal bases for $\mathcal{M}$. From the Schwartz inequality for $\mathbb{R}^3$, one can show (Naber 1992, theorem 1.3.1) that, if $v$ is timelike and $w$ is either timelike or null and nonzero, then $v \cdot w < 0$ if and only if $v^4 w^4 > 0$ in any orthonormal basis. In particular, one can define an equivalence relation on the set of all timelike vectors by decreeing that two such, $v$ and $w$, are equivalent if and only if $v \cdot w < 0$. For reasons that will emerge shortly we then say that $v$ and $w$ have the same time orientation. There are precisely two equivalence classes, one of which we select and designate future directed. Timelike vectors in the other class are then called past directed. One can show (Naber 1992, section 1.3 and corollary 1.4.5) that this classification can be extended to nonzero null vectors as well (but not to spacelike vectors). We will call an oriented, orthonormal basis time oriented if its timelike vector $e_4$ is future directed and will consider only these in what follows. An oriented, time-oriented, orthonormal basis for $\mathcal{M}$ will be called an admissible basis. If $\{e_1, e_2, e_3, e_4\}$ and $\{\hat{e}_1, \hat{e}_2, \hat{e}_3, \hat{e}_4\}$ are two such bases and if we write

$$\begin{aligned} e_b &= \Lambda^1{}_b \hat{e}_1 + \Lambda^2{}_b \hat{e}_2 + \Lambda^3{}_b \hat{e}_3 + \Lambda^4{}_b \hat{e}_4 \\ &= \Lambda^a{}_b \hat{e}_a, \quad b = 1, 2, 3, 4 \end{aligned} \qquad [1]$$

then the matrix $\Lambda = (\Lambda^a{}_b)$ ($a$ = row index, $b$ = column index) can be shown to satisfy the following three conditions (Naber 1992, section 1.3):

1. (orthogonality) $\Lambda^{\mathrm{T}} \eta \Lambda = \eta$,
   where T means transpose and

$$\eta = (\eta_{ab}) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$$

2. (orientability) $\det \Lambda = 1$, and
3. (time orientability) $\Lambda^4{}_4 \geq 1$.

We shall refer to any $4 \times 4$ matrix $\Lambda = (\Lambda^a{}_b)$ satisfying these three conditions as a Lorentz transformation (although one often sees the adjectives "proper" and "orthochronous" appended to emphasize conditions (2) and (3), respectively). The set $\mathcal{L}$ of all such matrices forms a group under matrix multiplication that we call simply the Lorentz group. It is a simple matter to show (Naber 1992, lemma 1.3.4) from the orthogonality condition (1) that, if $\Lambda^4{}_4 = 1$, then $\Lambda$ must be of the form

$$\begin{pmatrix} & & & 0 \\ & (R^i{}_j) & & 0 \\ & & & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

where $(R^i{}_j)$ is an element of SO(3), that is, a $3 \times 3$ orthogonal matrix with determinant 1. The set $\mathcal{R}$ of all matrices of this form is a subgroup of $\mathcal{L}$ called the rotation subgroup. Although it will play no role in what we do here, it should be pointed out that in many applications (e.g., in particle physics) it is necessary to consider the larger group of transformations of $\mathcal{M}$ generated by the Lorentz group and spacetime translations ($x^a \to x^a + \Lambda^a$, for some constants $\Lambda^a, a = 1, 2, 3, 4$). This is called the inhomogeneous Lorentz group, or Poincaré group.

## Physical Interpretation

For the purpose of describing how one is to think of Minkowski spacetime and the Lorentz group physically it will be convenient to distinguish (intuitively and terminologically, if not mathematically) between a "vector" in $\mathcal{M}$ and a "point" in $\mathcal{M}$ (the "tip" of a vector). The points in $\mathcal{M}$ are called events and are to be thought of as actual physical occurrences, albeit idealized as "point events" which have no spatial extension and no duration. One might picture, for example, an instantaneous collision, or explosion, or an "instant" in the history of some point material particle or photon ("particle of light").

Events are observed and identified by the assignment of coordinates. We will be interested in coordinates assigned in a very particular way by a

very particular type of observer. Specifically, our admissible observers preside over three-dimensional, right-handed, Cartesian spatial coordinate systems, relative to which photons always move along straight lines in any direction. With a single clock located at the origin, such an observer can determine the speed, $c$, of light *in vacuo* by the so-called Fizeau procedure (emit a photon from the origin when the clock there reads $t_1$, bounce it back from a mirror located at $(x^1, x^2, x^3)$, receive the photon at the origin again when the clock there reads $t_2$ and set $c = 2\sqrt{(x^1)^2 + (x^2)^2 + (x^3)^2/(t_2 - t_1)})$. Now place an identical clock at each spatial point and synchronize them by emitting from the origin a spherical electromagnetic wave (photons in all directions) and setting the clock whose location is $(x^1, x^2, x^3)$ to read $\sqrt{(x^1)^2 + (x^2)^2 + (x^3)^2}/c$ at the instant the wave arrives. An observer now assigns to an event the three spatial coordinates of the location at which it occurred in his coordinate system as well as the time reading on the clock at that location at the instant the event occurred. We shall assume also that our admissible observers are inertial in the sense of Newtonian mechanics (the trajectory of a particle on which no forces act, when described in terms of the coordinates just introduced, is a point or a straight line traversed at constant speed). It is an experimental fact (and quite a remarkable one) that all of these admissible observers (whether or not they are in relative motion) agree on the numerical value of the speed of light *in vacuo* ($c \approx 3.00 \times 10^{10}\,\mathrm{cm\,s^{-1}}$). We shall exploit this fact at the outset to have all of our admissible observers measure time in units of distance by simply multiplying their time coordinates $t$ by $c$. The resulting time coordinate is denoted $x^4 = ct$. In these units all speeds are dimensionless and the speed of light *in vacuo* is 1.

In our mathematical model $\mathcal{M}$ of the world of events, this very subtle and complex notion of an admissible observer is fully identified with the conceptually very simple notion of an admissible basis $\{e_1, e_2, e_3, e_4\}$. If $x \in \mathcal{M}$ is an event and if we write $x = x^a e_a$, then $(x^1, x^2, x^3)$ are the spatial and $x^4$ is the time coordinate supplied for $x$ by the corresponding observer. If $\{\hat{e}_1, \hat{e}_2, \hat{e}_3, \hat{e}_4\}$ is another basis/observer related to $\{e_1, e_2, e_3, e_4\}$ by [1] and if we write $x = \hat{x}^a \hat{e}_a$, then

$$\hat{x}^a = \Lambda^a{}_b x^b, \quad a = 1, 2, 3, 4 \qquad [2]$$

Thus, Lorentz transformations relate the space and time coordinates supplied for any given event by two admissible observers. If $(\Lambda^a{}_b) \in \mathcal{R}$, then the two observers differ only in the orientation of their spatial coordinate axes. On the other hand, for any real number $\theta$ one can define an element $L(\theta)$ of $\mathcal{L}$ by

$$L(\theta) = \begin{pmatrix} \cosh\theta & 0 & 0 & -\sinh\theta \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ -\sinh\theta & 0 & 0 & \cosh\theta \end{pmatrix} \qquad [3]$$

and, if two admissible bases are related by this Lorentz transformation, then the coordinate transformation [2] becomes

$$\begin{aligned} \hat{x}^1 &= (\cosh\theta)\, x^1 - (\sinh\theta)\, x^4 \\ \hat{x}^2 &= x^2 \\ \hat{x}^3 &= x^3 \\ \hat{x}^4 &= -(\sinh\theta)\, x^1 + (\cosh\theta)\, x^4 \end{aligned} \qquad [4]$$

Letting $\beta = \tanh\theta$ (so that $-1 < \beta < 1$) and suppressing $\hat{x}^2 = x^2$ and $\hat{x}^3 = x^3$, one obtains

$$\begin{aligned} \hat{x}^1 &= \frac{1}{\sqrt{1-\beta^2}} x^1 - \frac{\beta}{\sqrt{1-\beta^2}} x^4 \\ \hat{x}^4 &= -\frac{\beta}{\sqrt{1-\beta^2}} x^1 + \frac{1}{\sqrt{1-\beta^2}} x^4 \end{aligned} \qquad [5]$$

This corresponds to two observers whose spatial axes are oriented as shown in Figure 2 with the hatted coordinate system moving along the common $x^1$-, $\hat{x}^1$-axis with speed $|\beta|$, to the right if $\beta > 0$ and to the left if $\beta < 0$.

We remark that, reverting to traditional time units, $\beta = v/c$, where $|v|$ is the relative speed of the two coordinate systems, and [5] becomes what is generally referred to as a "Lorentz transformation" in elementary expositions of special relativity, that is,

$$\begin{aligned} \hat{x}^1 &= \frac{x^1 - vt}{\sqrt{1 - v^2/c^2}} \\ \hat{t} &= \frac{t - (v/c^2)x^1}{\sqrt{1 - v^2/c^2}} \end{aligned} \qquad [6]$$

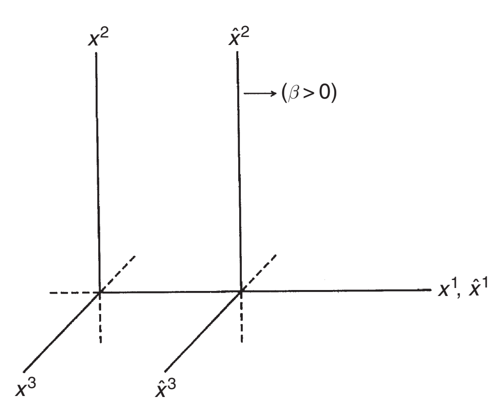

**Figure 2** Observers in standard configuration.

There is a sense in which, to understand the kinematic effects of special relativity, it is enough to restrict one's attention to the so-called special Lorentz transformations $L(\theta)$. Specifically, one can show (Naber 1992, theorem 1.3.5) that if $\Lambda \in \mathcal{L}$ is any Lorentz transformation, then there exists a real number $\theta$ and two rotations $R_1, R_2 \in \mathcal{R}$ such that $\Lambda = R_1 L(\theta) R_2$. Since $R_1$ and $R_2$ involve no relative motion, all of the kinematics is contained in $L(\theta)$. We shall explore these kinematic effects in more detail shortly.

Now suppose that $x$ and $x_0$ are two distinct events in $\mathcal{M}$ and consider the displacement vector $x - x_0$ from $x_0$ to $x$. If $\{e_1, e_2, e_3, e_4\}$ is an admissible basis and if we write $x = x^a e_a$ and $x_0 = x_0^a e_a$, then $x - x_0 = (x^a - x_0^a)e_a = \Delta x^a e_a$. If $x - x_0$ is null, then

$$(\Delta x^1)^2 + (\Delta x^2)^2 + (\Delta x^3)^2 = (\Delta x^4)^2$$

so the spatial separation of the two events is equal to the distance light would travel during the time lapse between the events. The same must be true in any other admissible basis since Lorentz transformations are the matrices of linear maps that preserve the Lorentz inner product. Consequently, all admissible observers agree that $x_0$ and $x$ are "connectible by a photon." They even agree as to which of the two events is to be regarded as the "emission" of the photon and which is to be regarded as its "reception" since one can show (Naber 1992, theorem 1.3.3) that, when a vector is either timelike or null and nonzero, the sign of its fourth coordinate is the same in every admissible basis (because $\Lambda^4{}_4 \geq 1$). Thus, $x^4 - x_0^4$ is either positive for all admissible observers ($x_0$ occurred before $x$) or negative for all admissible observers ($x_0$ occurred after $x$). Since photons move along straight lines in admissible coordinate systems we adopt the following terminology. If $x_0, x \in \mathcal{M}$ are such that $x - x_0$ is null, then the straight line in $\mathcal{M}$ containing $x_0$ and $x$ is called the world line of a photon in $\mathcal{M}$ and is to be thought of as the set of all events in the history of some particle of light that "experiences" both $x_0$ and $x$.

Let us now suppose instead that $x - x_0$ is timelike. Then, in any admissible basis,

$$(\Delta x^1)^2 + (\Delta x^2)^2 + (\Delta x^3)^2 < (\Delta x^4)^2$$

so the spatial separation of $x_0$ and $x$ is less than the distance light would travel during the time lapse between the events. In this case, one can prove (Naber 1992, section 1.4) that there exists an admissible basis $\{\hat{e}_1, \hat{e}_2, \hat{e}_3, \hat{e}_4\}$ in which $\Delta\hat{x}^1 = \Delta\hat{x}^2 = \Delta\hat{x}^3 = 0$, that is, there is an admissible observer for whom the two events occur at the same spatial location, one after the other. Thinking of this location as occupied by some material object (e.g., the observer's clock situated at that point) we find that the events $x_0$ and $x$ are both "experienced" by this material particle and that, moreover, $\sqrt{|g(x - x_0, x - x_0)|}$ is just the time lapse between the events recorded by a clock carried along by this material particle. To any other admissible observer this material particle appears "free" (not subject to forces) because it moves on a straight line with constant speed. This leads us to the following definitions. If $x_0, x \in \mathcal{M}$ are such that $x - x_0$ is timelike, then the straight line in $\mathcal{M}$ containing $x_0$ and $x$ is called the world line of a free material particle in $\mathcal{M}$ and $\sqrt{|g(x - x_0, x - x_0)|}$, usually written $\tau(x - x_0)$, or simply $\Delta\tau$, is the proper time separation of $x_0$ and $x$. One can think of $\tau(x - x_0)$ as a sort of "length" for $x - x_0$ measured, however, by a clock carried along by a free material particle that experiences both $x_0$ and $x$. It is an odd sort of length, however, since it satisfies not the usual triangle inequality, but the following "reversed" version.

**Reversed triangle inequality** (Naber 1992, theorem 1.4.2) *Let $x_0$, $x$ and $y$ be events in $\mathcal{M}$ for which $y - x$ and $x - x_0$ are timelike with the same time orientation. Then $y - x_0 = (y - x) + (x - x_0)$ is timelike and*

$$\tau(y - x_0) \geq \tau(y - x) + \tau(x - x_0) \qquad [7]$$

*with equality holding if and only if $y - x$ and $x - x_0$ are linearly dependent.*

The sense of the inequality in [7] has interesting consequences about which we will have more to say shortly.

Finally, let us suppose that $x - x_0$ is spacelike. Then, in any admissible basis

$$(\Delta x^1)^2 + (\Delta x^2)^2 + (\Delta x^3)^2 > (\Delta x^4)^2$$

so the spatial separation of $x_0$ and $x$ is greater than the distance light could travel during the time lapse that separates them. There is clearly no admissible observer for whom the events occur at the same location. No free material particle (or even photon) can experience both $x_0$ and $x$. However, one can show (Naber 1992, section 1.5) that, given any real number $T$ (positive, negative, or zero), one can find an admissible basis $\{\hat{e}_1, \hat{e}_2, \hat{e}_3, \hat{e}_4\}$ in which $\Delta\hat{x}^4 = T$. Some admissible observers will judge the events simultaneous, some will assert that $x_0$ occurred before $x$, and others will reverse the order. Temporal order, cause and effect, have no meaning for such pairs of events. For those admissible observers for whom the events are simultaneous ($\Delta\hat{x}^4 = 0$), the quantity $\sqrt{g(x - x_0, x - x_0)}$ is the distance between them and for this reason this quantity is called the proper spatial separation of $x_0$ and $x$ (whenever $x - x_0$ is spacelike).

For any two events $x_0, x \in \mathcal{M}, g(x - x_0, x - x_0)$ is given in any admissible basis by $(\Delta x^1)^2 + (\Delta x^2)^2 + (\Delta x^3)^2 - (\Delta x^4)^2$ and is called the interval separating $x_0$ and $x$. It is the closest analog in Minkowskian geometry to the (squared) length in Euclidean geometry. It can, however, assume any real value depending on the physical relationship between the events $x_0$ and $x$. Historically, of course, it was the various physical interpretations of this interval that we have just described which led Minkowski (Einstein *et al.* 1958) to the introduction of the structure that bears his name.

## Kinematic Effects

All of the well-known kinematic effects of special relativity (the addition of velocities formula, the relativity of simultaneity, time dilation, and length contraction) follow easily from what we have done. Because it eases visualization and because, as we mentioned earlier, it suffices to do so, we will limit our discussion to the special Lorentz transformations.

Let $\theta_1$ and $\theta_2$ be two real numbers and consider the corresponding elements $L(\theta_1)$ and $L(\theta_2)$ of $\mathcal{L}$ defined by [3]. Sum formulas for $\sinh\theta$ and $\cosh\theta$ imply that $L(\theta_1)L(\theta_2) = L(\theta_1 + \theta_2)$. Defining $\beta_i = \tanh\theta_i, i = 1, 2$, and $\beta = \tanh(\theta_1 + \theta_2)$, the sum formula for $\tanh\theta$ then gives

$$\beta = \frac{\beta_1 + \beta_2}{1 + \beta_1\beta_2} \qquad [8]$$

The physical interpretation is simple. One has three admissible observers whose spatial axes are related in the manner shown in **Figure 2**. If the speed of the second relative to the first is $\beta_1$ and the speed of the third relative to the second is $\beta_2$, then the speed of the third relative to the first is not $\beta_1 + \beta_2$ as a Newtonian predisposition would lead one to expect, but rather $\beta$, given by [8]. This is the relativistic addition of velocities formula.

We have seen already that, when the interval between $x_0$ and $x$ is spacelike, the events will be judged simultaneous by some admissible observers, but not by others. Indeed, if $\Delta x^4 = 0$ and the observers are related by [5], then $\Delta\hat{x}^4 = -(\beta/\sqrt{1-\beta^2})\Delta x^1 = -\beta\Delta\hat{x}^1$, which will not be zero unless $\beta = 0$ and so there is no relative motion ($\Delta\hat{x}^1$ cannot be zero since then $\Delta\hat{x}^a = 0$ for $a = 1, 2, 3, 4$ and $x = x_0$). This phenomenon is called the relativity of simultaneity and we now construct a simple geometrical representation of it.

Select two perpendicular lines in the plane to represent the $x^1$- and $x^4$-axes (the Euclidean orthogonality of the lines has no physical significance and is unnecessary, but makes the pictures easier to draw). The $\hat{x}^1$-axis will be represented by the straight line $\hat{x}^4 = 0$ which, from [5], is given by $x^4 = \beta x^1$ (in **Figure 3** we have assumed that $\beta > 0$). Similarly, the $\hat{x}^4$-axis is identified with the line $x^4 = (1/\beta)x^1$. Since Lorentz transformations leave the Lorentz inner product invariant, the hyperbolas $(x^1)^2 - (x^4)^2 = k$ coincide with $(\hat{x}^1)^2 - (\hat{x}^4)^2 = k$ and we calibrate the axes accordingly, for example, the branch of $(x^1)^2 - (x^4)^2 = 1$ with $x^1 > 0$ intersects the $x^1$-axis at the point $(x^1, x^4) = (1, 0)$ and intersects the $\hat{x}^1$-axis at the point $(\hat{x}^1, \hat{x}^4) = (1, 0)$. This necessitates a different scale on the hatted and unhatted axes, but one can show (Naber 1992, section 1.3) that, with this calibration, all coordinates can be obtained geometrically by projecting parallel to the opposite axis (e.g., the $x^4$- and $\hat{x}^4$-coordinates of an event result from projecting parallel to the $x^1$- and $\hat{x}^1$-axes, respectively).

Thus, a line of simultaneity in the hatted (respectively, unhatted) coordinates is parallel to the $\hat{x}^1$- (respectively, $x^1$-) axis so that, in general, a pair of events lying on one will not lie on the other (note, however, that these lines are "really" three-dimensional hyperplanes so what appears to be a point of intersection is actually a two-dimensional "plane of agreement", any two events in which are judged simultaneous by both observers).

For any two events whatsoever the relationship between the time lapse $\Delta\hat{x}^4$ in the hatted coordinates and the time lapse $\Delta x^4$ in the unhatted coordinates is, from [5],

$$\Delta\hat{x}^4 = -\frac{\beta}{\sqrt{1-\beta^2}}\Delta x^1 + \frac{1}{\sqrt{1-\beta^2}}\Delta x^4$$

so the two are generally not equal. Consider, in particular, two events on the world line of a point at rest in the unhatted coordinate system, for

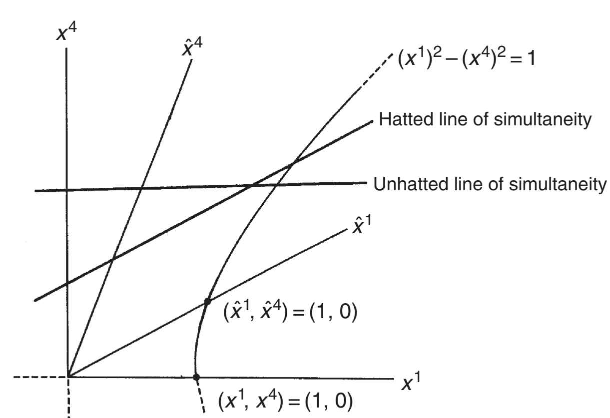

**Figure 3** Relativity of simultaneity.

example, two readings on the clock at rest at the origin in this system. Then $\Delta x^1 = 0$ so

$$\Delta \hat{x}^4 = \frac{1}{\sqrt{1-\beta^2}} \Delta x^4 > \Delta x^4$$

This effect is entirely symmetrical since, if $\Delta \hat{x}^1 = 0$, then [5] implies

$$\Delta x^4 = \frac{1}{\sqrt{1-\beta^2}} \Delta \hat{x}^4 > \Delta \hat{x}^4$$

Each observer judges the other's clocks to be running slow. This phenomenon is called time dilation and is clearly visible in the spacetime diagram in Figure 4 (e.g., both observers agree on the time reading "0" for the clock at the origin of the unhatted system, but the line $\hat{x}^4 = 1$ intersects the world line of the clock, i.e., the $x^4$-axis, at a point below $(x^1, x^4) = (0, 1)$).

We should emphasize that this phenomenon is quite "real" in the physical sense. For example, certain types of elementary particles (mesons) found in cosmic radiation are so short-lived (at rest) that, even if they could travel at the speed of light, the time required to traverse our atmosphere would be some ten times their normal life span. They should not be able to reach the earth, but they do. Time dilation "keeps them young" in the sense that what seems a normal life time to the meson appears much longer to us.

Finally, since admissible observers generally disagree on which events are simultaneous and since the only way to measure the "length" of a moving object (say, a measuring rod) is to locate its end points "simultaneously," it should come as no surprise that length, like simultaneity, and time, depends on the admissible observer measuring it. Specifically, let us consider a measuring rod lying at rest along the $\hat{x}^1$-axis of the hatted coordinate

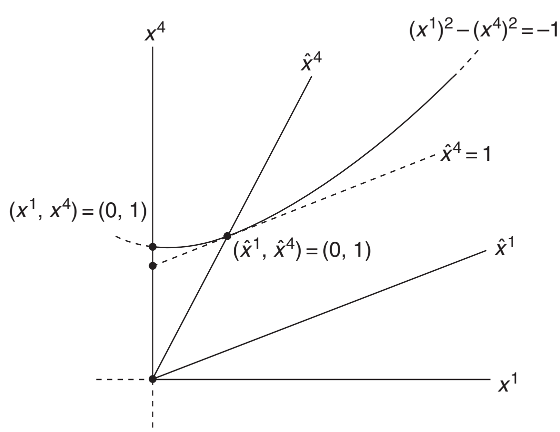

**Figure 4** Time dilation.

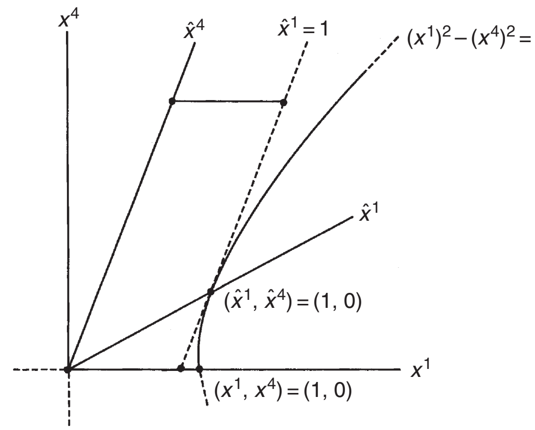

**Figure 5** Length contraction.

system. Its "length" in this coordinate system is $\Delta \hat{x}^1$. The world lines of its end points are two straight lines parallel to the $\hat{x}^4$-axis. If the unhatted observer locates two events on these world lines "simultaneously" their coordinates will satisfy $\Delta x^4 = 0$ and, by [5] $\Delta \hat{x}^1 = (1/\sqrt{1-\beta^2})\Delta x^1$ so

$$\Delta x^1 = \sqrt{1-\beta^2}\, \Delta \hat{x}^1 < \Delta \hat{x}^1$$

and the moving measuring rod appears contracted in its direction of motion by a factor of $\sqrt{1-\beta^2}$. As for time dilation, this phenomenon, known as length contraction, is entirely symmetrical, quite real, and clearly visible in a spacetime diagram (Figure 5).

## The Relativity Principle

We have found that admissible observers can disagree about some rather startling things (whether or not two events are simultaneous, the time lapse between two events even when no one thinks they are simultaneous, and the length of a measuring rod). This would be a matter of no concern at all, of course, if one could determine, in any given situation, who was really right. Surely, two events are either simultaneous or they are not and we need only sort out which admissible observer has the correct view of the situation? Unfortunately (or fortunately, depending on one's point of view) this distinction between the judgments made by different admissible observers is precisely what physics forbids.

**The relativity principle** (Einstein *et al.* 1958). *All admissible observers are completely equivalent for the formulation of the laws of physics.*

We must be clear that this is not a mathematical statement. It is rather a statement about the physical world around us and how it should be described, gleaned from observations, some of which are

complex and subtle and some of which are commonplace (a passenger in a smooth, quiet airplane traveling at constant groundspeed cannot "feel" his motion relative to the earth). It is a powerful guide for constructing the laws of relativistic physics, but even more fundamentally it prohibits us from regarding any particular admissible observer as having a privileged view of the universe. In particular, we are forbidden from attaching any objective significance to such questions as, "were the two supernovae simultaneous?", "How long did the meson survive?", and "What is the distance between the Crab Nebula and Alpha Centauri?" This is severe, but one must deal with it.

## Particles and 4-Momentum

If $I \subseteq \mathbb{R}$ is an interval, then a map $\alpha : I \to \mathcal{M}$ is a curve in $\mathcal{M}$. Relative to any admissible basis we can write

$$\alpha(\xi) = x^a(\xi)\, e_a$$

for each $\xi \in I$. We shall assume that $\alpha$ is smooth in the sense that each $x^a(\xi), a = 1, 2, 3, 4$, is infinitely differentiable ($C^\infty$) on $I$ and the velocity vector

$$\alpha'(\xi) = \frac{dx^a}{d\xi} e_a$$

is nonzero for every $\xi \in I$ (we adopt the usual custom, in a vector space, of identifying the tangent space at each point with the vector space itself). This definition of smoothness clearly does not depend on the choice of admissible basis for $\mathcal{M}$. The curve $\alpha$ is said to be spacelike, timelike, or null if

$$\alpha'(\xi) \cdot \alpha'(\xi) = \eta_{ab} \frac{dx^a}{d\xi} \frac{dx^b}{d\xi}$$

is positive, negative, or zero, respectively, for each $\xi \in I$. A timelike curve $\alpha$ for which $\alpha'(\xi)$ is future directed for each $\xi \in I$ is called a timelike world line and its image is identified with the set of all events in the history of some (not necessarily free) point material particle. If $I = [\xi_0, \xi_1]$ and $\alpha : [\xi_0, \xi_1] \to \mathcal{M}$ is a timelike world line, then the proper time length of $\alpha$ is defined by

$$\begin{aligned} L(\alpha) &= \int_{\xi_0}^{\xi_1} \sqrt{|\boldsymbol{g}(\alpha'(\xi), \alpha'(\xi))|}\, d\xi \\ &= \int_{\xi_0}^{\xi_1} \sqrt{-\eta_{ab} \frac{dx^a}{d\xi} \frac{dx^b}{d\xi}}\, d\xi \end{aligned}$$

and interpreted as the time lapse between the events $\alpha(\xi_0)$ and $\alpha(\xi_1)$ as recorded by a clock carried along by the particle whose world line is $\alpha$. This interpretation is easily motivated by writing out a Riemann sum approximation to the integral and appealing to our interpretation of the proper time separation $\Delta\tau = \sqrt{-\eta_{ab}\, \Delta x^a\, \Delta x^b}$. There are subtleties, however, both mathematical and physical (Naber 1992, section 1.4). The mathematical ones are addressed by the following result (which combines theorems 1.4.6 and 1.4.8 of Naber (1992)).

**Theorem** *Let $x_0$ and $x$ be two events in $\mathcal{M}$. Then $x - x_0$ is timelike and future directed if and only if there exists a timelike world line $\alpha : [\xi_0, \xi_1] \to \mathcal{M}$ in $\mathcal{M}$ with $\alpha(\xi_0) = x_0$ and $\alpha(\xi_1) = x$ and, in this case,*

$$L(\alpha) \leq \tau(x - x_0) \qquad [9]$$

*with equality holding if and only if $\alpha$ is a parametrization of a timelike straight line.*

The inequality [9] asserts that if two material particles experience both $x_0$ and $x$, then the one that is free (and so can be regarded as at rest in some admissible coordinate system) has longer to wait for the occurrence of the second event (moving clocks run slow). For many years this basically obvious fact was christened "The Twin Paradox."

Just as a smooth curve in Euclidean space has an arc length parametrization, so a timelike world line has a proper time parametrization defined as follows. For each $\xi$ in $[\xi_0, \xi_1]$ let

$$\tau = \tau(\xi) = \int_{\xi_0}^{\xi} \sqrt{|\boldsymbol{g}(\alpha'(\zeta), \alpha'(\zeta))|}\, d\zeta$$

(the proper time length of $\alpha$ from $\alpha(\xi_0)$ to $\alpha(\xi)$). Then $\tau = \tau(\xi)$ has a smooth inverse $\xi = \xi(\tau)$ so $\alpha$ can be reparametrized by $\tau$. We will abuse our notation slightly and write

$$\alpha(\tau) = x^a(\tau) e_a$$

The velocity vector with this parametrization is denoted

$$U = U(\tau) = \frac{dx^a}{d\tau} e_a$$

called the 4-velocity of the world line and is the unit tangent vector field to $\alpha$, that is,

$$U(\tau) \cdot U(\tau) = -1 \qquad [10]$$

for each $\tau$. An admissible observer is, of course, more likely to parametrize a world line by his own time coordinate $x^4$. Then

$$\alpha'(x^4) = \frac{dx^1}{dx^4} e_1 + \frac{dx^2}{dx^4} e_2 + \frac{dx^3}{dx^4} e_3 + e_4$$

so

$$\left|\boldsymbol{g}\left(\alpha'(x^4),\, \alpha'(x^4)\right)\right| = 1 - \|\boldsymbol{V}\|^2$$

where

$$\|V\| = \sqrt{\left(\frac{dx^1}{dx^4}\right)^2 + \left(\frac{dx^2}{dx^4}\right)^2 + \left(\frac{dx^3}{dx^4}\right)^2}$$

is the usual magnitude of the particle's velocity vector

$$\begin{aligned} V &= V(x^4) \\ &= \frac{dx^1}{dx^4} e_1 + \frac{dx^2}{dx^4} e_2 + \frac{dx^3}{dx^4} e_3 \\ &= V^i e_i \end{aligned}$$

in the given admissible coordinate system. One finds then that

$$U = \left(1 - \|V\|^2\right)^{-1/2} (V + e_4) \qquad [11]$$

We shall identify a material particle in $\mathcal{M}$ with a pair $(\alpha, m)$, where $\alpha$ is a timelike world line and $m$ is a positive constant called the particle's proper mass (or rest mass). If each $dx^a/d\xi$, $a = 1, 2, 3, 4$, is constant, then $(\alpha, m)$ is a free material particle with proper mass $m$. The 4-momentum of $(\alpha, m)$ is defined by $P = mU$. Thus,

$$P \cdot P = -m^2 \qquad [12]$$

In any admissible basis we write

$$\begin{aligned} P &= P^a e_a = mU^a e_a = m\frac{dx^a}{d\tau} e_a \\ &= m\left(1 - \|V\|^2\right)^{-1/2} (V + e_4) \qquad [13] \end{aligned}$$

The "spatial part" of $P$ in these coordinates is

$$\boldsymbol{P} = \frac{m}{\sqrt{1 - \|V\|^2}} V$$

which, for $\|V\| \ll 1$, is approximately $mV$. Identifying $m$ with the inertial mass of Newtonian mechanics (measured by an observer for whom the particle's speed is small), this is simply the classical momentum of the particle. Somewhat more explicitly, if one expands $1/\sqrt{1 - \|V\|^2}$ by the Binomial Theorem one finds that

$$\begin{aligned} P^i &= \frac{m}{\sqrt{1 - \|V\|^2}} V^i \\ &= mV^i + \frac{1}{2} mV^i \|V\|^2 + \cdots, \quad i = 1, 2, 3 \qquad [14] \end{aligned}$$

which gives the components of the classical momentum plus "relativistic corrections." In order to preserve a formal similarity with Newtonian mechanics one often sees $m/\sqrt{1 - \|V\|^2}$ referred to as the "relativistic mass" of the particle, but we shall avoid this terminology. The fourth component of $P$ is given by

$$\begin{aligned} P^4 &= -P \cdot e_4 \\ &= \frac{m}{\sqrt{1 - \|V\|^2}} = m + \frac{1}{2} m \|V\|^2 + \cdots \qquad [15] \end{aligned}$$

The appearance of the term $(1/2)m\|V\|^2$ corresponding to the Newtonian kinetic energy suggests that $P^4$ be denoted $E$ and called the total relativistic energy measured by the given admissible observer for the particle:

$$E = -P \cdot e_4 \qquad [16]$$

Now, one must understand that the concept of "energy" in physics is a subtle one and simply giving $-P \cdot e_4$ this name does not ensure that there is any physical content. Whether or not the name is appropriate can only be determined experimentally. In particular, one should ask if the appearance of the term $m$ in [15] is consistent with the view that $P^4$ represents the "energy" of the particle. Observe that if $\|V\| = 0$ (i.e., if the particle is at rest relative to the given observer), then [15] gives

$$E = m \; (= mc^2, \text{ in standard units}) \qquad [17]$$

which we interpret as saying that, even when the particle is at rest, it still has energy. If this is really "energy" in the physical sense, then it should be possible to liberate and use it. That this is, indeed, possible has, of course, been rather convincingly demonstrated.

Next we observe that not only material particles, but also photons possess "momentum" and "energy" and therefore should have 4-momentum (witness, e.g., the photoelectric effect in which photons collide with and eject electrons from their orbits in an atom). Unlike a material particle, however, a photon's characteristic feature is not proper mass, but frequency $\nu$, or wavelength $\lambda = 1/\nu$, related to its energy $\mathcal{E}$ by $\mathcal{E} = h\nu$ ($h$ being Planck's constant) and these are highly observer dependent (Doppler effect). There is, moreover, no "proper frequency" analogous to "proper mass" since there is no admissible observer for whom the photon is at rest. In an attempt to model these features we consider a point $x_0 \in \mathcal{M}$, a future directed null vector $N$ and an interval $I \subseteq \mathbb{R}$. The curve $\alpha : I \to \mathcal{M}$ defined by

$$\alpha(\xi) = x_0 + \xi N \qquad [18]$$

is a parametrization of the world line of a photon through $x_0$. Being null, $N$ can be written in any admissible basis as

$$N = (-N \cdot e_4)(\boldsymbol{d} + e_4) \qquad [19]$$

where

$$\boldsymbol{d} = \left[(N \cdot e_1)^2 + (N \cdot e_2)^2 + (N \cdot e_3)^2\right]^{-1/2} \left[(N \cdot e_1)e_1 + (N \cdot e_2)e_2 + (N \cdot e_3)e_3\right] \qquad [20]$$

is the direction vector of the world line in the corresponding spatial coordinate system. Now, by analogy with [16], we define a photon in $\mathcal{M}$ to be a curve in $\mathcal{M}$ of the form [18], take $N$ to be its 4-momentum and define the energy $\mathcal{E}$ of the photon in the admissible basis $\{e_1, e_2, e_3, e_4\}$ by

$$\mathcal{E} = -N \cdot e_4 \qquad [21]$$

Then, by [19],

$$N = \mathcal{E}(\boldsymbol{d} + e_4) \qquad [22]$$

The corresponding frequency $\nu$ and wavelength $\lambda$ are then defined by $\nu = \mathcal{E}/h$ and $\lambda = 1/\nu$. In another admissible basis, one has $N = \hat{\mathcal{E}}(\hat{\boldsymbol{d}} + \hat{e}_4)$, where $\hat{\boldsymbol{d}}$ and $\hat{\mathcal{E}}$ are defined by the hatted versions of [20] and [21]. One can then show (Naber 1992, section 1.8) that

$$\frac{\hat{\mathcal{E}}}{\mathcal{E}} = \frac{\hat{\nu}}{\nu} = \frac{1 - \beta \cos\theta}{\sqrt{1 - \beta^2}} = (1 - \beta\cos\theta) + \frac{1}{2}\beta^2(1 - \beta\cos\theta) + \cdots \qquad [23]$$

where $\beta$ is the relative speed of the two spatial coordinate systems and $\theta$ is the angle (in the unhatted spatial coordinate system) between the direction $\boldsymbol{d}$ of the photon and the direction of motion of the hatted spatial coordinate system. Equation [23] is the formula for the relativistic Doppler effect with the first term in the series being the classical formula.

We conclude this section by examining a few simple interactions between particles of the sort modeled by our definitions, assuming only that 4-momentum is conserved in the interaction. For convenience, we will use the term free particle to refer to either a free material particle or a photon. If $\mathcal{A}$ is a finite set of free particles, then each element of $\mathcal{A}$ has a unique 4-momentum which is a future-directed timelike or null vector. The sum of any such collection of vectors is timelike and future directed, except when all of the vectors are null and parallel, in which case the sum is null and future directed (Naber 1992, lemma 1.4.3). We call this sum the total 4-momentum of $\mathcal{A}$. Now we formulate a definition which is intended to model a finite set of free particles colliding at some event with a (perhaps new) set of free particles emerging from the collision (e.g., an electron and proton collide, with a neutron and neutrino emerging from the collision). A contact interaction in $\mathcal{M}$ is a triple $(\mathcal{A}, x, \tilde{\mathcal{A}})$, where $\mathcal{A}$ and $\tilde{\mathcal{A}}$ are two finite sets of free particles, neither of which contains a pair of particles with linearly dependent 4-momenta (which would presumably be physically indistinguishable) and $x \in \mathcal{M}$ is an event such that

1. $x$ is the terminal point of all of the particles in $\mathcal{A}$ (i.e., for each world line $\alpha : [\xi_0, \xi_1] \to \mathcal{M}$ of a particle in $\mathcal{A}$, $\alpha(\xi_1) = x$);
2. $x$ is the initial point of all the particles in $\tilde{\mathcal{A}}$, and
3. the total 4-momentum of $\mathcal{A}$ equals the total 4-momentum of $\tilde{\mathcal{A}}$.

Properly (3) is called the conservation of 4-momentum. If $\mathcal{A}$ consists of a single free particle, then $(\mathcal{A}, x, \tilde{\mathcal{A}})$ is called a decay (e.g., a neutron decays into a proton, an electron and an antineutrino).

Consider, for example, an interaction $(\mathcal{A}, x, \tilde{\mathcal{A}})$ for which $\tilde{\mathcal{A}}$ consists of a single photon. The total 4-momentum of $\tilde{\mathcal{A}}$ is null so the same must be true of $\mathcal{A}$. Since the 4-momenta of the individual particles in $\mathcal{A}$ are timelike or null and future directed their sum can be null only if they are, in fact, all null and parallel. Since $\mathcal{A}$ cannot contain distinct photons with parallel 4-momenta, it must consist of a single photon which, by (3), must have the same 4-momentum as the photon in $\tilde{\mathcal{A}}$. In essence, "nothing happened at $x$." We conclude that *no nontrivial interaction of the type modeled by our definition can result in a single photon and nothing else*. Reversing the roles of $\mathcal{A}$ and $\tilde{\mathcal{A}}$ shows that, if 4-momentum is to be conserved, *a photon cannot decay*.

Next let us consider the decay of a single material particle into two material particles, for example, the spontaneous disintegration of an atom through $\alpha$-emission. Thus, we consider a contact interaction $(\mathcal{A}, x, \tilde{\mathcal{A}})$ in which $\mathcal{A}$ consists of a single free material particle of proper mass $m_0$ and $\tilde{\mathcal{A}}$ consists of two free material particles with proper masses $m_1$ and $m_2$. Let $P_0, P_1$, and $P_2$ be the 4-momenta of the particles of proper mass $m_0$, $m_1$, and $m_2$, respectively. Then $P_0 = P_1 + P_2$. Appealing to the "reversed triangle inequality," the fact that $P_1$ and $P_2$ are linearly independent and future directed, and [12] we conclude that

$$m_0 > m_1 + m_2 \qquad [23]$$

The excess mass $m_0 - (m_1 + m_2)$ of the initial particle is regarded, via [17], as a measure of the amount of energy required to split $m_0$ into two pieces. Stated somewhat differently, when the two particles in $\tilde{\mathcal{A}}$ were held together to form the single particle in $\mathcal{A}$, the "binding energy" contributed to the mass of this latter particle.

Reversing the roles of $\mathcal{A}$ and $\tilde{\mathcal{A}}$ in the last example gives a contact interaction modelling an inelastic collision (two free material particles with masses $m_1$ and $m_2$ collide and coalesce to form a third of mass $m_0$). The inequality [23] remains true, of course, and a somewhat more detailed analysis (Naber 1992, section 1.8) yields an approximate formula for $m_0 - (m_1 + m_2)$ which can be compared (favorably) with the Newtonian formula for the loss in kinetic energy that results from the collision (energy which, classically, is viewed as taking the form of heat in the combined particle). An analysis of the interaction in which both $\mathcal{A}$ and $\tilde{\mathcal{A}}$ consist of an electron and a photon yields (Naber 1992, section 1.8) a formula for the so-called Compton effect. Many more such examples of this sort are treated in great detail in Synge (1972, chapter VI, § 14).

## Charged Particles and Electromagnetic Fields

A charged particle in $\mathcal{M}$ is a triple $(\alpha, m, q)$, where $(\alpha, m)$ is a material particle and $q$ is a nonzero real number called the charge of the particle. Charged particles do two things of interest to us. By their very presence they create electromagnetic fields and they also respond to the electromagnetic fields created by other charges.

Charged particles "respond" to an electromagnetic field by experiencing changes in 4-momentum. The quantitative nature of this response, that is, the equation of motion, is generally taken to be the so-called Lorentz 4-force law which expresses the proper time rate of change of the particle's 4-momentum at each point of the world line as a linear function of the 4-velocity. Thus, at each point $\alpha(\tau)$ of the world line

$$\frac{\mathrm{d}P(\tau)}{\mathrm{d}\tau} = q\tilde{F}_{\alpha(\tau)}(U(\tau)) \qquad [24]$$

where $\tilde{F}_{\alpha(\tau)}:\mathcal{M} \to \mathcal{M}$ is a linear transformation determined, in each admissible coordinate system, by the classical electric $\boldsymbol{E}$ and magnetic $\boldsymbol{B}$ fields (here we are assuming that the contribution of $q$ to the ambient electromagnetic field is negligible, that is, $(\alpha, m, q)$ is a "test charge"). Let us write [24] more simply as

$$\tilde{F}(U) = \frac{m}{q}\frac{\mathrm{d}U}{\mathrm{d}\tau} \qquad [25]$$

Dotting both sides of [25] with $U$ gives

$$\tilde{F}(U) \cdot U = \frac{m}{q}\frac{\mathrm{d}U}{\mathrm{d}\tau} \cdot U = \frac{m}{2q}\frac{\mathrm{d}}{\mathrm{d}\tau}(U \cdot U) = \frac{m}{2q}\frac{\mathrm{d}}{\mathrm{d}\tau}(-1) = 0$$

Since any future-directed timelike unit vector $u$ is the 4-velocity of some charged particle, we find that $\tilde{F}(u) \cdot u = 0$ for any such vector. Linearity then implies $\tilde{F}(v) \cdot v = 0$ for any timelike vector. Now, if $u$ and $v$ are timelike and future directed, then $u + v$ is timelike so $0 = \tilde{F}(u + v) \cdot (u + v) = \tilde{F}(u) \cdot v + u \cdot \tilde{F}(v)$ and therefore $\tilde{F}(u) \cdot v = -u \cdot \tilde{F}(v)$. But $\mathcal{M}$ has a basis of future-directed timelike vectors so

$$\tilde{F}(x) \cdot y = -x \cdot \tilde{F}(y) \qquad [26]$$

for all $x, y \in \mathcal{M}$. Thus, at each point, the linear transformation $\tilde{F}$ must be skew-symmetric with respect to the Lorentz inner product. One could therefore model an electromagnetic field on $\mathcal{M}$ by an assignment to each point of a skew-symmetric linear transformation whose job it is to assign to the 4-velocity of a charged particle whose world line passes through that point the change in 4-momentum that the particle should expect to experience because of the presence of the field. However, a slightly different perspective has proved more convenient. Notice that a skew-symmetric linear transformation $\tilde{F}:\mathcal{M} \to \mathcal{M}$ and the Lorentz inner product together determine a bilinear form $F:\mathcal{M} \times \mathcal{M} \to \mathbb{R}$ given by

$$F(x, y) = \tilde{F}(x) \cdot y$$

which is also skew-symmetric $(F(y, x) = \tilde{F}(y) \cdot x = -F(x, y))$ and that, conversely, a skew-symmetric bilinear form uniquely determines a skew-symmetric linear transformation. Now, an assignment of a skew-symmetric bilinear form to each point of $\mathcal{M}$ is nothing other than a 2-form on $\mathcal{M}$ and it is in the language of forms that we choose to phrase classical electromagnetic theory (a concise introduction to this language is available, for example, in Spivak (1965, chapter 4).

Nature imposes a certain restriction on which 2-forms can reasonably represent an electromagnetic field on $\mathcal{M}$ ("Maxwell's equations"). To formulate these we introduce a source 1-form $J$ as follows: If

$x^1, x^2, x^3, x^4$ is any admissible coordinate system on $\mathcal{M}$, then

$$J = J_1 dx^1 + J_2 dx^2 + J_3 dx^3 - \rho dx^4 \qquad [27]$$

where $\rho : \mathcal{M} \to \mathbb{R}$ is a charge density function and $\boldsymbol{J} = J_1 e_1 + J_2 e_2 + J_3 e_3$ is a current density vector field (these are to be regarded as the usual "smoothed out," pointwise versions of "charge per unit volume" and "charge flow per unit area per unit time" as measured by the corresponding admissible observer). Now, our formal definition is as follows: The electromagnetic field on $\mathcal{M}$ determined by the source 1-form $J$ on $\mathcal{M}$ is a 2-form $F$ on $\mathcal{M}$ that satisfies Maxwell's equation

$$dF = 0 \qquad [28]$$

and

$$^*d^*F = J \qquad [29]$$

A few comments are in order here. We have chosen units in which not only the speed of light, but also various other constants that one often finds in Maxwell's equations (the dielectric constant $\epsilon_0$ and magnetic permeability $\mu_0$) are 1 and a factor of $4\pi$ in [29] is "normalized out." The $^*$ in [29] is the Hodge star operator determined by the Lorentz inner product and the chosen orientation of $\mathcal{M}$. This is a natural isomorphism

$$^* : \Omega^p(\mathcal{M}) \to \Omega^{4-p}(\mathcal{M}), \quad p = 0, 1, 2, 3, 4$$

of the $p$-forms on $\mathcal{M}$ to the $(4-p)$-forms on $\mathcal{M}$ and is most simply defined as follows: let $x^1, x^2, x^3, x^4$ be any admissible coordinate system on $\mathcal{M}$. If $1 \in \Omega^0(\mathcal{M})$ is the constant function (0-form) on $\mathcal{M}$ whose value is $1 \in \mathbb{R}$, then

$$^*1 = dx^1 \wedge dx^2 \wedge dx^3 \wedge dx^4$$

is the volume form on $\mathcal{M}$. If $1 \le i_1 < \cdots < i_k \le 4$, then $^*(dx^{i_1} \wedge \cdots \wedge dx^{i_k})$ is uniquely determined by

$$\left(dx^{i_1} \wedge \cdots \wedge dx^{i_k}\right) \wedge^* \left(dx^{i_1} \wedge \cdots \wedge dx^{i_k}\right) = -dx^1 \wedge dx^2 \wedge dx^3 \wedge dx^4$$

Thus, for example, $^*dx^2 = dx^1 \wedge dx^3 \wedge dx^4$, $^*(dx^1 \wedge dx^2) = -dx^3 \wedge dx^4$, $^*(dx^1 \wedge dx^2 \wedge dx^3 \wedge dx^4) = -1$, etc. It follows that, if $\mu$ is a $p$-form on $\mathcal{M}$, then

$$^{**}\mu = (-1)^{p+1}\mu \qquad [30]$$

(a more thorough discussion is available in Choquet-Bruhat *et al.* (1977, chapter V A3)). In particular, [29] is equivalent to

$$d^*F = {}^*J \qquad [31]$$

On regions in which there are no charges, so that $J = 0$, [28] and [31] become the source free Maxwell equations

$$dF = 0 \qquad [32]$$

and

$$d^*F = 0 \qquad [33]$$

that is, both $F$ and $^*F$ are closed 2-forms.

Any 2-form $F$ on $\mathcal{M}$ can be written in any admissible coordinate system as $F = (1/2)F_{ab}dx^a \wedge dx^b$ (summation convention!), where $(F_{ab})$ is the skew-symmetric matrix of components of $F$. In order to make contact with the notation generally employed in physics, we introduce the following names for these components:

$$(F_{ab}) = \begin{pmatrix} 0 & B^3 & -B^2 & E^1 \\ -B^3 & 0 & B^1 & E^2 \\ B^2 & -B^1 & 0 & E^3 \\ -E^1 & -E^2 & -E^3 & 0 \end{pmatrix} \qquad [34]$$

Thus,

$$\begin{aligned} F = {} & E^1 dx^1 \wedge dx^4 + E^2 dx^2 \wedge dx^4 \\ & + E^3 dx^3 \wedge dx^4 + B^3 dx^1 \wedge dx^2 \\ & + B^2 dx^3 \wedge dx^1 + B^1 dx^2 \wedge dx^3 \end{aligned} \qquad [35]$$

Computing $^*F, dF, d^*F$ and $^*d^*F$ and writing $\boldsymbol{E} = E^1 e_1 + E^2 e_2 + E^3 e_3$ and $\boldsymbol{B} = B^1 e_1 + B^2 e_2 + B^3 e_3$ one finds that $dF = 0$ is equivalent to

$$\operatorname{div} \boldsymbol{B} = 0 \qquad [36]$$

and

$$\operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \qquad [37]$$

while $^*d^*F = J$ is equivalent to

$$\operatorname{div} \boldsymbol{E} = \rho \qquad [38]$$

and

$$\operatorname{curl} \boldsymbol{B} - \frac{\partial \boldsymbol{E}}{\partial t} = \boldsymbol{J} \qquad [39]$$

Equations [36]–[39] are the more traditional renderings of Maxwell's equations.

In another admissible coordinate system $\hat{x}^1, \hat{x}^2, \hat{x}^3, \hat{x}^4$ on $\mathcal{M}$ (related to the first by [2]) the 2-form $F$ would be written $F = (1/2)\hat{F}_{ab} d\hat{x}^a \wedge d\hat{x}^b$. Setting $\hat{x}^a = \Lambda^a{}_\alpha x^\alpha$ and $\hat{x}^b = \Lambda^b{}_\beta x^\beta$ gives $F = (1/2)(\Lambda^a{}_\alpha \Lambda^b{}_\beta \hat{F}_{ab}) dx^\alpha \wedge dx^\beta$, so

$$F_{\alpha\beta} = \Lambda^a{}_\alpha \Lambda^b{}_\beta \hat{F}_{ab}, \quad \alpha, \beta = 1, 2, 3, 4 \qquad [40]$$

Now, suppose that we wish to describe the electromagnetic field of a uniformly moving charge. According to the relativity principle, it does not matter at all whether we view the charge as moving

relative to a "fixed" admissible observer, or the observer as moving relative to a "stationary" charge. Thus, we shall write out the field due to a charge fixed at the origin of the hatted coordinate system ("Coulomb's law") and transform, by [40], to an unhatted coordinate system moving relative to it. Relative to $\hat{x}^1, \hat{x}^2, \hat{x}^3, \hat{x}^4$, the familiar inverse square law for a fixed point charge $q$ located at the spatial origin gives $\hat{\boldsymbol{B}} = 0$ and $\hat{\boldsymbol{E}} = (q/\hat{r}^3)\hat{\boldsymbol{r}}$, where $\hat{\boldsymbol{r}} = \hat{x}^1\hat{e}_1 + \hat{x}^2\hat{e}_2 + \hat{x}^3\hat{e}_3$ and $\hat{r} = ((\hat{x}^1)^2 + (\hat{x}^2)^2 + (\hat{x}^3)^2)^{1/2}$ (note that $\hat{\boldsymbol{E}}$ is defined only on $\mathcal{M} - \text{Span}\{\hat{e}_4\}$). Thus,

$$(\hat{F}_{ab}) = \frac{q}{\hat{r}^3}\begin{pmatrix} 0 & 0 & 0 & \hat{x}^1 \\ 0 & 0 & 0 & \hat{x}^2 \\ 0 & 0 & 0 & \hat{x}^3 \\ -\hat{x}^1 & -\hat{x}^2 & -\hat{x}^3 & 0 \end{pmatrix} \qquad [41]$$

It is a simple matter to verify that, on its domain, $(\hat{F}_{ab})$ satisfies the source free Maxwell equations. Taking $\Lambda$ to be the special Lorentz transformation corresponding to [5] and writing out [40] with $(\hat{F}_{ab})$ given by [41] yields

$$\begin{aligned} E^1 &= q\left(\frac{\hat{x}^1}{\hat{r}^3}\right) \\ E^2 &= \frac{q}{\sqrt{1-\beta^2}}\left(\frac{\hat{x}^2}{\hat{r}^3}\right) \\ E^3 &= \frac{q}{\sqrt{1-\beta^2}}\left(\frac{\hat{x}^3}{\hat{r}^3}\right) \\ B^1 &= 0 \\ B^2 &= \frac{-q\beta}{\sqrt{1-\beta^2}}\left(\frac{\hat{x}^3}{\hat{r}^3}\right) \\ B^3 &= \frac{q\beta}{\sqrt{1-\beta^2}}\left(\frac{\hat{x}^2}{\hat{r}^3}\right) \end{aligned} \qquad [42]$$

We wish to express these in terms of measurements made by the unhatted observer at the instant the charge passes through his spatial origin. Setting $x^4 = 0$ in [5] gives

$$\hat{x}^1 = \frac{1}{\sqrt{1-\beta^2}}x^1, \quad \hat{x}^2 = x^2, \quad \hat{x}^3 = x^3$$

and so

$$\hat{r}^2 = \frac{1}{1-\beta^2}(x^1)^2 + (x^2)^2 + (x^3)^2$$

which, for convenience, we write $r_\beta^2$. Making these substitutions in [42] gives

$$\begin{aligned} \boldsymbol{E} &= \frac{q}{\sqrt{1-\beta^2}}\left(\frac{1}{r_\beta^3}\right)\left(x^1e_1 + x^2e_2 + x^3e_3\right) \\ &= \frac{q}{\sqrt{1-\beta^2}}\left(\frac{1}{r_\beta^3}\right)\boldsymbol{r} \end{aligned} \qquad [43]$$

and

$$\begin{aligned} \boldsymbol{B} &= \frac{q}{\sqrt{1-\beta^2}}\left(\frac{1}{r_\beta^3}\right)\left(0e_1 - \beta x^3e_2 + \beta x^2 e_3\right) \\ &= \frac{q}{\sqrt{1-\beta^2}}\left(\frac{1}{r_\beta^3}\right)((\beta e_1)\times \boldsymbol{r}) \end{aligned} \qquad [44]$$

for the field of a charge moving uniformly with velocity $\beta e_1$ at the instant the charge passes through the origin. Observe that when $\beta \ll 1, r_\beta \approx r$, so [43] says that the electric field of a slowly moving charge is approximately the Coulomb field. When $\beta \ll 1$, [44] reduces to the Biot–Savart law.

Let us consider one other simple application, that is, the response of a charged particle $(\alpha, m, q)$ to an electromagnetic field which, for some admissible observer, is constant and purely magnetic. For simplicity, we assume that, for this observer $\boldsymbol{E} = \boldsymbol{0}$ and $\boldsymbol{B} = be_3$, where $b$ is a nonzero constant. The corresponding 2-form $F$ has components

$$(F_{ab}) = \begin{pmatrix} 0 & b & 0 & 0 \\ -b & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

(from [34]). The corresponding linear transformation $\tilde{F}$ has the same matrix relative to this basis so, with $\alpha(\tau) = x^a(\tau)e_a$ and $U(\tau) = U^a(\tau)e_a$, the Lorentz 4-force law [25] reduces to the system of linear differential equations

$$\frac{\mathrm{d}U^1}{\mathrm{d}\tau} = \frac{bq}{m}U^2, \qquad \frac{\mathrm{d}U^2}{\mathrm{d}\tau} = -\frac{bq}{m}U^1$$
$$\frac{\mathrm{d}U^3}{\mathrm{d}\tau} = 0, \qquad \frac{\mathrm{d}U^4}{\mathrm{d}\tau} = 0$$

The system is easily solved and the results easily integrated to give

$$\begin{aligned} \alpha(\tau) &= x_0 + a\sin\left(\frac{bq\tau}{m} + \phi\right)e_1 \\ &\quad + a\cos\left(\frac{bq\tau}{m} + \phi\right)e_2 \\ &\quad + c\tau e_3 + \left(1 + \frac{a^2b^2q^2}{m^2} + c^2\right)\tau e_4 \end{aligned} \qquad [45]$$

where $x_0 = x_0^a e_a \in \mathcal{M}$ is constant and $a, \phi$, and $c$ are real constants with $a > 0$ (we have used $U \cdot U = -1$ to eliminate one other arbitrary real constant). Note that, at each point on $\alpha$, $(x^1 - x_0^1)^2 + (x^2 - x_0^2)^2 = a^2$. Thus, if $c \neq 0$ the spatial trajectory in this coordinate system is a helix along the $e_3$-direction (i.e., along the magnetic field lines). If $c = 0$, the trajectory is a circle in the $x^1$–$x^2$ plane. This case is of some practical significance since one can

introduce constant magnetic fields in a bubble chamber so as to induce a particle of interest to follow a circular path. We show now how to measure the charge-to-mass ratio for such a particle. Taking $c = 0$ in [45] and computing $U(\tau)$, then using [11] to solve for the coordinate velocity vector $\boldsymbol{V}$ of the particle gives

$$\boldsymbol{V} = \frac{abq/m}{\sqrt{1 - \|\boldsymbol{V}\|^2}}\left(\cos\left(\frac{bq\tau}{m} + \phi\right)e_1 + \sin\left(\frac{bq\tau}{m} + \phi\right)e_2\right)$$

From this one computes

$$\|\boldsymbol{V}\|^2 = \left(1 + \frac{m^2}{a^2b^2q^2}\right)^{-1}$$

(note that this is a constant). Solving this last equation for $q/m$ (and assuming $q > 0$ for convenience) one arrives at

$$\frac{q}{m} = \frac{1}{a|b|}\frac{\|\boldsymbol{V}\|}{\sqrt{1 - \|\boldsymbol{V}\|^2}}$$

Since $a$, $b$, and $\|\boldsymbol{V}\|$ are measurable, one obtains the desired charge-to-mass ratio.

To conclude we wish to briefly consider the existence and use of "potentials" for electromagnetic fields. Suppose $F$ is an electromagnetic field defined on some connected, open region $X$ in $\mathcal{M}$. Then $F$ is a 2-form on $X$ which, by [28], is closed. Suppose also that the second de Rham cohomology $H^2(X;\mathbb{R})$ of $X$ is trivial (since $\mathcal{M}$ is topologically $\mathbb{R}^4$ this will be the case, for example, when $X$ is all of $\mathcal{M}$, or an open ball in $\mathcal{M}$, or, more generally, an open "star-shaped" region in $\mathcal{M}$). Then, by definition, every closed 2-form on $X$ is exact so, in particular, there exists a 1-form $A$ on $X$ satisfying

$$F = \mathrm{d}A \qquad [46]$$

In particular, such a 1-form $A$ always exists locally on a neighborhood of any point in $X$ for any $F$. Such an $A$ is not uniquely determined, however, because, if $A$ satisfies [46], then so does $A + \mathrm{d}f$ for any smooth real-valued function (0-form) $f$ on $X$ ($\mathrm{d}^2 = 0$ implies $\mathrm{d}(A + \mathrm{d}f) = \mathrm{d}A + \mathrm{d}^2 f = \mathrm{d}A = F$). Any 1-form $A$ satisfying [46] is called a (gauge) potential for $F$. The replacement $A \to A + \mathrm{d}f$ for some $f$ is called a gauge transformation of the potential and the freedom to make such a replacement without altering [46] is called gauge freedom.

One can show that, given $F$, it is always possible to locally solve $\mathrm{d}A = F$ for $A$ subject to an arbitrary specification of the 0-form ${}^*\mathrm{d}^*A$. More precisely, if $F$ is any 2-form satisfying $\mathrm{d}F = 0$ and $g$ is an arbitrary 0-form, then locally, on a neighborhood of any point, there exists a 1-form $A$ satisfying

$$\mathrm{d}A = F \quad \text{and} \quad {}^*\mathrm{d}^*A = g \qquad [47]$$

(a more general result is proved in Parrott (1987, appendix 2) and a still more general one in section 2.9 of this same source). The usefulness of the second condition in [47] can be illustrated as follows. Suppose we are given some (physical) configuration of charges and currents (i.e., some source 1-form $J$) and we wish to find the corresponding electromagnetic field $F$. We must solve Maxwell's equations $\mathrm{d}F = 0$ and ${}^*\mathrm{d}^*F = J$ (subject to whatever boundary conditions are appropriate). Locally, at least, we may seek instead a corresponding potential $A$ (so that $F = \mathrm{d}A$). Then the first of Maxwell's equations is automatically satisfied ($\mathrm{d}F = \mathrm{d}(\mathrm{d}A) = 0$) and we need only solve ${}^*\mathrm{d}^*(\mathrm{d}A) = J$. To simplify the notation let us temporarily write $\delta = {}^*\mathrm{d}^*$ and consider the operator $\Delta = \mathrm{d} \circ \delta + \delta \circ \mathrm{d}$ on forms (variously called the Laplace–Beltrami operator, Laplace–de Rham operator, or Hodge Laplacian on Minkowski spacetime). Then

$$\Delta A = \mathrm{d}(\delta A) + \delta(\mathrm{d}A) = \mathrm{d}({}^*\mathrm{d}^*A) + {}^*\mathrm{d}^*(\mathrm{d}A) \qquad [48]$$

According to the result quoted above, we may narrow down our search by imposing the condition ${}^*\mathrm{d}^*A = 0$, that is

$$\delta A = 0 \qquad [49]$$

(this is generally referred to as imposing the Lorentz gauge). With this, [48] becomes $\Delta A = {}^*\mathrm{d}^*(\mathrm{d}A)$ and to satisfy the second Maxwell equation we must solve

$$\Delta A = J \qquad [50]$$

Thus, we see that the problem of (locally) solving Maxwell's equations for a given source $J$ reduces to that of solving [49] and [50] for the potential $A$. To understand how this simplifies the problem, we note that a calculation in admissible coordinates shows that the operator $\Delta$ reduces to the componentwise d'Alembertian $\Box$, defined on real-valued functions by

$$\Box = \frac{\partial^2}{\partial(x^1)^2} + \frac{\partial^2}{\partial(x^2)^2} + \frac{\partial^2}{\partial(x^3)^2} - \frac{\partial^2}{\partial(x^4)^2}$$

Thus, eqn [50] decouples into four scalar equations

$$\Box A_a = J_a, \quad a = 1, 2, 3, 4 \qquad [51]$$

each of which is the well-studied inhomogeneous wave equation.

# Introductory Article: Quantum Mechanics

**G F dell'Antonio**, Università di Roma "La Sapienza," Rome, Italy

## Historical Background

In this section we shall briefly recall the basic empirical facts and the first theoretical attempts from which the theory and the formalism of present-day quantum mechanics (QM) has grown. In the next sections we shall give the mathematical and computational structure of QM, mention the physical problems that QM has solved with much success, and describe the serious conceptual consistency problems which are posed by QM (and which remain unsolved up to now).

Empirical rules of discretization were observed already, starting from the 1850s, in the absorption and in the emission of light. Fraunhofer noticed that the dark lines in the absorption spectrum of the light of the sun coincide with the bright lines in the emission lines of all elements. G Kirchhoff and R Bunsen reached the conclusion that the relative intensities of the emission and absorption of light implied that the ratio between energy emitted and absorbed is independent of the atom considered. This was the starting point of the analysis by Planck.

On the other hand, by the end of the eighteenth century, the spatial structure of the atom had been investigated; the most successful model was that of Rutherford, in which the atom appeared as a small nucleus of charge $Z$ surrounded by $Z$ electrons attracted by the nucleus according to Coulomb's law. This model represents, for distances of the order of the size of an atom, a complete departure from Newton's laws combined with the laws of classical electrodynamics; indeed, according to these laws, the atom would be unstable against collapse, and would certainly not exhibit a discrete energy spectrum. We must conclude that the classical laws are inadequate for the description of emission and absorption of light, in which the internal structure of the atom plays a major role.

The birth of the old quantum theory is placed traditionally at the date of M Planck's discussion of the blackbody radiation in 1900.

Planck put forward the postulate that light is emitted and absorbed by matter in discrete energy quanta through "resonators" that have an energy proportional to their frequency. This assumption led, through the use of Gibb's rules of Statistical Mechanics applied to a gas of resonators, to a law (Planck's law) which reproduces the empirical findings on the radiation from a blackbody. It led Einstein to ascribe to light (which had, since the times of Maxwell, a successful description in terms of waves) a discrete, particle-like nature. Nine years later A Einstein gave further support to Planck's postulate by showing that it can reproduce correctly the energy fluctuations in blackbody radiation and even clarifies the properties of specific heat. Soon afterwards, Einstein (1924, 1925) proved that the putative particle of light satisfied the relativistic laws (relation between energy and momentum) of a particle with zero mass.

This dual nature of light received further support from the experiments on the Compton effect and from description, by Einstein, of the photoelectric effect (Einstein 1905). It should be emphasized that while Planck considered with light in interaction with matter $\nu$ as composed of bits of energy $h\nu$ ($h \simeq 6,6 \times 10^{-27}$ erg s), Einstein's analysis went much further in assigning to the quantum of light properties of a particle-like (localized) object. This marks a complete departure from the laws of classical electromagnetism. Therefore, quoting Einstein,

> It is conceivable that the wave theory of light, which retains its effectiveness for the representation of purely optical phenomena and is based on continuous functions over space, will lead to contradiction with the experiments when applied to phenomena in which there is creation or conversion of light; indeed these phenomena can be better

> described on the assumption that light is distributed discontinuously in space and described by a finite number of quanta which move without being divided and which must be absorbed or emitted as a whole.

Notice that, for wavelength of $8 \times 10^3$Å, a 30 W lamp emits roughly $10^{20}$ photons $s^{-1}$; for macroscopic objects the discrete nature of light has no appreciable consequence.

Planck's postulate and energy conservation imply that in emitting and absorbing light the atoms of the various elements can lose or gain energy only by discrete amounts. Therefore, atoms as producers or absorbers of radiation are better described by a theory that assigns to each atom a (possible infinite) discrete set of states which have a definite energy.

The old quantum theory of matter addresses precisely this question. Its main proponent is N Bohr (Bohr 1913, 1918). The new theory is entirely phenomenological (as is Planck's theory) and based on Rutherford's model and on three more postulates (Born 1924):

(i) The states of the atom are stable periodic orbits, as given by Newton's laws, of energy $E_n, n \in Z^+$, given by $E_n = h\nu_n f(n)$, where $h$ is Plank's constant, $\nu_n$ is the frequency of the electron on that orbit, and $f(n)$ is for each atom a function approximately linear in $Z$ at least for small values of $Z$.
(ii) When radiation is emitted or absorbed, the atom makes a transition to a different state. The frequency of the radiation emitted or absorbed when making a transition is $\nu_{n,m} = h^{-1}|E_n - E_m|$.
(iii) For large values of $n$ and $m$ and small values of $(n-m)/(n+m)$ the prediction of the theory should agree with those of the classical theory of the interaction of matter with radiation.

Later, A Sommerfeld gave a different version of the first postulate, by requiring that the allowed orbits be those for which the classical action is an integer multiple of Planck's constant.

The old quantum theory met success when applied to simple systems (atoms with $Z < 5$) but it soon appeared evident that a new, radically different point of view was needed and a fresh start; the new theory was to contain few free parameters, and the role of postulate (iii) was now to fix the value of these parameters.

There were two (successful) attempts to construct a consistent theory; both required a more sharply defined mathematical formalism. The first one was sparked by W Heisenberg, and further important ideas and mathematical support came from M Born, P Jordan, W Pauli, P Dirac and, on the mathematical side, also by J von Neumann and A Weyl. This formulation maintains that one should only consider relations between observable quantities, described by elements that depend only on the initial and final states of the system; each state has an internal energy. By energy conservation, the difference between the energies must be proportional (with a universal constant) to the frequency of the radiation absorbed or emitted. This is enough to define the energy of the state of a single atom modulo an additive constant. The theory must also take into account the probability of transitions under the influence of an external electromagnetic field.

We shall give some details later on, which will help to follow the basis of this approach.

The other attempt was originated by L de Broglie following early remarks by HW Bragg and M Brillouin. Instead of emphasizing the discrete nature of light, he stressed the possible wave nature of particles, using as a guide the Hamilton–Jacobi formulation of classical mechanics. This attempt was soon supported by the experiments of Davisson and Germer (1927) of scattering of a beam of ions from a crystal. These experiments showed that, while electrons are recorded as "point particles," their distribution follows the law of the intensity for the diffraction of a (dispersive) wave. Moreover, the relation between momentum and frequency was, within experimental errors, the same as that obtained by Einstein for photons.

The theory started by de Broglie was soon placed in almost definitive form by E Schrödinger. In this approach one is naturally led to formulate and solve partial differential equations and the full development of the theory requires regularity results from the theory of functions.

Schrödinger soon realized that the relations which were found in the approach of Heisenberg could be easily (modulo technical details which we shall discuss later) obtained within the formalism he was advocating and indeed he gave a proof that the two formalisms were equivalent. This proof was later refined, from the mathematical point of view, by J von Neumann and G Mackey.

In fact, Schrödinger's approach has proved much more useful in the solution of most physical problems in the nonrelativistic domain, because it can rely on the developments and practical use of the theory of functions and of partial differential equations. Heisenberg's "algebraic" approach has therefore a lesser role in solving concrete problems in (nonrelativistic) QM.

If one considers processes in which the number of particles may change in time, one is forced to

introduce a Hilbert space that accommodates states with an arbitrarily large number of particles, as is the case of the theory of relativistic quantized field or in quantum statistical mechanics; it is then more difficult to follow the line of Schrödinger, due to difficulties in handling spaces of functions of infinitely many variables. The approach of Heisenberg, based on the algebra of matrices, has a rather natural extension to suitable algebras of operators; the approach of Schrödinger, based on the description of a state as a (wave) function, encounters more difficulties since one must introduce functionals over spaces of functions and the description of dynamics does not have a simple form.

From this point of view, the generalization of Heisenberg's approach has led to much progress in the understanding of the structure of the resulting theory. Still some relevant results have been obtained in a Schrödinger representation. We shall not elaborate further on this point.

We shall end this introductory section with a short description of the emergence of the structure of QM in Heisenberg's and Schrödinger's approaches; this will provide a motivation for the axiom of QM which we shall introduce in the following section. For an extended analysis, see, for example, Jammer (1979).

The specific form that was postulated by de Broglie (1923) for the wave nature of a particle relies on the relation of geometrical optics with wave propagation and on the formulation of Hamiltonian mechanics as a sort of "wave front propagation" through the solution of the Hamilton–Jacobi equation and the introduction of group velocity.

By the analogy with electromagnetic wave, it is natural to associate with a free nonrelativistic particle of momentum $p$ and mass $m$ the plane wave

$$\phi_p(x,t) = e^{i(px-Et)/\hbar}, \quad \hbar = \frac{h}{2\pi}, \ E = \frac{p^2}{2m}$$

Schrödinger obtained the equation for a quantum particle in a field of conservative forces with potential $V(x)$ by considering an analogy with the propagation of an electromagnetic wave in a medium with refraction index $n(x,\omega)$ that varies slowly on the scale of the wavelength. Indeed, in this case the "wave" follows the laws of geometrical optics, and has therefore a "particle-like" behavior. If one denotes by $\hat{u}(x,\omega)$ the Fourier transom (with respect to time) of a generic component of the electric field and one assumes that the field be essentially monochromatic (so that the support of $\hat{u}(x,\omega)$ as a function of $\omega$ is in a very small neighborhood of $\omega_0$), one finds that $\hat{u}(x,\omega)$ is an approximate solution of the equation

$$-\Delta\hat{u}(x,\omega) = \frac{\omega_0^2}{c^2} n^2(x,\omega)\hat{u}(x,\omega) \qquad [1]$$

Writing $u(x,\omega) = A(x,\omega)\, e^{i(\omega/c)W(x,\omega)}$ the phase $W(x,\omega)$ satisfies, in the high-frequency limit, the eikonal equation $|\nabla W(x,\omega)|^2 = n^2(x,\omega)$. One can define for the solution a *phase velocity* $v_f$ and it turns out that $v_f = c/|\nabla W(x,\omega)|$.

On the other hand, classical mechanics can also be described by propagation of surfaces of constant value for the solution $W(x, t)$ of the Hamilton–Jacobi equation $H(x,\nabla W) = E$, with $H = p^2/2m + V(x)$. Recall that high-frequency (the realm of geometric optics) corresponds to small distances. This analogy led Schrödinger (1926) to postulate that the dynamics satisfied by the waves associated with the particles was given by the (Schrödinger) equation

$$i\hbar\frac{\partial\psi(x,t)}{\partial t} = -\frac{\hbar^2}{2m}\Delta_x\psi(x,t) + V(x)\psi(x,t) \qquad [2]$$

This wave was to describe the particle and its motion, but, being complex valued, it could not represent any measurable property. It is a mathematical property of the solutions of [2] that the quantity $\int|\psi(x,t)|^2\, d^3x$ is preserved in time. Furthermore, if one sets

$$\rho(x,t) \equiv |\psi(x,t)|^2$$

$$j(x,t) \equiv -i\frac{\hbar}{2m}[\bar{\psi}(x,t)\nabla\psi(x,t) - \psi(x,t)\nabla\bar{\psi}(x,t)] \qquad [3]$$

one easily verifies the local conservation law

$$\frac{\partial\rho}{\partial t} + \mathrm{div}\, j(x,t) = 0 \qquad [4]$$

These mathematical properties led to the statistical interpretation given by Max Born: in those experiments in which the position of the particles is measured, the integral of $|\psi(x,t)|^2$ over a region $\Omega$ of space gives the probability that at time $t$ the particle is localized in the region $\Omega$. Moreover, the current associated with a charged particle is given locally by $j(x,t)$ defined above.

Let us now briefly review Heisenberg's approach. At the heart of this approach are: empirical formulas for the intensities of emission and absorption of radiation (dispersion relations), Sommerfeld's quantum condition for the action and the vague statement "the analogue of the derivative for the discrete action variable is the corresponding finite difference quotient." And, most important, the remark that the correct description of atomic physics was through quantities associated with pairs of states, that is, (infinite) matrices and the

empirical fact that the frequency (or rather the wave number) $\omega_{k,j}$ of the radiation (emitted or absorbed) in the transition between the atomic levels $k$ and $j$ ($k \neq j$) satisfies the Ritz combination principle $\omega_{m,j} + \omega_{j,k} = \omega_{m,k}$. It easy to see that any doubly indexed family satisfying this relation must have the form $\omega_{m,k} = E_m - E_k$ for suitable constant $E_j$.

It was empirically verified by Kramers that the dipole moment of an atom in an external monochromatic external field with frequency $\nu$ was proportional to the field with a coefficient (of polarization)

$$P - \frac{e^2}{4\pi m} \sum_i \left[ \frac{f_i}{\nu_i^2 - \nu^2} - \frac{F_i}{\nu_i^2 - \nu^2} \right] \qquad [5]$$

where $e$, $m$ are the charge and the mass of the electron and $f_i, F_i$ are the probabilities that the frequency $\nu$ is emitted or absorbed.

A detailed analysis of the phenomenon of polarization in classical mechanics, with the clearly stated aim "of presenting the results in a way that may give hints for the construction of a New Mechanics" was made by Max Born (1924). He makes use of action-angle variables $\{J_i, \theta_i\}$ assuming that the atom can be considered as a collection of harmonic oscillators with frequency $\nu_i$ coupled linearly to the electric field of frequency $\mu$.

In the dipole approximation one obtains the following result for the polarization $P$ (linear response in energy to the electric field):

$$P = - \sum_{(\nu \cdot m) > 0} 2(m \cdot \nabla_J) \frac{|A(J)|^2 (\nu \cdot m)}{((m \cdot \nu)^2 - \mu} \qquad [6]$$

where $\nu_k = \partial H / \partial J_k$, $H$ is the interaction Hamiltonian), and $A(J)$ is a suitable matrix. In order to derive the new dynamics, having as a guide the correspondence principle, one has to compare this result with the Kramers dispersion relation, which we write (to make the comparison easier) in the form

$$P = \frac{e^2}{4\pi m} \sum_{n,m} \frac{f_{m,n}}{\nu_{n,m}^2 - \mu^2} - \frac{f_{n,m}}{\nu_{n,m}^2 - \mu^2} \qquad E_m > E_n \qquad [7]$$

Bohr's rule implies that $\nu(n + \tau, n) = (E(n + \tau - E(n))/\hbar$.

Born and Heisenberg noticed that, for $n$ sufficiently large and $k$ small, one can approximate the differential operator in [6] with the corresponding difference operator, with an error of the order of $k/n$. Therefore, [6] could be substituted by

$$P = - \hbar^{-1} \sum_{m_k > 0} \left[ \frac{|A_{n+m,n}|^2}{\nu(n+m)^2 - \mu^2} - \frac{|A_{n-m,n}|^2}{\nu(n-m)^2 - \mu^2} \right] \qquad [8]$$

The conclusion Born and Heisenberg drew is that the matrix $A$ that takes the place of the momentum in the classical theory must be such that $|A_{n+m,n}|^2 = e^2 \hbar m^{-1} f(n+m, n)$. In the same vein, considering the polarization in a static electric field, it is possible to find an expression for the matrix that takes the place of the coordinate $x$ in classical Hamiltonian theory.

In general, the new approach (matrix mechanics) associates matrices with some relevant classical observables (such as functions of position or momentum) with a time dependence that is derived from the empirical dispersion relations of Kramers, the correspondence principle, Bohr's rule, Sommerfeld action principle and first- (and second-) order perturbation theory for the interaction of an atom with an external electromagnetic field. It was soon clear to Born and Jordan (1925) that this dynamics took the form $i\hbar \dot{A} = AH - HA$ for a matrix $H$ that for the case of the hydrogen atom is obtained for the classical Hamiltonian with the prescription given for the coordinates $x$ and $p$. It was also seen as plausible the relation $[\hat{x}_h, \hat{p}_k] = \mathrm{i}I$ among the matrices $\hat{x}_k$ and $\hat{p}_k$ corresponding to position and momentum. One year later P Dirac (1926) pointed out the structural identity of this relation with the Poisson bracket of Hamiltonian dynamics, developed a "quantum algebra" and a "quantum differentiation" and proved that any $^*$-derivation $\delta$ (derivation which preserves the adjoint) of the algebra $\mathcal{B}_N$ of $N \times N$ matrices is inner, that is, is given by $\delta(a) = \mathrm{i}[a, h]$ for a Hermitian matrix $h$. Much later this theorem was extended (with some assumptions) to the algebra of all bounded operators on a separable Hilbert space. Since the derivations are generators of a one-parameter continuous group of automorphisms, that is, of a dynamics, this result led further strength to the ideas of Born and Heisenberg.

The algebraic structure introduced by Born, Jordan, and Heisenberg (1926) was used by Pauli (1927) to give a purely group-theoretical derivation of the spectrum of the hydrogen atom, following the lines of the derivation in symplectic mechanics of the SO(4) symmetry of the Coulomb system. This remarkable success gave much strength to the Heisenberg formulation of QM, which was soon recognized as an efficient instrument in the study of the atomic world.

The algebraic formulation was also instrumental in the description given by Pauli (1928) of the "spin" (a property of electrons empirically postulated by Goudsmidt and Uhlenbeck to account for a hyperfine splitting of some emission lines) as "internal" degree of freedom without reference to spatial coordinates and still connected with the

properties of the the system under the group of spatial rotations. This description through matrices has a major role also in the formulation by Pauli of the exclusion principle (and its relation with Fermi–Dirac statistics), which gave further credit to the Heisenberg's theory by helping in reproducing correctly the classification of the atoms.

These features may explain why the "standard" formulation of the axioms of QM given in the next section shows the influence of Heisenberg's approach. On the other hand, comparison with experiments is usually set in the framework in Schrödinger's approach. Posing the problems in terms of properties of the solution of the Schrödinger equation, one is led to a pragmatic use of the formalism, leaving aside difficulties of interpretation. This separation of "the axioms" from the "practical use" may be one of the reasons why a serious analysis of the axioms and of the problems that arise from them is apparently not a concern for most of the research in QM, even from the point of view of mathematical physics.

One should stress that both the approach of Born and Heisenberg and that of de Broglie and Schrödinger are rooted in a mixture of attention to the experimental data, deep understanding of the previous theory, bold analogies and approximations, and deep concern for the consistency of the "new mechanics."

There is an essential difference between the starting points of the two approaches. In Heisenberg's approach, the atom has *a priori* no spatial structure; the description is entirely in terms of its properties under emission and absorption of light, and therefore its observable quantities are represented by matrices. Dynamics enters through the study of the interaction with the electromagnetic field, and some analogies with the classical theory of electrodynamics in an asymptotic regime (correspondence principle). In this way, as we have briefly indicated, the special role of some matrices, which have a mutual relation similar to the relation of position and momentum in Hamiltonian theory. Following this analogy, it is possible to extend the theory beyond its original scope and consider phenomena in which the electrons are not bound to an atom.

In the approach of Schrödinger, on the other hand, particles and collections of particles are represented by spatial structures (waves). Spatial coordinates are therefore introduced *a priori*, and the position of a particle is related to the intensity of the corresponding wave (this was stressed by Born). Position and momentum are both basic measurable quantities as in classical mechanics. Physical interpretation forces the particle wave to be square integrable, and mathematics provides a limitation on the simultaneous localization in momentum and position leading to Heisenberg's uncertainty principle. Dynamics is obtained from a particle–wave duality and an analogy with the relativistic wave equation in the low-energy regime. The presence of bound states with quantized energies is seen as a consequence of the well-known fact that waves confined to a bounded spatial region have their wave number (and therefore energy) quantized.

## Formal Structure

In this section we describe the formal mathematical structure that is commonly associated with QM. It constitutes a coherent mathematical theory, but the interpretation axiom it contains leads to conceptual difficulties.

We state the axioms in the form in which they were codified by J von Neumann (1966); they constitute a mathematically precise rendering of the formalism of Born, Heisenberg, and Jordan. The formalism of Schrödinger *per se* does not require general statements about the category of observables.

**Axiom I**

(i) Observables are represented by self-adjoint operators in a complex separable Hilbert space $\mathcal{H}$.
(ii) Every such operator represents an observable.

**Remark** Axiom I (ii) is introduced only for mathematical simplicity. There is no physical justification for part (ii). In principle, an observable must be connected to a procedure of measurement (observation) and for most of the self-adjoint operators on $\mathcal{H}$ (e.g., in the Schrödinger representation for $\mathrm{i}x_k(\partial/\partial x_h)x_k$) such procedure has not yet been given).

**Axiom II**

(i) Pure states of the systems are represented by normalized vectors in $\mathcal{H}$.
(ii) If a measurement of the observable $A$ is made on a system in the state represented by the element $\phi \in \mathcal{H}$, the average of the numerical values one obtains is $<\phi, A\phi>$, a real number because $A$ is self-adjoint (we have denoted by $<\phi, \psi>$ the scalar product in $\mathcal{H}$).

**Remark** Notice that Axiom II makes no statement about the outcome of a single measurement.

Using the natural complex structure of $\mathcal{B}(\mathcal{H})$, pure states can be extended as linear real functionals on $\mathcal{B}(\mathcal{H})$.

One defines a state as any linear real positive functional on $\mathcal{B}(\mathcal{H})$ (all bounded operators on the separable Hilbert space $\mathcal{H}$) and says that a state is normal if it is continuous in the strong topology. It can be proved that a normal state can be decomposed into a convex combination of at most a denumerable set of pure states. With these definitions a state is pure iff it has no nontrivial decomposition. It is worth stressing that this statement is true only if the operators that correspond to observable quantities generate all of $\mathcal{B}(\mathcal{H})$; one refers to this condition by stating that there are no superselection rules.

By general results in the theory of the algebra $\mathcal{B}(\mathcal{H})$, a normal state $\rho$ is represented by a positive operator of trace class $\sigma$ through the formula $\rho(A) = Tr(\sigma A)$. Since a positive trace-class operator (usually referred to as density matrix in analogy with its classical counterpart) has eigenvalues $\lambda_k$ that are positive and sum up to 1, the decomposition of the normal state $\rho$ takes the form $\sigma = \sum_k \lambda_k \Pi_k$, where $\Pi_k$ is the projection operator onto the $k$th eigenstate (counting multiplicity).

It is also convenient to know that if a sequence of normal states $\sigma_k$ on $\mathcal{B}(\mathcal{H})$ converges weakly (i.e., for each $A \in \mathcal{B}(\mathcal{H})$ the sequence $\sigma_k(A)$ converges) then the limit state is normal. This useful result is false in general for closed subalgebras of $\mathcal{B}(\mathcal{H})$, for example, for algebras that contain no minimal projections.

Note that no pure state is dispersion free with respect to all the observables (contrary to what happens in classical mechanics). Recall that the dispersion of the state $\rho_\sigma$ with respect to the observable $A$ is defined as $\Delta_\sigma(A) \equiv \sigma(A^2) - (\sigma(A))^2$.

The connection of the state with the outcome of a single measurement of an observable associated with an operator $A$ is given by the following axiom, which we shall formulate only for the case when the self-adjoint operator $A$ has only discrete spectrum. The generalization to the other case is straightforward but requires the use of the spectral projections of $A$.

**Axiom III**

(i) If $A$ has only discrete spectrum, the possible outcomes of a measurement of $A$ are its eigenvalues $\{a_k\}$.

(ii) If the state of the system immediately before the measurement is represented by the vector $\phi \in \mathcal{H}$, the probability that the outcome be $a_k$ is $\sum_h |<\psi, \phi_h^{A;k}>|$, where $\phi_h^{A;k}$ are a complete orthonormal set in the Hilbert space spanned by the eigenvectors of $A$ to the eigenvalue $a_k$.

(iii) If a system is in the pure state $\phi$ and one performs a measurement of the observable $A$ with outcome $a_j \in (b-\delta, b+\delta)$ for some $b, \delta \in R$ then immediately after the measurement the system can be in any (not necessarily pure) state which lies in the convex hull of the pure states which are in the spectral subspace of the operator $A$ in the interval $\Delta_{b;\delta} \equiv (b-\delta, b+\delta)$.

*Note* Statements (ii) and (iii) can be extended without modification to the case in which the initial state is not a pure state, and is represented by a density matrix $\sigma$.

**Remark 1** Axiom III makes sure that if one performs, immediately after the first, a further measurement of the same observable $A$ the outcome will still lie in the interval $\Delta_{b;\delta}$. This is needed to give some objectivity to the statement made about the outcome; notice that one must place the condition "immediately after" because the evolution may not leave invariant the spectral subspaces of $A$. If the operator $A$ has, in the interval $\Delta_{b;\delta}$, only discrete (pure point) spectrum, one can express Axiom III in the following way: the outcome can be any state that can be represented by a convex affine superposition of the eigenstates of $A$ with eigenvalues contained in $\Delta_{b;\delta}$.

In the very special case when $A$ has only one eigenvalue in $\Delta_{b;\delta}$ and this eigenvalue is not degenerate, one can state Axiom III in the following form (commonly referred to as "reduction of the wave packet"): the system after the measurement is pure and is represented by an eigenstate of the operator $A$.

**Remark 2** Notice that the third axiom makes a statement about the state of the system after the measurement is completed.

It follows from Axiom III that one can measure "simultaneously" only observables which are represented by self-adjoint operators that commute with each other (i.e., their spectral projections mutually commute). It follows from the spectral representation of the self-adjoint operators that a family $\{A_k\}$ of commuting operators can be considered (i.e., there is a representation in which they are) functions over a common measure space.

Axioms I–III give a mathematically consistent formulation of QM and allow a statistical description (and statistical prediction) of the outcome of the measurement of any observable. It is worth remarking that while the predictions will have only a statistical nature, the dynamical evolution of the observables (and by duality of the states) will be described by deterministic laws. The intrinsically statistical aspect of the predictions comes only from

the third postulate, which connects the mathematical content of the theory with the measurement process.

The third axiom, while crucial for the connection of the mathematical formalism with the experimental data, contains the seed of the conceptual difficulties which plague QM and have not been cured so far.

Indeed, the third axiom indicates that the process of measurement is described by laws that are intrinsically different from the laws that rule the evolution without measurement. This privileged role of the changing by effect of a measurement leads to serious conceptual difficulties since the changing is independent of whether or not the result is recorded by some observer; one should therefore have a way to distinguish between measurements and generic interactions with the environment.

A related problem that is originated by Axiom III is that the formulation of this axiom refers implicitly to the presence of a classical observer that certifies the outcomes of measurements and is allowed to make use of classical probability theory. This observer is not subjected therefore to the laws of QM.

These two aspects of the conceptual difficulties have their common origin in the separation of the measuring device and of the measured systems into disjoint entities satisfying different laws. The difficulties in the theory of measurement have not yet received a satisfactory answer, but various attempts have been made, with various degree of success, and some of them are described briefly in the section "Interpretation problems." It appears therefore that QM in its present formulation is a refined and successful instrument for the description of the nonrelativistic phenomena at the Planck scale, but its internal consistency is still standing on shaky ground.

Returning to the axioms, it is worth remarking explicitly that according to Axiom II a state is a linear functional over the observables, but it is represented by a sesquilinear function on the complex Hilbert space $\mathcal{H}$. Since Axiom II states that any normalized element of $\mathcal{H}$ represents a state (and elements that differ only by a phase represent the same state) together with $\phi, \gamma$ also $\xi \equiv a\phi + b\psi$, $|a|^2 + |b|^2 = 1$ represent a state superposition of $\phi$ and $\psi$ (superposition principle).

But for an observable $A$, one has in general $\rho_\xi(A) \neq |a|^2 \rho_\phi(A) + |b|^2 \rho_\psi(A)$, due to the cross-terms in the scalar product. The superposition principle is one of the characteristic features of QM. The superposition of the two pure states $\phi$ and $\psi$ has properties completely different from those of a statistical mixture of the same two states, defined by the density matrix $\sigma = |a|^2 \Pi_\phi + |b|^2 \Pi_\psi$, where we have denoted by $\Pi_\phi$ the orthogonal projection onto the normalized vector $\phi$. Therefore, the search for these interference terms is one of the means to verify the predictions of QM, and their smallness under given conditions is a sign of quasiclassical behavior of the system under study.

Strictly connected to superposition are entanglement and the partial trace operation. Suppose that one has two systems which when considered separately are described by vectors in two Hilbert spaces $\mathcal{H}_i, i = 1, 2$, and which have observables $A_i \in \mathcal{B}(\mathcal{H}_i)$. When we want to study their mutual interaction, it is natural to describe both of them in the Hilbert space $\mathcal{H}_1 \otimes \mathcal{H}_2$ and to consider the observables $A_1 \otimes I$ and $I \otimes A_2$.

When the systems interact, the interaction will not in general commute with the projection operator $\Pi_1$ onto $\mathcal{H}_1$. Therefore, even if the initial state is of the form $\phi_1 \otimes \phi_2, \phi_i \in \mathcal{H}_i$, the final state (after the interaction) is a vector $\xi \in \mathcal{H}_1 \otimes \mathcal{H}_2$ which cannot be written as $\xi = \zeta_1 \otimes \zeta_2$ with $\zeta_i \in \mathcal{H}_i$. It can be shown, however, that there always exist two orthonormal family vectors $\phi_n \in \mathcal{H}_1$ and $\psi_n \in \mathcal{H}_2$ such that $\xi = \sum c_n \phi_n \otimes \psi_n$ for suitable $c_n \in C$, $\sum |c_n|^2 = 1$ (this decomposition is not unique in general).

Recalling that $\rho_{\phi\otimes\psi}(A_1 \otimes I) = \rho_\phi(A_1)$, one can write

$$\rho_\xi(A_1 \otimes I) = \sum |c_n|^2 \rho_{\zeta_n}(A_1) = \rho_\sigma(A_1)$$
$$\sigma \equiv \sum_n |c_n|^2 \Pi_{\phi_n}$$

The map $\Gamma_2 : \rho_\xi \to \rho_{\sigma_1}$ is called reduction or also conditioning) with respect to $\mathcal{H}_2$; it is also called "partial trace" with respect to $\mathcal{H}_2$. The first notation reflects the analogy with conditioning in classical probability theory.

The map $\Gamma_2$ can be extended by linearity to a map from normal states (density matrices) on $\mathcal{B}(\mathcal{H}_1 \otimes \mathcal{H}_2)$ to normal states on $\mathcal{B}(\mathcal{H}_1)$ and gives rise to a positivity-preserving and trace-preserving map.

One can in fact prove (Takesaki 1971) that any conditioning for normal states of a von Neumann algebra $\mathcal{M}$ is completely positive in the sense that it remains positive after tensorization of $\mathcal{M}$ with $\mathcal{B}(\mathcal{K})$, where $\mathcal{K}$ is an arbitrary Hilbert space.

It can also be proved that a partial converse is true, that is, that every completely positive trace-preserving map $\Phi$ on normal states of a von Neumann algebra $\mathcal{A} \subset \mathcal{B}(\mathcal{H})$ can be written, for a suitable choice of a larger Hilbert space $\mathcal{K}$ and partial isometries $V_k$, in the form (Kraus form) $\Phi(a) = \sum_k V_k^* a V_k$.

But it must be remarked that, if $U(t)$ is a one-parameter group of unitary operators on $\mathcal{H}_1 \otimes \mathcal{H}_2$ and $\sigma$ is a density matrix, the one-parameter family of maps $\Gamma(t) \equiv \sigma \to \Gamma_2(U(t)\sigma U^*(t))$ does not, in general, have the semigroup property $\Gamma(t+s) = \Gamma(t) \cdot \Gamma(s)$ $s, t > 0$ and therefore there is in general no generator (of a reduced dynamics) associated with it. Only in special cases and under very strong hypothesis and approximations is there a reduced dynamics given by a semigroup (Markov property).

Since entanglement and (nontrivial) conditioning are marks of QM, and on the other side the Markov property described above is typical of conditioning in classical mechanics, it is natural to search for conditions and approximations under which the Markov property is recovered, and more generally under which the coherence properties characteristic of QM are suppressed (decoherence). We shall discuss briefly this problem in the section "Interpretation problems," devoted to the attempts to overcome the serious conceptual difficulties that descend from Axiom III.

It is seen from the remarks and definitions above that normal states (density matrices) play the role that in classical mechanics is attributed to measures over phase space, with the exception that pure states in QM do not correspond to Dirac measures (later on we shall discuss the possibility of describing a quantum-mechanical states with a function (Wigner function) on phase space).

In this correspondence, evaluation of an observable (a measurable function over phase space) over a state (a normalized, positive measure) is related to finding the (Hilbert space) trace of the product of an operator in $\mathcal{B}(\mathcal{H})$ with a density matrix. Notice that the trace operation shares some of the properties of the integral, in particular $\operatorname{tr} AB = \operatorname{tr} BA$ if $A$ is in trace class and $B \in \mathcal{B}(\mathcal{H})$ (cf. $g \in L^1$ and $f \in L^\infty$) and $\operatorname{tr} AB > 0$ if $A$ is a density matrix and $B$ is a positive operator. This suggests to define functions over the density matrices that correspond to quantities which are important in the theory of dynamical systems, in particular the entropy.

This is readily done if the Hilbert space is finite dimensional, and in the infinite-dimensional case if one takes as observables all Hermitian bounded operators. In quantum statistical mechanics one is led to consider an infinite collection of subsystems, each one described with a Hilbert space (finite or infinite dimensional) $\mathcal{H}_i, i = 1, 2, \ldots$, the space of representation is a subspace $\mathcal{K}$ of $\mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \cdots$, and the observables are a (weakly closed) subalgebra $\mathcal{A}$ of $\mathcal{B}(\mathcal{K})$ (typically constructed as an inductive limit of elements of the form $I \otimes I \cdots \otimes A_k \otimes I \cdots$). In this context one also considers normal states on $\mathcal{A}$ and defines a trace operation, with the properties described above for a trace. Most of the definitions (e.g., of entropy) can be given in this enlarged context, but differences may occur, since in general $\mathcal{A}$ does not contain finite-dimensional projections, and therefore the trace function is not the trace commonly defined in a Hilbert space. We shall not describe further this very interesting and much developed theory, of major relevance in quantum statistical mechanics. For a thorough presentation see Ohya and Petz (1993).

The simplest and most-studied example is the case when each Hilbert space $\mathcal{H}_i$ is a complex two-dimensional space. The resulting system is constructed in analogy with the Ising model of classical statistical mechanics, but in contrast to that system it possesses, for each value of the index $i$, infinitely many pure states. The corresponding algebra of observables is a closed subalgebra of $(C^2 \times C^2)^{\otimes Z}$ and generically does not contain any finite-dimensional projection.

This model, restricted to the case $(C^2 \times C^2)^K$, $K$ a finite integer, has become popular in the study of quantum information and quantum computation, in which case a normalized element of $\mathcal{H}_i$ is called a q-bit (in analogy with the bits of information in classical information theory). It is clear that the unit sphere in $(C^2 \times C^2)$ contains many more than four points, and this gives much more freedom for operations on the system. This is the basis of quantum computation and quantum information, a very interesting field which has received much attention in recent years.

## Quantization and Dynamics

The evolution in nonrelativistic QM is described by the Schrödinger equation in the representation in which for an $N$-particle system the Hilbert space is $L^2(R^{3N} \otimes C^k$, where $C^k$ is a finite-dimensional space which accounts for the fact that some of the particles may have a spin content.

Apart from (often) inessential parameters, the Schrödinger equation for spin-0 particles can be written typically as

$$
\begin{aligned}
&\mathrm{i}\hbar \frac{\partial \phi}{\partial t} = H\phi \\
&\quad H \equiv \sum_{k=1}^{N} m_k (\mathrm{i}\hbar \nabla_k + A_k)^2 \\
&\qquad + \sum_{k=1}^{N} V_k(x_k) + \sum_{i \neq k, 1}^{N} V_{i,k}(x_i - x_k)
\end{aligned} \qquad [9]
$$

where $\hbar$ is Planck's constant, $A_k$ are vector-valued functions (vector potentials), and $V_k$ and $V_{i,k}$ are scalar-valued function (scalar potentials) on $R^3$.

If some particles have of spin 1/2, the corresponding kinetic energy term should read $-(\mathrm{i}\hbar\sigma\cdot\nabla)^2$, where $\sigma_k$, $k=1, 2, 3$, are the Pauli matrices and one must add a term $W(x)$ which is a matrix field with values in $C^k\otimes C^k$ and takes into account the coupling between the spin degrees of freedom. Notice that the local operator $\mathrm{i}\sigma\cdot\nabla$ is a "square root" of the Laplacian.

A relativistic extension of the Schrödinger equation for a free particle of mass $m\geq 0$ in dimension 3 was obtained by Dirac in a space of spinor-valued functions $\psi_k(x,t), k=0,1,2,3$, which carries an irreducible representation of the Lorentz group. In analogy with the electromagnetic field, for which a linear partial differential equation (PDE) can be written using a four-dimensional representation of the Lorentz group, the relativistic Dirac equation is the linear PDE

$$\mathrm{i}\sum_{k=0}^{3}\gamma_k\frac{\partial}{\partial x_k}\psi=m\psi,\quad x_0\equiv ct$$

where the $\gamma_k$ generate the algebra of a representation of the Lorentz group. The operator $\sum(\partial/\partial x_k)\gamma_k$ is a local square root of the relativistically invariant d'Alembert operator $-\partial^2/\partial x_0^2+\Delta-m\cdot I$.

When one tries to introduce (relativistically invariant) local interactions, one faces the same problem as in the classical mechanics, namely one must introduce relativistically covariant fields (e.g., the electromagnetic field), that is, systems with an infinite number of degrees of freedom. If this field is considered as external, one faces technical problems, which can be overcome in favorable cases. But if one tries to obtain a fully quantized theory (by also quantizing the field) the obstacles become unsurmountable, due also to the nonuniqueness of the representation of the canonical commutation relations if these are taken as the basis of quantization, as in the finite-dimensional case.

In a favorable case (e.g., the interaction of a quantum particle with the quantized electromagnetic field) one can set up a perturbation scheme in a parameter $\alpha$ (the physical value of $\alpha$ in natural units is roughly 1/137). We shall come back later to perturbation schemes in the context of the Schrödinger operator; in the present case one has been able to find procedures (renormalization) by which the series in $\alpha$ that describe relevant physical quantities are well defined term by term. But even in this favorable case, where the sum of the first few terms of the series is in excellent agreement with the experimental data, one has reasons to believe that the series is not convergent, and one does not even know whether the series is asymptotic.

One is led to wonder whether the structure of fields (operator-valued elements in the dual of compactly supported smooth functions on classical spacetime), taken over in a simple way from the field structure of classical electromagnetism, is a valid instrument in the description of phenomena that take place at a scale incomparably smaller than the scale (atomic scale) at which we have reasons to believe that the formalisms of Schrödinger and Heisenberg provide a suitable model for the description of natural phenomena.

The phenomena which are related to the interaction of a quantum nonrelativistic particle interacting with the quantized electromagnetic field take place at the atomic scale. These phenomena have been the subject of very intense research in theoretical physics, mostly within perturbation theory, and the analysis to the first few orders has led to very spectacular results (although there is at present no proof that the perturbation series are at least asymptotic).

In this field rigorous results are scarce, but recently some progress has been made, establishing, among other things, the existence of the ground state (a nontrivial result, because there is no gap separating the ground-state energy from the continuous part of the spectrum) and paving the way for the description of scattering phenomena; the latter result is again nontrivial because the photon field may lead to an anomalous infrared (long-range) behavior, much in the same way that the long-range Coulomb interaction requires a special treatment in nonrelativistic scattering theory.

This contribution to the Encyclopedia is meant to be an introduction to QM and therefore we shall limit ourselves to the basic structure of nonrelativistic theory, which deals with systems of a finite number of particles interacting among themselves and with external (classical) potential fields, leaving for more specialized contributions a discussion of more advanced items in QM and of the successes and failures of a relativistically invariant theory of interaction between quantum particles and quantized fields.

We shall return therefore to basics.

One may begin a section on dynamics in QM by discussing some properties of the solutions of the Schrödinger equation, in particular dispersive effects and the related scattering theory, the problem of bound states and resonances, the case of time-dependent perturbation and the ionization effect, the binding of atoms and molecules, the Rayleigh scattering, the Hall effect and other effects in nanophysics, the various multiscale and adiabatic limits, and in general all the physical problems that

have been successfully solved by Schrödinger's QM (as well as the very many interesting and unsolved problems).

We will consider briefly these issues and the approximation schemes that have been developed in order to derive explicit estimates for quantities of physical interest. Since there are very many excellent reviews of present-day research in QM (e.g., Araki and Ezawa (2004), Blanchard and Dell'Antonio (2004), Cycon *et al.* (1986), Islop and Sigal (1996), Lieb (1990), Le Bris (2005), Simon (2002), and Schlag (2004)) we refer the reader to the more specialized contributions to this Encyclopedia for a detailed analysis and precise statements about the results.

We prefer to come back first to the foundations of the theory; we shall take the point of view of Heisenberg and start discussing the mapping properties of the algebra of observables and of the states. Since transition probabilities play an important role, we consider only transformations $\alpha$ which are such that, for any pair of pure states $\phi_1$ and $\phi_2$, one has $<\alpha(\phi_1), \alpha(\phi_2)> = <\phi_1, \phi_2>$. We call these maps Wigner automorphisms.

A result of Wigner (see Weyl (1931)) states that if $\alpha$ is a Wigner automorphism then there exists a unique operator $U_\alpha$, either unitary or antiunitary, such that $\alpha(P) = U^*_\alpha P U_\alpha$ for all projection operators. If there is a one-parameter group of such automorphisms, the corresponding operators are all unitary (but they need not form a group).

A generalization of this result is due to Kadison. Denoting by $I_{1,+}$ the set of density matrices, a Kadison automorphism $\beta$ is, by definition, such that for all $\sigma_1, \sigma_2 \in I_{1,+}$ and all $0 < s < 1$ one has $\beta(s\sigma_1 + (1-s)\sigma_2) = s\beta(\sigma_1) + (1-s)\beta(\sigma_2)$. For Kadison automorphisms the same result holds as for Wigner's.

A similar result holds for automorphisms of the observables. Notice that the product of two Hermitian operators is not Hermitian in general, but Hermiticity is preserved under Jordan's product defined as $A \times B \equiv (1/2)[AB + BA]$.

A Segal automorphism is, by definition, an automorphism of the Hermitian operators that preserves the Jordan product structure. A theorem of Segal states that $\gamma$ is a Segal automorphism if and only if there exist an orthogonal projector $E$, a unitary operator $U$ in $E\mathcal{H}$, and an antiunitary operator $V$ in $(I-E)\mathcal{H}$ such that $\gamma(A) = WAW^*$, where $W \equiv U \oplus V$.

We can study now in more detail the description of the dynamics in terms of automorphism of Wigner or Kadison type when it refers to states and of Segal type when it refers to observables. We require that the evolution be continuous in suitable topologies. The strongest result refers to Wigner's case. One can prove that if a one-parameter group of Wigner automorphism $\alpha_t$ is measurable in the weak topology (i.e., $\alpha_t\sigma(A)$ is measurable in $t$ for every choice of $A$ and $\sigma$) then it is possible to choose the $U(t)$ provided by Wigner's theorem in such a way that they form a group which is continuous in the strong topology. Similar results are obtained for the cases of Kadison and Segal automorphism, but in both cases one has to assume continuity of $\alpha_t$ in a stronger topology (the strong operator topology in the Segal case, the norm topology in Kadison's). Weak continuity is sufficient if the operator product is preserved (in this case one speaks of automorphisms of the algebra of bounded operators). The existence of the continuous group $U(t)$ defines a Hamiltonian evolution. One has indeed:

**Theorem 1** (Stone). *The map $t \to U(t), t \in R$ is a weakly continuous representation of $R$ in the set of unitary operators in a Hilbert space $\mathcal{H}$ if and only if there exists a self-adjoint operator $H$ on (a dense set of) $\mathcal{H}$ such that $U(t) = \mathrm{e}^{itH}$ and therefore*

$$\phi \in D(H) \to \mathrm{i}\frac{dU(t)}{dt}\phi = HU(t)\phi \qquad [10]$$

*The operator $H$ is called generator of the dynamics described by $U(t)$.*

*Note* In Schrödinger's approach the operator described in Stone's theorem is called Hamiltonian, in analogy with the classical case. In the case of one particle of mass $m$ in $R^3$ subject to a conservative force with potential energy $V(x)$ it has the following form, in units in which $\hbar = 1$:

$$H = -\frac{1}{2m}\Delta + V(x), \quad \Delta = \sum_k \frac{\partial^2_{x_k}}{\partial x_k^2} \qquad [11]$$

If the potential $V$ depends on time, Stone's theorem is not directly applicable but still the spectral properties of the self-adjoint operators $H_t$ and of the Kernel of the group $\tau \to \mathrm{e}^{\mathrm{i}H_t\tau}$ are essential to solve the (time-dependent) Schrödinger equation.

The semigroup $t \to \mathrm{e}^{-tH_0}$ is usually a positivity-preserving semigroup of contractions and defines a Markov process; in favorable cases, the same is true of $t \to \mathrm{e}^{-tH}$ (Feynmann–Kac formula).

There is an analogous situation in the general theory of dynamical systems on a von Neumann algebra; in analogy with the case of elliptic operators, one defines as "dissipation" a map $\Delta$ on a von Neumann algebra $\mathcal{M}$ which satisfies $\Delta(a^*a) \geq a^*\Delta(a) + \Delta(a^*)a$ for all $a \in \mathcal{M}$. The positive dissipation $\Delta$ is called completely positive if it remains positive after tensorization with $\mathcal{B}(\mathcal{K})$ for any

Hilbert space $\mathcal{K}$. Notice that according to this definition every $^*$-derivation is a completely positive dissipation. For dissipations there is an analog of the theorem of Stinespring, and often bounded dissipation can be written as

$$\Delta(a) = \mathrm{i}[h, a] + \sum V_k^* a V_k - \left(\frac{1}{2}\right) \sum \{V_k^* V_k, a\} \quad \text{for } a \in \mathcal{M}$$

(the symbols $\{.,.\}$ denote the anticommutator).

In general terms, by quantization is meant the construction of a theory by deforming a commutative algebra of functions on a classical phase $X$ in such a way that the dynamics of the quantum system can be derived from the prescription of deformation, usually by deforming the Poisson brackets if $X$ is a cotangent bundle $T^*\mathcal{M}$ (Halbut 2002, Landsman 2002). We shall discuss only the Weyl quantization (Weyl 1931) that has its roots in Heisenberg's formulation of QM and refers to the case in which the configuration space is $R^N$, or, with some variant (Floquet–Zak) the $N$-dimensional torus. We shall add a few remarks on the Wick (anti-Weyl) quantization. More general formulations are needed when one tries to quantize a classical system defined on the cotangent bundle of a generic variety and even more so if it defined on a generic symplectic manifold.

The Weyl quantization is a mathematically accurate rendering of the essential content of the procedure adopted by Born and Heisenberg to construct dynamics by finding operators which play the role of symplectic coordinates.

Consider a system with one degree of freedom. The first naive attempt would be to find operators $\hat{q}, \hat{p}$ that satisfy the relation

$$[\hat{q}, \hat{p}] \subset \mathrm{i}I \qquad [12]$$

and to construct the Hamiltonian in analogy with the classical case. To play a similar role, the operators $\hat{q}$ and $\hat{p}$ must be self-adjoint and satisfy [12] at least in a weak sense. If both are bounded, [12] implies $\mathrm{e}^{-\mathrm{i}b\hat{p}}\hat{q}\mathrm{e}^{-\mathrm{i}b\hat{p}} = \hat{q} + bI$ (the exponential is defined through a convergent series) and therefore the spectrum of $\hat{q}$ is the entire real line, a contradiction. Therefore, that inclusion sign in [12] is strict and we face domain problems, and as a consequence [12] has many inequivalent solutions ("equivalence" here means "unitary equivalence").

Apart from "pathological" ones, defined on $L^2$-spaces over multiple coverings of $R$, there are inequivalent solutions of [12] which are effectively used in QM.

The most common solution is on the Hilbert space $L^2(R)$ (with Lebesgue measure), with $\hat{x}$ defined as the essentially self-adjoint operator that acts on the smooth functions with compact support as multiplication by the coordinate $x$ and $\hat{p}$ is defined similarly in Fourier space. This representation can be trivially generalized to construct operators $\hat{q}_k$ and $\hat{p}_k$ in $L^2(R^N)$.

Another frequently used representation of [12] is on $L^2(S^1)$ (and when generalized to $N$ degrees of freedom, on $T^N$). In this representation, the operator $\hat{p}$ is defined by $c_k \to kc_k$ on functions $f(\theta) = \sum_{k=-M}^{N} c_k \mathrm{e}^{\mathrm{i}k\theta/2\pi}, 0 \geq M, N < \infty$. In this case the operator $\hat{q}$ is defined as multiplication by the angle coordinate $\theta$. It is easy to check that this representation is inequivalent to the previous one and that [12] is satisfied (as an identity) on the (dense) set of vectors which are in the domain both of $\hat{p}\hat{q}$ and of $\hat{q}\hat{p}$. But notice that the domain of essential self-adjointness of $\hat{p}$ is not left invariant by the action of $\hat{q}$ ($\theta f(\theta)$ is a function on $S^1$ only if $f(2\pi) = 0$).

We shall denote $\hat{p}$ in this representation by the symbol $\partial/\partial\theta_{\mathrm{per}}$ and refer to it as the Bloch representation. It can be modified by setting the action of $\hat{p}$ as $c_n \to nc_n + \alpha, 0 < \alpha < 2\pi$, and this gives rise to the various Bloch–Zak and magnetic representations.

The Bloch representation can be extended to periodic functions on $R^1$ noticing that $L^2(R) = L^2(S^1) \otimes l^2(N)$; similarly, the Bloch–Zak and the magnetic representation can be extended to $L^2(R^N)$.

The difference between the representations can be seen more clearly if one considers the one-parameter groups of unitary operators generated by the "canonical operators" $\hat{q}$ and $\hat{p}$. In the Schrödinger representation on $L^2(R)$, these groups satisfy

$$U(a)V(b) = \mathrm{e}^{\mathrm{i}ab}V(b)U(a)$$
$$U(a) = \mathrm{e}^{\mathrm{i}a\hat{q}}, \qquad V(b) = \mathrm{e}^{\mathrm{i}b\hat{p}}$$

and therefore, setting $z = a + \mathrm{i}b$ and $W(z) \equiv \mathrm{e}^{-\mathrm{i}ab/2}V(b)U(a)$ one has

$$W(z)W(z') = \mathrm{e}^{-\mathrm{i}\omega(z,z')/2}W(z+z') \qquad z \in C, \quad \omega(z,z') = \mathrm{Im}(\bar{z}, z') \qquad [13]$$

The unitary operators $W(z)$ are therefore projective representations of the additive group $C$. This generalizes immediately to the case of $N$ degrees of freedom; the representation is now of the additive group $C^N$ and $\omega$ is the standard symplectic form on $C^N$.

In the Bloch representation, the unitaries $U(a)V(b)U^*(a)V^*(b)$ are not multiples of the identity, and have no particularly simple form. The map $C^N \ni z \to W(z)$ with the structure [13] is called Weyl system; it plays a major role in QM. The following

theorem has therefore a major importance in the mathematical theory of QM.

**Theorem 2** (von Neumann 1965). *There exists only one, modulo unitary equivalence, irreducible representation of the Weil system.*

The proof of this theorem follows a general pattern in the theory of group representations. One introduces an algebra $\mathcal{W}^{(N)}$ of operators

$$W_f \equiv \int f(z) W(z) \mathrm{d}z, \quad f \in L^1(C^N)$$

called Weyl algebra.

It easy to see that $|W_f| = |f|_1$ and that $f \to W_f$ is a linear isomorphism of algebras if one considers $\mathcal{W}^{(N)}$ with its natural product structure and $L^1$ as a noncommutative algebra with product structure

$$f * g \equiv \int \mathrm{d}z' f(z - z') g(z') \exp \frac{\mathrm{i}}{2} \omega(z, z') \qquad [14]$$

So far the algebra $\mathcal{W}^{(N)}$ is a concrete algebra of bounded operators on $L^2(R^2)$. But it can also be considered an abstract $C^*$-algebra which we still denote by $\mathcal{W}^{(N)}$.

It is easy to see that, according to [14], if $f_0$ is chosen to be a suitable Gaussian, then $W_{f_0}$ is a projection operator which commutes with all the $W_f$'s. Moreover, $W_f W_g = \phi_{f,g} W_{f*g}$ for a suitable phase factor $\phi$. Considering the Gelfand–Neumark–Segal construction for the $C^*$-algebra $\mathcal{W}^{(N)}$, one finds that these properties lead to a decomposition of any representation in cyclic irreducible equivalent ones, completing the proof of the theorem.

The Weyl system has a representation (equivalent to the Schrödinger one) in the space $L^2(R^N, g)$, where $g$ is Gauss's measure. This allows an extension in which $C^N$ is replaced by an infinite-dimensional Banach space equipped with a Gauss measure (weak distribution (Segal 1965, Gross 1972, Wiener 1938)). Uniqueness fails in this more general setting (uniqueness is strictly connected with the compactness of the unit ball in $C^N$). Notice that in the Schrödinger representation (and, therefore, in any other representation) the Hamiltonian for the harmonic oscillator defines a positive self-adjoint operator

$$N = \sum_1^N N_k, \quad N_k = -\frac{\partial^2}{\partial x_{k^2}} + x_k^2 - 1$$

The spectrum of each of the commuting operators $N_k$ consists of the positive integers (including 0) and is therefore called number operator for the $k$th degree of freedom. The operator $N_k$ can be written as $N_k = a_k^* a_k$, where $a_k = (1/\sqrt{2})(x_k + \partial/\partial x_k)$ and $a_k^*$ is the formal adjoint of $a_k$ in $L^2(R)$. One has $|a_k(N_k + 1)^{-1/2}| < 1$. In the domain of $N$ these operators satisfy the following relations (canonical commutation relations)

$$\begin{aligned} [a_k, a_h^*] &= \delta_{k,h}, \qquad [a_h, a_k] = 0 \\ [N_k, a_h] &= -a_h \delta_{h,k}, \qquad [N_h, a_k^*] = a_k^* \delta_{h,k} \end{aligned} \qquad [15]$$

In view of the last two relations, the operator $a_k$ is called the annihilation operator (relative to the $k$th degree of freedom) and its formal adjoint is called the creation operator. The operators $a_k$ have as spectrum the entire complex plane, the operators $a_k^*$ have empty spectrum; the eigenvectors of $N_k$ are the Hermite polynomials in the variable $x_k$. The eigenvectors of $a_k$ (i.e., the solutions in $L^2(R)$ of the equation $a_k \phi_\lambda = \lambda \phi_\lambda$, $\lambda \in C$) are called coherent states; they have a major role in the Bargmann–Fock–Segal quantization and in general in the semiclassical limit.

The operators $\{N_k\}$ generate a maximal abelian system and therefore the space $L^2(R^N)$ has a natural representation as the symmetrized subspace of $\oplus_k (C^N)^k$ (Fock representation). In this representation, a natural basis is given by the common eigenvectors $\phi_{\{n_k\}}, k = 1, \ldots, N$, of the operators $N_k$. A generic vector can be written as

$$\psi = \sum_{\{n_k\}} c_{\{n_k\}} \phi_{\{n_k\}}, \quad \sum_{\{n_k\}} |c_{\{n_k\}}|^2 < \infty$$

and therefore can be represented by the sequence $c_{\{n_k\}}$.

Notice that the creation operators do not create particles in $R^N$ but rather act as a shift in the basis of the Hermite polynomials.

It is traditional to denote by $\gamma(L^2(R^N))$ the Fock representation (also called second quantization because for each degree of freedom the wave function is written in the quantized basis of the harmonic oscillator) and to denote by $\Gamma(A)$ the lift of a matrix $A \in B(C^N)$. These notations are especially used if $C^N$ is substituted with a Banach space $X$. This terminology was introduced by Segal in his work on quantization of the wave equation; it is used ever since, mostly in a perturbative context.

In the theory of quantized fields, the space $C^N$ is substituted with a Banach space, $X$, of functions. In this setting, "second quantization" (Segal 1965, Nelson 1974) considers the state $\phi_{\{n_k\}}$ as representing a configuration of the system in which there are precisely $n_k$ particles in the $k$th physical state (this presupposes having chosen a basis in the space of distribution on $R^3$). There is no problem in doing this (Gross 1972) and one can choose for $X$ a suitable Sobolev space (which one depends on the Gaussian measure given in $X$) if one wants that the

generalization of the commutation relations [15] be of the form $[a^*(f), a(g)] = <f, g>$ with a suitable scalar product $<\cdot,\cdot>$ in $X$. The problem with quantization of relativistic fields is that, in order to ensure locality, one is forced to use a Sobolev space of negative index (depending on the dimension of physical space), and this gives rise to difficulties in the definition of the dynamics for nonlinear vector fields.

One should notice that in the work of Segal (1965), and then in Constructive field theory (Nelson 1974), the Fock representation is placed in a Schrödinger context exhibiting the relevant operators as acting on a space $L^2(X, g)$, where $X$ is a subspace of the space of Schwartz distributions on the physical space of the particles one wants to describe and $g$ is a suitably defined Gauss measure on $X$.

The Fock representation is related to the Bargmann–Fock–Segal representation (Bargmann 1967), a representation in a space of holomorhic functions on $C^N$ square integrable with respect to a Gaussian measure. For its development, this representation relies on the properties of Toeplitz operators and on Tauberian estimates. It is much used in the study of the semiclassical limit and in the formulation of QM in systems for which the classical version has, for phase space, a manifold which is not a cotangent bundle (e.g., the 2-sphere).

**Remark** The Fock representation associated with the Weyl system in the infinite-dimensional context can describe only particles obeying Bose–Einstein statistics; indeed, the states are qualified by their particle content for each element of the basis chosen and there is no possibility of identifying each particle in an $N$-particle state. This is obvious in the finite-dimensional case: the Hermite polynomial of order 2 cannot be seen as "composed" of two polynomials of order 1.

In the infinite-dimensional context, if one wants to treat particles which obey Fermi–Dirac statistics, one must rely on the Pauli exclusion principle (Pauli 1928), which states that two such particles cannot be in the same configuration; to ensure this, the wave function must be antisymmetric under permutation of the particle symbols. It is a matter of fact (and a theorem in relativistic quantum field theory which follows in that theory from covariance, locality and positivity of the energy (Streater and Wightman 1964) that particles with half-integer spin obey the Fermi–Dirac statistics. Therefore, to quantize such systems, one must introduce (commutation) relations different from those of Weyl. Since it must now be that $(a^*)^2 = 0$, due to antisymmetry, it is reasonable to introduce the following relations (canonical anticommutation relations:

$$\begin{aligned} &\{a_k, a_h^*\} = \delta_{k,h}, \qquad \{a_h, a_k\} = 0 \\ &[N_k, a_h] = -a_h \delta_{h,k}, \quad \{A, B\} \equiv AB - BA \end{aligned} \qquad [16]$$

The Hilbert space is now $\otimes^N \mathcal{H}_2$, where $\mathcal{H}_2$ is a two-dimensional complex Hilbert space. Notice that $\mathcal{H}_2$ carries an irreducible two-dimensional representation of $sU(2) \equiv o(3)$ (spin representation) so that this quantization associates spin 1/2 and antisymmetry.

The operators in [16] are all bounded (in fact bounded by 1 in norm). The Fock representation is constructed as in the case of Weyl (see Araki (1988)), with $n_k$ equal 0 or 1 for each index $k$. The infinite-dimensional case is defined in the same way, and leads to inequivalent irreducible representations (Araki 1988); only in one of them is the number operator defined and bounded below. Some of these representations can be given a Schrödinger-like form, with the introduction of a gauge and an integration formalism based on a trace (Gross 1972). This system is much used in quantum statistical mechanics because it deals with bounded operators and can take advantage of strong results in the theory of $C^*$-algebras. In the finite-dimensional case (and occasionally also in the general case) it is used in quantum information (the space $\mathcal{H}_2$ is the space of a quantum bit).

Returning to the Weyl system, we now introduce the strictly related Wigner function which plays an important role in the analysis of the semiclassical limit and in the discussion of some scaling limits, in particular the hydrodynamical limit and the Bose–Einstein condensation when $N \to \infty$.

The Wigner function $W_\phi$ for a pure state $\phi$ is a real-valued function on the phase space of the classical system which represents the state faithfully. It is defined as

$$W_\psi(x, \xi) = (2\pi)^{-n} \int_{R^n} \mathrm{e}^{-\mathrm{i}(\xi, x)} \psi\left(x + \frac{y}{2}\right) \bar{\psi}\left(x - \frac{y}{2}\right) \mathrm{d}y$$

The Wigner function is not positive in general (the only exceptions are those Gaussian states that satisfy $\Delta(x) \cdot \Delta(p) \geq \hbar$). But is has the interesting property that its marginals reproduce correctly the Born rule. In fact, one has $\int W_\phi(x, \xi)\, \mathrm{d}x = |\hat{\phi}(\xi)|^2$. If the function $\phi(t, x)$ $x \in R^n$ is a solution of the free Schrödinger equation $\mathrm{i}\hbar \partial\phi/\partial t = -\hbar^2 \Delta$ then its Wigner function satisfies the Liouville (transport) equation $\partial W_\phi / \partial t + \xi \cdot \nabla W = 0$.

The Wigner function is strictly linked with the Weyl quantization. This quantization associates with every function $\sigma(p, x)$ in a given regularity

class an operator $\sigma(D,x)$ (the Weyl symbol of the function $\sigma$) defined by

$$(\sigma(D,x)f,g) \equiv \int \sigma(\xi,x)W(f,g)(\xi,x)\,\mathrm{d}\xi\,\mathrm{d}x$$
$$W(f,g)(\xi,x) \equiv \int \mathrm{e}^{-\mathrm{i}(\xi,p)}f\left(x+\frac{p}{2},x-\frac{p}{2}\right)\mathrm{d}p$$

It can be verified that the action of $F$ preserves the Schwartz classes $S$ and $S'$ and is unitary in $L^2(R^{2N})$. Moreover, one has $\sigma(D,x)^* = \bar{\sigma}(D,x)$.

The relation between Weyl's quantization and Wigner functions can be readily seen from the natural duality between bounded operators and pure states:

$$\mathrm{tr}(\hat{A}\,\hat{\rho}) \equiv \int a(p,q)\rho(p,q)\,\mathrm{d}p\,\mathrm{d}q$$
$$\rho(p,q) = \int \mathrm{e}^{\mathrm{i}(p,q')}\rho(q',q)\,\mathrm{d}q'$$

We give now a brief discussion of the general structure of a quantization, and apply it to the Weyl quantization. By quantization of a Hamiltonian system we mean a correspondence, parametrized by a small parameter $\hbar$, between classical observables (real functions on a phase space $\mathcal{F}$) and quantum observables (self-adjoint operators on a Hilbert space $\mathcal{H}$) with the property that the corresponding structures coincide in the limit $\hbar \to 0$ and the difference for $\hbar \neq 0$ can be estimated in a suitable topology.

This last requirement is important for the applications and, from this point of view, Weyl's quantization gives stronger results than the other formalisms of quantization.

We limit our analysis to the case $\mathcal{F} \equiv T^*X$, with $X \equiv R^N$, and we make use of the realization of $\mathcal{H}$ as $L^2(R^N)$.

Let $\{x_i\}$ be Cartesian coordinates in $R^N$ and consider a correspondence $A \to \hat{A}$ that satisfies the following requirements:

1. $A \leftrightarrow \hat{A}$ is linear;
2. $x_k \leftrightarrow \hat{x}_k$ where $\hat{x}_k$ is multiplication by $x_k$;
3. $p_k \leftrightarrow -\mathrm{i}\hbar\partial/\partial x_k$;
4. if $f$ is a continuous function in $R^N$, one has $f(x) \leftrightarrow f(\hat{x})$ and $\hat{f}(p) = (Ff)(\hat{x})$, where $F$ denotes a Fourier transform;
5. $L_\zeta \leftrightarrow \hat{L}_\zeta, \zeta \equiv (\alpha,\beta), \alpha,\beta \in R^N$, where $L_\zeta$ is the generator of the translations in phase space in the direction $\zeta$ and $\hat{L}_\zeta$ is the generator of the one-parameter group $t \to W(t\zeta)$ associated with $\zeta$ by the Weyl system.

Note that (1) and (4) imply (2) and (3) through a limit procedure.

Under the correspondence $A \leftrightarrow \hat{A}$, linear symplectic maps correspond to unitary transformations. This is not in general the case for nonlinear maps.

One can prove that conditions (1)–(5) give a complete characterization of the map $A \leftrightarrow \hat{A}$. Moreover, the correspondence cannot be extended to other functions in phase space. Indeed, one has:

**Theorem 3** (van Hove). *Let $G$ be the class of functions $C^\infty$ on $R^{2N}$ which are generators of global symplectic flows. For $g \in G$ let $\Phi_g(t)$ be the corresponding group. There cannot exist for every $g$ a correspondence $g \leftrightarrow \hat{g}$, with $\hat{g}$ self-adjoint, such that $\hat{g}(x,p) = g(\hat{x},\hat{p})$.*

We described the Weyl quantization as a correspondence between functions in the Schwartz class $S$ and a class of bounded operators. Weyl's quantization can be extended to a much wider class of functions. Operators that can be so constructed are called Fourier integral operators. One uses the notation $\hat{\sigma} \equiv \sigma(D,x)$.

We have the following useful theorems (Robert 1987):

**Theorem 4** *Let $l_1,\ldots,l_K$ be linear functions on $R^N$ such that $\{l_i l_k\} = 0$. Let $P$ be a polynomial and let $\sigma(\xi,x) \equiv P[l_1(\xi,x), l_K(\xi,x)]$. Then*

(i) *$\sigma(D,x)$ maps $S$ in $L^2(R^N)$ and self-adjoint;*
(ii) *if $g$ is continuous, then $(g(\sigma)(D,x) = g(\sigma(D,x))$.*

One proves that $\sigma(D,x)$ extends to a continuous map $S'(X) \to S'(X)$ and, moreover,

**Theorem 5** (Calderon–Vaillancourt). *If $\sigma_0 \equiv \sum_{|\alpha|+|\beta|\leq 2N+1} |D_\xi^\alpha D_x^\beta \sigma| < \infty$ the norm of the operator $\sigma(D,x)$ is bounded by $\sigma_0$.*

Any operator obtained from a suitable class of functions through Weyl's quantization is called a pseudodifferential operator. If $\sigma(q,p) = P(p)$, where $P$ is a polynomial, $\hat{\sigma}(p,q)$ is a differential operator.

Moreover, if $\sigma(p,x) \in L^2$ then $\sigma(D,x)$ is a Hilbert–Schmidt operator and

$$|\sigma(D,x)|_{\mathrm{HS}} = (2\pi\hbar)^{-n/2}\left[\int |A(z)|^2\,\mathrm{d}z\right]^{1/2}$$

Pseudodifferential operators turn out to be very important in particular in the quantum theory of molecules (Le Bris 2003), where adiabatic analysis and Peierls substitution rules force the use of pseudodifferential operators.

The next important problem in the theory of quantization is related to dynamics.

Let $\beta$ be a quantization procedure and let $H(p,q)$ be a classical Hamiltonian on phase space. Let $A_t$ be

the evolution of a classical observable $A$ under the flow defined by $H$ and assume that $\beta(A_t)$ is well defined or all $t$.

Is there a self-adjoint operator $\hat{H}$ such that $\beta(A_t) = e^{it\hat{H}} \beta(A) e^{-it\hat{H}}$? If so, can one estimate $|\hat{H} - \beta(H)|$? Conversely, if the generator of the quantized flow is, by definition, $\hat{H}$ (as is usually assumed), is it possible to give an estimate of the difference $|\beta(A_t) - (\beta(A))_t|\phi$ for a dense set of $\phi \in \mathcal{H}$, where $A_t \equiv e^{it\hat{H}} A e^{-it\hat{H}}$, or to estimate $|\tilde{A}_t - A_t|_\infty$, where $\tilde{A}_t$ is defined by $\beta(\tilde{A}_t) = (\beta(A))_t$. Is it possible to write an asymptotic series in $\hbar$ for the differences?

For the Weyl quantization some quantitative results have been obtained if one makes use of the semiclassical observables (Robert 1987). We shall not elaborate further on this point.

For completeness, we briefly mention another quantization procedure which is often used in mathematical physics.

### Wick Quantization

This quantization assigns positive operators to positive functions, but does not preserve polynomial relations. It is strictly related to the Bargmann–Fock–Segal representation.

Call coherent state centered in the point $(y, \eta)$ of phase space the normalized solution of $(i\hat{p} + \hat{x} - i\eta + x)\phi_{y,\eta}(x) = 0$.

Wick's quantization of the classical observable $A$ is by definition the map $A \to \mathrm{Op}^W(A)$, where

$$\mathrm{Op}^W(A)\psi \equiv (2\pi\hbar)^{-n} \int A(y, \eta)(\psi, \bar{\phi}_{y,\eta})\phi_{y,\eta}\, dy\, d\eta$$

One can prove, either directly or going through Weyl's representation, that

1. if $A \geq 0$ then $\mathrm{Op}^W_\hbar(A) \geq 0$;
2. the Weyl symbol of the operator $\mathrm{Op}^W_\hbar(A)$ is
$$(\pi\hbar)^{-n} \int\int A(y, \eta) e^{-\frac{1}{\hbar}[(x-y)^2 + (\xi-\eta)^2]}\, dy\, d\eta$$
3. for every $A \in O(0)$ one has $\|\mathrm{Op}^W_\hbar(A) - \hat{A}\| = O(\hbar)$.

Wick's quantization associates with every vector $\phi \in \mathcal{H}$ a positive Radon measure $\mu_\phi$ in phase space, called Husimi measure. It is defined by $\int A\, d\mu_\psi = (\mathrm{Op}^W_\hbar(A)\psi \cdot \psi)$, $A \in S(z)$. Wick's quantization is less adapted to the treatment of nonrelativistic particles, in particular Eherenfest's rule does not apply, and the semiclassical propagation theorem has a more complicated formulation. It is very much used for the analysis in Fock space in the theory of quantized relativistic fields, where a special role is assigned to Wick ordering, according to which the polynomials in $\hat{x}_\hbar$ and $\hat{p}_\hbar$ are reordered in terms of creation and annihilation operators by placing all creation operators to the left.

We now come back to Schrödinger's equation and notice that it can be derived within Heisenberg's formalism and Weyl's quantization scheme from the Hamiltonian of an $N$-particle system in Hamiltonian mechanics (at least if one neglects spin, which has no classical analog).

Apart from (often) inessential parameters, the Schrödinger equation for $N$ scalar particles in $R^3$ can be written as

$$i\hbar \frac{\partial\phi}{\partial t} = \sum_{k=1}^{N} (i\hbar\nabla_k + A_k)^2 \phi + V\phi \equiv H\phi \qquad \phi \in L^2(R^{3N}) \tag{17}$$

where $A_k$ are vector-valued functions (vector potentials) and $V = V_k(x_k) + V_{i,k}(x_i - x_k)$ are scalar-valued function (scalar potentials) on $R^3$.

Typical problems in Schrödinger's quantum mechanics are:

1. Self-adjointness of $H$, existence of bound states (discrete spectrum of the operator), their number and distribution, and, in general, the properties of the spectrum.
2. Existence, completeness, and continuity properties of the wave operators
$$W_\pm \equiv s - \lim_{\mp\infty} e^{itH_0} e^{-itH} \tag{18}$$
and the ensuing existence and properties of the $S$-matrix and of the scattering cross sections. In [18] $H_0$ is a suitable reference operator, usually $-\Delta$ (with periodic boundary conditions if the potentials are periodic in space), for which Schrödinger's equation can be somewhat analytically controlled.
3. Existence and property of a semiclassical limit.

In [17] and [18] we have implicitly assumed that $H$ is time independent; very interesting problems arise when $H$ depends on time, in particular if it is periodic or quasiperiodic in time, giving rise to ionization phenomena. In the periodic case, one is helped by Floquet's theory, but even in this case many interesting problems are still unsolved.

If the potentials are sufficiently regular, the spectrum of $H$ consists of an absolutely continuous part (made up of several bands in the space-periodic case) and a discrete part, with few accumulation points.

On the contrary, if $V(x, \omega)$ is a measurable function on some probability space $\Omega$, with a suitable distribution (e.g., Gaussian), the spectrum may have totally different properties almost surely.

For example, in the case $N=1$ (so that the terms $V_{i,j}$ are absent) in one and two spatial dimensions the spectrum is pure point and dense, with eigenfunctions which decrease at infinity exponentially fast (although not uniformly); as a consequence, the evolution group does not give rise to a dispersive motion. The same is true in three dimensions if the potential is sufficiently strong and the kinetic energy content of the initial state is sufficiently limited. This very interesting behavior is due roughly to the randomness of the "barriers" generated by the potential and is also present, to a large extent, for potentials quasiperiodic in space (Pastur and Figotin 1992).

In these as well as in most problems related to Schrödinger's equation, a crucial role is taken by the resolvent operator $(H - \lambda I)^{-1}$, where $\lambda$ is any complex number outside the spectrum of $H$; many of the results are obtained when the difference $(H - \lambda I)^{-1} - (H_0 - \lambda I)^{-1}$ is a compact operator.

Problems of type (1) and (2) are of great physical interest, and are of course common with theoretical physics and quantum chemistry (Le Bris 2003), although the instruments of investigation are somewhat different in mathematical physics. The semiclassical limit is often more of theoretical interest, but its analysis has relevance in quantum chemistry and its methods are very useful whenever it is convenient to use multiscale methods, as in the study of molecular spectra.

We start with a brief description of point (3); it provides a valid instrument in the description of quantum-mechanical systems at a scale where it is convenient to use units in which the physical constant $\hbar$ has a very small value ($\hbar \simeq 10^{-27}$ in CGS units). From Heisenberg's commutation relations, $[\hat{x}, \hat{p}] \subset \hbar I$, it follows that the product of the dispersion (uncertainty) of the position and momentum variables is proportional to $\hbar$ and therefore at least one of these two quantities must have very large values (compared to $\hbar$). One considers usually the case in which these dispersions have comparable values, which is therefore very small, of the order of magnitude $\hbar^{1/2}$ (but very large as compared with $\hbar$). In order to make connection with the Hamilton–Jacobi formalism of classical mechanics one can also consider the case in which the dispersion in momentum is of the order $\hbar$ (the WKB method).

The semiclassical limit takes advantage mathematically from the fact that the parameter $\hbar$ is very small in natural units, and performs an asymptotic analysis, in which the terms of "lowest order" are exactly described and the difference is estimated. The problem one faces is that the Schrödinger equation becomes, in the "mathematical limit" $\hbar \to 0$, a very singular PDE (the coefficients of the differential terms go to zero in this limit).

Dividing each term of the equation by $\hbar$ (because we do not want to change the scale of time) leads, in the case of one quantum particle in $R^3$ in potential field $V(x)$ (we treat, for simplicity, only this case), to the equation

$$\mathrm{i}\frac{\partial \phi(x,t)}{\partial t} = -\hbar \Delta \phi(x,t) + \hbar^{-1} V(x) \phi(x,t) \qquad [19]$$

It is convenient therefore to "rescale" the spatial variables by a factor $\hbar^{1/2}$ (i.e., choose different units) setting $x = \sqrt{\hbar} X$ and look for solutions of [19] which remain regular in the limit $\hbar \to 0$ as functions of the rescaled variable $X$. One searches therefore for solutions that on the "physical scale" have support that becomes "vanishingly small" in the limit. It is therefore not surprising that, in the limit, these solutions may describe point particles; the main result of semiclassical analysis is that he coordinates of these particles obey Hamilton's laws of classical mechanics.

This can be roughly seen as follows (accurate estimates are needed to make this empirical analysis precise). Using multiscale analysis, one may write the solution in the form $\phi(X, x, t)$ and seek solutions which are smooth in $X$ and $x$. Both terms on the right-hand side of [19] contain contributions of order $-2$ and $-1$ in $\sqrt{\hbar}$ and in order to have regular solutions one must have cancellations between equally singular contributions. For this, one must perform an expansion to the second order of the potential (assumed at least twice differentiable) around a suitable trajectory $q(t)$, $q \in R^3$, and choose this trajectory in such a way that the cancellations take place.

A formal analysis shows that this is achieved only if the trajectory chosen is precisely a solution of the classical Lagrange equations. Of course, a more refined analysis and good estimates are needed to make this argument precise, and to estimate the error that is made when one neglects in the resulting equation terms of order $\sqrt{\hbar}$; in favorable cases, for each chosen $T$ the error in the solution for most initial conditions of the type described is of order $\sqrt{\hbar}$ for $|t| < T$.

This semiclassical result is most easily visualized using the formalism of Wigner functions (the technical details, needed to to make into a proof the formal arguments, take advantage of regularity estimates in the theory of functions).

In natural units, one defines

$$W_{\hbar,\rho}(x,\xi,t) = \left(\frac{\mathrm{i}}{2\pi}\right)^N W_\rho\left(x, \frac{\xi}{\hbar}, t\right)$$

In terms of the Wigner function $W_{\hbar,\rho}$ the Schrödinger equation [19] takes the form

$$\frac{\partial f^\hbar}{\partial t} + \xi \cdot \nabla_x f^\hbar + K_\hbar * f^\hbar = 0 \qquad [20]$$
$$\rho^\hbar(t=0) = \rho_0(\hbar)$$

where

$$K_\hbar = \frac{\mathrm{i}}{(2\pi)^N} \mathrm{e}^{-\mathrm{i}\xi,y}\hbar^{-1}\left[V\left(x+\frac{\hbar y}{2}\right) - V\left(x-\frac{\hbar y}{2}\right)\right]$$

It can be proved (Robert 1987) that if the potential is sufficiently regular and if the initial datum converges in a suitable topology to a positive measure $f_0$, then, for all times, $W_{\hbar,\rho}(x,t)$ converges to a (weak) solution of the Liouville equation

$$\frac{\partial f}{\partial t} + \xi \cdot \nabla_x f - \nabla V(x) \cdot \nabla_\xi f = 0$$

This leads to the semiclassical limit if, for example, one considers a sequence of initial data $\rho_{\phi_n}$ where $\phi_n$ is a sequence of functions centered at $x_0$ with Fourier transform centered at $p_0$ and dispersion of order $\hbar^{1/2}$ both in position and in momentum. In this case, the limit measure is a Dirac measure centered on the classical paths.

In the course of the proof of the semiclassical limit theorem, one becomes aware of the special status of the Hamiltonians that are at most quadratic in $\hat{x}$ and $\hat{p}$. Indeed, it is easy to verify that for these Hamiltonians the expectation values of $\hat{x}$ and $\hat{p}$ obey the classical equation of motion (P Ehrenfest rule).

From the point of view of Heisenberg, this can be understood as a consequence of the fact that operators at most bilinear in $a$ and $a^*$ form an algebra $\mathcal{D}$ under commutation and, moreover, the homogeneous part of order 2 is a closed subalgebra such that its action on $\mathcal{D}$ (by commutation) has the same structure as the algebra of generators of the Hamiltonian flow and its tangent flow. Apart from (important) technicalities, the proof of the semiclassical limit theorem reduces to the proof that one can estimate the contribution of the terms of order higher than 2 in the expansion of the quantum Hamiltonian at the classical trajectory as being of order $\hbar^{1/2}$ in a suitable topology (Hepp 1974).

We end this overview by giving a brief analysis of problems (1) and (2), which refer to the description of phenomena that are directly accessible to comparison with experimental data, and therefore have been extensively studied in theoretical physics and quantum chemistry (Mc Weeny 1992); some of them have been analyzed with the instruments of mathematical physics, often with considerable success. We give here a very naive introduction to these problems and refer the reader to the more specialized contributions to this Encyclopedia for a rigorous analysis and exact statements.

Of course, most of the problems of physical interest are not "exactly solvable," in the sense that rarely the final result is given explicitly in terms of simple functions. As a consequence, exact numerical results, to be compared with experimental data, are rarely obtained in physically relevant problems, and most often one has to rely on approximation schemes with (in favorable cases) precise estimates on the error.

Formal perturbation theory is the easiest of such schemes, but it seldom gives reliable results to physically interesting problems. One writes

$$H_\epsilon \equiv H + \epsilon V \qquad [21]$$

where $\epsilon$ is a small real parameter, and sets a formal scheme in case (1) by writing

$$H_\epsilon\phi_\epsilon \equiv E_\epsilon\phi_\epsilon,\ E_\epsilon \equiv \sum_0^\infty \epsilon^k E_k,\ \phi_\epsilon \equiv \sum_0^\infty \epsilon^k \phi_k$$

and, in case (2), iterating Duhamel's formula

$$\mathrm{e}^{-\mathrm{i}tH_\epsilon} = \mathrm{e}^{-\mathrm{i}tH_0} + \mathrm{i}\epsilon\int_0^t \mathrm{e}^{-\mathrm{i}(t-s)H_\epsilon} V \mathrm{e}^{-\mathrm{i}sH_0}\mathrm{d}s \qquad [22]$$

Very seldom the perturbation series converges, and one has to resort to more refined procedures.

In some cases, it turns out to be convenient to consider the formal primitive $\tilde{E}_\epsilon$ of $E_\epsilon$ (as a differentiable function of $\epsilon$) and prove that it is differentiable in $\epsilon$ for $0 < \epsilon < \epsilon_0$ (but not for $\epsilon = 0$). In favorable cases, this procedure may lead to

$$E_\epsilon = \sum_0^N \epsilon^k E_k + R_N(\epsilon), \quad \lim_{N\to\infty} |R_N|(\epsilon) = +\infty$$

with explicit estimates of $|R_N(\epsilon)|$ for $0 \le \epsilon < \epsilon_0$.

Re-summation techniques of the formal power series may be of help in some cases.

The estimate of the lowest eigenvalues of an operator bounded below is often done by variational analysis, making use of min–max techniques applied to the quadratic form $Q(\phi) \equiv (\phi, H\phi)$.

Semiclassical analysis can be useful to search for the distribution of eigenvalues and in the study of the dynamics of states whose dispersions both in position and in momentum are very large in units in which $\hbar = 1$.

A case of particular interest in molecular and atomic physics occurs when the physical parameters which appear in $H_\epsilon$ (typically the masses of the particles involved in the process) are such that one

can *a priori* guess the presence of coordinates which have a rapid dependence on time (fast variables) and a complementary set of coordinates whose dependence on time is slow. This suggests that one can try an asymptotic analysis, often in connection with adiabatic techniques. Seldom one deals with cases in which the hypotheses of elementary adiabatic theorems are satisfied, and one has to refine the analysis, mostly through subtle estimates which ensure the existence of quasi invariant subspaces.

Asymptotic techniques and refined estimates are also needed to study the effective description of a system of $N$ interacting identical particles when $N$ becomes very large; for example, in statistical mechanics, one searches for results which are valid when $N \to \infty$.

The most spectacular results in this direction are the proof of stability of matter by E Lieb and collaborators, and the study of the phenomenon of Bose–Einstein condensation and the related Gross–Pitaevskii (nonlinear Schrödinger) equation. The experimental discovery of the state of matter corresponding to a Bose–Einstein condensate is a clear evidence of the nonclassical behavior of matter even at a comparatively macroscopic size. From the point of view of mathematical physics, the ongoing research in this direction is very challenging.

One should also recognize the increasing role that research in QM is taking in applications, also in connection with the increasing success of nanotechnology. In this respect, from the point of view of mathematical physics, the study of nanostructure (quantum-mechanical systems constrained to very small regions of space or to lower-dimensional manifolds, such as sheets or graphs) is still in its infancy and will require refined mathematical techniques and most likely entirely new ideas.

Finally, one should stress the important role played by numerical analysis (Le Bris 2003) and especially computer simulations. In problems involving very many particles, present-day analytical techniques provide at most qualitative estimates and in favorable cases bounds on the value of the quantities of interest. Approximation schemes are not always applicable and often are not reliable.

Hints for a progress in the mathematical treatment of some relevant physical phenomena of interest in QM (mostly in condensed matter physics) may come from the *ab initio* analysis made by simulations on large computers; this may provide a qualitative and, to a certain extent, quantitative behavior of the solutions of Schrödinger's equation corresponding to "typical" initial conditions. In recent times the availability of more efficient computing tools has made computer simulation more reliable and more apt to concur with mathematical investigation to a fuller comprehension of QM.

## Interpretation Problems

In this section we describe some of the conceptual problems that plague present-day QM and some of the attempts that have been made to cure these problems, either within its formalism or with an altogether different approach.

### Approaches within the QM Formalism

We begin with the approaches "from within." We have pointed out that the main obstacle in the measurement problem is the description of what occurs during an act of measurement. Axiom III claims that it must be seen as a "destruction" act, and the outcome is to some extent random. The final state of the system is one of the eigenstates of the observable, and the dependence on the initial state is only through an *a priori* probability assignment; the act of measurement is therefore not a causal one, contrary to the (continuous) causal reversible description of the interaction with the environment. One should be able to distinguish *a priori* the acts of measurement from a generic interaction.

There is a further difficulty. Due to the superposition principle, if a system $\mathcal{S}$ on which we want to make a measurement of the property associated with the operator $A$ "interacts" with an instrument $\mathcal{I}$ described by the operator $S$, the final state $\xi$ of the combined system will be a coherent superposition of tensor product of (normalized) eigenstates of the two systems

$$\xi = \sum_{n,m} c_{n,m} \phi_n^A \otimes \psi_m^S, \quad \sum_{n,m} |c_{n,m}|^2 = 1 \qquad [23]$$

Measurement as described by Axiom III of QM claims that once the measurement is over, the measured system is, with probability $\sum_m |c_{n,m}|^2$, in the state $\phi_n^A$ and the instrument is in a state which carries the information about the final state of the system (after all, what one reads at the end is an indicator of the final state of the instrument).

It is therefore convenient to write $\xi$ in the form

$$\xi = \sum d_n \phi_n^A \otimes \zeta_n, \quad \sum_n |d_n|^2 = 1 \qquad [24]$$

(this defines $\zeta_n$ if the spectrum of $A$ is pure point and nondegenerate). It is seen from [24] that, due to the reduction postulate, we know that the the measured system is in the state $\phi_{n_0}^A$ if a measurement of an observable $T$ with nondegenerate spectrum,

eigenvectors $\{\zeta_n\}$, and eigenvalues $\{z_n\}$ gives the results $z_{n_0}$.

Along these lines, one does not solve the measurement problem (the outcome is still probabilistic) but at least one can find the reason why the measuring apparatus may be considered "classical."

It is more convenient to go back to [23] and to assume that one is able to construct the measuring apparatus in such a way that one divides (roughly) its pure (microscopic) states in sets $\Phi_n$ (each corresponding to a "macroscopic" state) which are (roughly) in one-to-one correspondence to the eigenstates of $A$. The sets $\Phi_n$ contain a very large number, $N_{\Phi_n}$, of elements, so that the sets $\Phi_n$ need not be given with extreme precision. And the sets $\Phi_n$ must be in a sense "stable" under small external perturbations.

It is clear from this rough description that the apparatus should contain a large number of small components and still its interaction with the "small" system $A$ should lead to a more or less sudden change of the sets $\Phi_n$.

A concrete model of this mechanism has been proposed by K Hepp (1972) for the case when $A$ is a $2 \times 2$ matrix, and the measuring apparatus is made of a chain of $N$ spins, $N \to \infty$; the analysis was recently completed by Sewell (2005) with an estimate on the error which is made if $N$ is finite but large. This is a dynamical model, in which the observable $A$ (a spin) interacts with a chain of spins ("moves over the spins") leaving the trace of its passage. It is this trace (final macroscopic state of the apparatus) which is measured and associated with the final state of $A$. The interaction is not "instantaneous" but may require a very short time, depending on the parameters used to describe the apparatus and the interaction.

We call "decoherence" the weakening of the superposition principle due to the interaction with the environment.

Two different models of decoherence have been analyzed in some detail; we shall denote them thermal-bath model and scattering model; both are dynamical models and both point to a solution, to various extents, of the problem of the reduction to a final density matrix which commutes with the operator $A$ (and therefore to the suppression of the interference terms).

The thermal-bath model makes use of the Heisenberg representation and relies on results of the theory of $C^*$-algebras. This approach is closely linked with (quantum) statistical mechanics; its aim is to prove, after conditioning with respect to the degrees of freedom of the bath, that a special role emerges for a commuting set of operators of the measured system, and these are the observables that specify the outcome of the measurement in probabilistic terms.

The scattering approach relies on the Schrödinger approach to QM, and on results from the theory of scattering. This approach describes the interaction of the system $\mathcal{S}$ (typically a heavy particle) with an environment made of a large number of light particles and seeks to describe the state of $\mathcal{S}$ after the interaction when one does not have any information on the final state of the light particle. One seeks to prove that the reduced density matrix is (almost) diagonal in a given representation (typically the one given by the spatial coordinates). This defines the observable (typically, position) that can be measured and the probability of each outcome.

Both approaches rely on the loss of information in the process to cancel the effect of the superposition principle and to bring the measurement problem within the realm of classical probability theory. None of them provides a causal dependence of the result of the measurement on the initial state of the system.

We describe only very briefly these attempts.

In its more basic form, the "scattering approach" has as starting point the Schrödinger equation for a system of two particles, one of which has mass very much smaller than the other one. The heavy particle may be seen as representing the system on which a measurement is being made. The outline of the method of analysis (which in favorable cases can be made rigorous) (Joos and Zeh 1985, Tegmark 1993) is the following. One chooses units in which the mass of the heavy particle is 1, and one denotes by $\epsilon$ the mass of the light particle. If $x$ is the coordinate of the heavy particle and $y$ that of the light one, and if the initial state of the system is denoted by $\Phi_0(x, y)$, the solution of the equation for the system is (apart from inessential factors)

$$\Phi_t = \exp\{\mathrm{i}(-\Delta_x - \epsilon^{-1}\Delta_y + W(x) + V(x-y))t\}\Phi_0$$

Making use of center-of-mass and relative coordinates, one sees that when $\epsilon$ is very small one should be able to describe the system on two timescales, one fast (for the light particle) and one slow (for the heavy one) and, therefore, place oneself in a setting which may allow the use of adiabatic techniques. In this setting, for the measure of the heavy particle (e.g., its position) one may be allowed to consider the light particle in a scattering regime, and use the wave operator corresponding to a potential $V_x(y) \equiv V(y - x)$.

Taking the partial trace with respect to the degrees of freedom of the light particle (this

corresponds to no information of its final state) one finds, at least heuristically, that the state of the heavy particle is now described (due to the trace operation) by a density matrix $\sigma$ for which in the coordinate representation the off-diagonal terms $\sigma_{x,x'}$ are slightly suppressed by a factor $\xi_{x,x'} = 1 - (W_x^+\psi, W_{x'}^+\psi)$ where $\psi$ represents the initial state of the light particle and $W_x^+$ is the wave operator for the motion of the light particle in the potential $\epsilon V_x$. One must assume that function $\phi$ which represents the initial state of the heavy particle is sufficiently localized so that $\xi_{x,x'} < 1$ for every $x' \neq x$ in its support.

If the environment is made of very many particles (their number $N(\epsilon)$ must be such that $\lim_{\epsilon \to 0} \epsilon N(\epsilon) = \infty$) and the heavy particle can be supposed to have separate interactions with all of them, the off-diagonal elements of the density matrix tend to 0 as $\epsilon \to 0$ and the resulting density matrix tends to have the form $\Phi(x, x') = \delta(x - x') \rho(x), \rho(x) \geq 0, \int \rho(x)\, dx = 1$. If it can be supposed that all interactions take place within a time $T(\epsilon) \leq \epsilon^\alpha$, $\alpha > 0$ one has $\rho(x) = |\psi(x)|^2$.

If the interactions are not independent, the analysis becomes much more involved since it has to be treated by many-body scattering theory; this suggests that the scattering approach can be hardly used in the context of the "thermal-bath model." In any case, the selection of a "preferred basis" (the coordinate representation) depends on the fact that one is dealing with a scattering phenomenon. A few steps have been made for a rigorous analysis (Teta 2004) but we are very far from a mathematically satisfactory answer.

The thermal-bath approach has been studied within the algebraic formulation of QM and stands on good mathematical ground (Alicki 2002, Blanchard *et al.* 2003, Sewell 2005). Its drawback is that it is difficult to associate the formal scheme with actual physical situations and it is difficult to give a realistic estimate on the decoherence time.

The thermal-bath approach attributes the decoherence effect to the practical impossibility of distinguishing between a vast majority of the pure states of the systems and the corresponding statistical mixtures. In this approach, the observables are represented by self-adjoint elements of a weakly closed subalgebra $\mathcal{M}$ of all bounded operators $\mathcal{B}(\mathcal{H})$ on a Hilbert space $\mathcal{H}$. This subalgebra may depend on the measuring apparatus (i.e, not all the apparatuses are fit to measure a set of observables). A "classical" observable by definition commutes with all other observables and therefore must belong to the center of $\mathcal{A}$ which is isomorphic to a collection of functions on a probability space $\mathcal{M}$. So the appearance of classical properties of a quantum system corresponds to the "emergence" of an algebra with nontrivial center. Since automorphic evolutions of an algebra preserve its center, this program can be achieved only if we admit the loss of quantum coherence, and this requires that the quantum systems we describe are open and interact with the environment, and moreover that the commutative algebra which emerges be stable for time evolution.

It may be shown that one must consider quantum environment in the thermodynamic limit, that is, consider the interaction of the system to be measured with a thermal bath. A discussion of the possible emergence of classical observables and of the corresponding dynamics is given by Gell-Mann (1993). In all these approaches, the commutative subalgebra is selected by the specific form of the interaction; therefore, the measuring apparatus determines the algebra of classical observables.

On the experimental side, a number of very interesting results have been obtained, using very refined techniques; these experiments usually also determine the "decoherence time." The experimental results, both for the collision model (Hornberger *et al.* 2003) and for the thermal-bath model (Hackermueller *et al.* 2004), are done mostly with fullerene (a molecule which is heavy enough and is not deflected too much after a collision with a particle of the gas). They show a reasonable accordance with the (rough) theoretical conclusions.

The most refined experiments about decoherence are those connected with quantum optics (circularly polarized atoms in superconducting cavities). These are not related to the wave nature of the particles but in a sense to the "wave nature" of a photon as a single unit. The electromagnetic field is now regarded as an incoherent superposition of states with an arbitrarily large number of photons. Polarized photons can be produced one by one, and they retain their individuality and their polarization until each of them interacts with "the environment" (e.g., the boundary of the cavity or a particle of the gas). In a sense, these experimental results refer to a "decoherence by collision" theory.

The experiments by Haroche (2003) prove that coherence may persist for a measurable interval of time and are the most controlled experiments on coherence so far.

### Other Approaches

We end this section with a brief discussion of the problem of "hidden variables" and a presentation of an entirely different approach to QM, originated by

D Bohm (1952) and put recently on firm mathematical grounds by Duerr *et al.* (1999). The approach is radically different from the traditional one and it is not clear at present whether it can give a solution to the measurement problem and a description of all the phenomena which traditional QM accounts for. But it is very interesting from the point of view of the mathematics involved.

We have remarked that the formulation of QM that is summarized in the three axioms given earlier has many unsatisfactory aspects, mainly connected with the superposition principle (described in its extremal form by the Schrödinger's cat "paradox") and with the problem of measurement which reveals, for example, through the Einstein–Rosen–Podolski "paradox," an intrinsic nonlocality if one maintains that their "objective" properties can be attributed to systems which are far apart. From the very beginning of QM, attempts have been made to attribute these features to the presence of "hidden variables"; the statistical nature of the predictions of QM is, from this point of view, due to the incompleteness of the parameters used to describe the systems. The impossibility of matching the statistical prediction of QM (confirmed by experimental findings) with a local theory based on hidden variables and classical probability theory has been known for sometime (Kochen and Specker 1967), also through the use of "Bell inequalities" (Bell 1964) among correlations of outcomes of separate measurements performed on entangled system (mainly two photons or two spin-1/2 particles created in a suitable entangled state).

A proof of the intrinsic nonlocality of QM (in the above sense) was given by L Hardy (see Haroche (2003)).

While experimental results prove that one cannot substitute QM with a "naive" theory of hidden variables, more refined attempts may have success. We shall only discuss the approach of Bohm (following a previous attempt by de Broglie) as presented in Duerr *et al.* (1999). It is a dynamical theory in which representative points follow "classical paths" and their motion is governed by a time-dependent vector "velocity" field (in this sense, it is not Newtonian). In a sense, Bohmian mechanics is a minimal completion of QM if one wants to keep the position as primitive observable. To these primitive objects, Bohm's theory adds a complex-valued function $\phi$ (the "guiding wave" in Bohm's terminology) defined on the configuration space $\mathcal{Q}$ of the particles. In the case of particles with spin, the function $\phi$ is spinor-valued. Dynamics is given by two equations: one for the coordinates of the particles and one for the guiding wave. If $x \equiv x_1, \ldots, x_N$ describes the configuration of the points, the dynamics in a potential field $V(x)$ is described in the following way: for the wave $\phi$ by a nonrelativistic Schrödinger equation with potential $V$ and for the coordinates by the ordinary differential equation (ODE)

$$\dot{x}_k = (\hbar/m_k)\mathrm{Im}\left[\frac{\phi^* \nabla_k \phi}{\phi^* \phi}\right](x), \quad x_k \in R^3$$

where $m_k$ is the mass of the $m$th particle.

Notice that the vector field is singular at the zeros of the wave function, therefore global existence and uniqueness must be proved. To see why Bohmian mechanics is empirically equivalent to QM, at least for measurement of position, notice that the equation for the points coincides with the continuity equation in QM. It follows that if one has at time zero a collection of points distributed with density $|\phi_0|^2$, the density at time $t$ will be $|\phi(t)|^2$ where $\phi(t)$ is the solution of the Schrödinger equation with initial datum $\phi_0$.

Bohm (1952) formulated the theory as a modification of Newton's laws (and in this form it has been widely used) through the introduction of a "quantum potential" $V_{\mathrm{Q}}$. This was achieved by writing the wave function in its polar form $\phi = R\mathrm{e}^{\mathrm{i}S/\hbar}$ and writing the continuity equation as a modified Hamilton–Jacobi equation. The version of Bohm's theory discussed in Duerr *et al.* (1999) introduces only the guiding wave function and the coordinates of the points, and puts the theory on firm mathematical grounds. Through an impressive series of mathematical results, these authors and their collaborators deal with the completeness of the velocity vector field, the asymptotic behavior of the points trajectories (both for the scattering regime and for the trapped trajectories, which are shown to correspond to bound states in QM), with a rigorous analysis of the theorem on the flux across a surface (a cornerstone in scattering theory) and the detailed analysis of the "two-slit" experiment through a study of the interaction with the measuring apparatus. The theory is completely causal, both for the trajectories of the points and for the time development of the pilot wave, and can also accommodate points with spin. It leads to a mathematically precise formulation of the semiclassical limit, and it may also resolve the measurement problem by relating the pilot wave of the entire system to its approximate decomposition in incoherent superposition of pilot wave associated with the particle and to the measuring apparatus (this would be the way to see the "collapse of the wave function" in QM). A weak point of this approach is the relation of the representative points with observable quantities.

# Introductory Article: Topology

**Tsou Sheung Tsun**, University of Oxford, Oxford, UK

## Introduction

This will be an elementary introduction to general topology. We shall not even touch upon algebraic topology, which will be dealt with in Cohomology Theories, although in some mathematics departments it is introduced in an advanced undergraduate course.

We believe such an elementary article is useful for the encyclopaedia, purely for quick reference. Most of the concepts will be familiar to physicists, but usually in a general rather vague sense. This article will provide the rigorous definitions and results whenever they are needed when consulting other articles in the work. To make sure that this is the case, we have in fact experimentally tested the article on physicists for usefulness.

Topology is very often described as "rubber-sheet geometry," that is, one is allowed to deform objects without actually breaking them. This is the all-important concept of continuity, which underlies most of what we shall study here.

We shall give full definitions, state theorems rigorously, but shall not give any detailed proofs. On the other hand, we shall cite many examples, with a view to applications to mathematical physics, taking for granted that familiar more advanced concepts there need not be defined. By the same token, the choice of topics will also be so dictated.

## ",1,5,1,0,0pc,0pc,0pc,0pc>Essential Concepts

**Definition 1** Let $X$ be a set. A collection $\mathcal{T}$ of subsets of $X$ is called a *topology* if the following are satisfied:

(i) $\emptyset, X \in \mathcal{T}$.

(ii) Let $\mathcal{I}$ be an index set. then

$$A_\alpha \in \mathcal{T}, \alpha \in \mathcal{I} \implies \bigcup_{\alpha \in \mathcal{I}} A_\alpha \in \mathcal{T}$$

(iii) $A_i \in \mathcal{T}, i = 1, \ldots, n \implies \bigcap_{i=1}^{n} A_i \in \mathcal{T}$.

**Definition 2** A member of the topology $\mathcal{T}$ is called an *open set* (of $X$ with topology $\mathcal{T}$).

**Remark** The last two properties are more easily put as *arbitrary* unions of open sets are open, and *finite* intersections of open sets are open. One can easily see the significance of this: if we take the "usual topology" (which will be defined in due course) of the real line, then the intersection of all open intervals $(-1/n, 1/n), n$ a positive integer, is just the single point {0}, which is manifestly not open in the usual sense.

**Example** If we postulate that $\emptyset$, and the entire set $X$, are the only open subsets, we get what is called the *indiscrete* or *coarsest* topology. At the other extreme, if we postulate that all subsets are open, then we get the *discrete* or *finest* topology. Both seem quite unnatural if we think in terms of the real line or plane, but in fact it would be more unnatural to explicitly exclude them from the definition. They prove to be quite useful in certain respects.

**Definition 3** A subset of $X$ is *closed* if its complement in $X$ is open.

**Remarks**

(i) One could easily build a topology using closed sets instead of open sets, because of the simple relation that the complement of a union is the intersection of the complements.

(ii) From the definitions, there is nothing to prevent a set being both open and closed, or neither

**Definition 4** A set equipped with a topology is called a *topological space* (with respect to the given topology). Elements of a topological space are sometimes called *points*.

**Definition 5** Let $x \in X$. A *neighborhood* of $x$ is a subset of $X$ containing an open set which contains $x$.

**Remark** This seems a clumsy definition, but turns out to be more useful in the general case than restricting to open neighborhoods, which is often done.

**Definition 6** A subcollection of open sets $\mathcal{B} \subseteq \mathcal{T}$ is called a *basis* for the topology $\mathcal{T}$ if every open set is a union of sets of $\mathcal{B}$.

**Definition 7** A subcollection of open sets $\mathcal{S} \subseteq \mathcal{T}$ is called a *sub-basis* for the topology $\mathcal{T}$ if every open set is a union of finite intersections of sets of $\mathcal{S}$.

**Definition 8** The *closure* $\bar{A}$ of a subset $A$ of $X$ is the smallest closed set containing $A$.

**Definition 9** The *interior* $\mathring{A}$ of a subset $A$ of $X$ is the largest open set contained in $A$.

**Remark** It is sometimes useful to define the *boundary* of $A$ as the set $\bar{A} \backslash \mathring{A} = \{x \in \bar{A}, x \notin \mathring{A}\}$.

**Definition 10** Let $A$ be a subset of a topological space $X$. A point $x \in X$ is called a *limit point* of $A$ if every open set containing $x$ contains some point of $A$ other than $x$.

**Definition 11** A subset $A$ of $X$ is said to be *dense* in $X$ if $\bar{A} = X$.

**Definition 12** A topological space $X$ is called a *Hausdorff space* if for any two distinct points $x, y \in X$, there exist an open neighborhood of $A$ of $x$ and an open neighborhood $B$ of $y$ such that $A$ and $B$ are disjoint (that is, $A \cap B = \emptyset$).

**Remark and Examples**

(i) This is looking more like what we expect. However, certain mildly non-Hausdorff spaces turn out to be quite useful, for example, in twistor theory. A "pocket" furnishes such an example. Explicitly, consider $X$ to be the subset of the real plane consisting of the interval $[-1, 1]$ on the $x$-axis, together with the interval $[0, 1]$ on the line $y = 1$, where the following pairs of points are identified: $(x, 0) \cong (x, 1), 0 < x \leq 1$. Then the two points (0, 0) and (0, 1) do not have any disjoint neighborhoods. Strictly speaking, one needs the notion of a quotient topology, introduced below.

(ii) For a more "truly" non-Hausdorff topology, consider the space of positive integers $\mathbb{N} = \{1, 2, 3, \dots\}$, and take as open sets the following: $\emptyset$, $\mathbb{N}$, and the sets $\{1, 2, \dots, n\}$ for each $n \in \mathbb{N}$. This space is neither Hausdorff nor compact (see later for definition of compactness).

**Definition 13** Let $X$ and $Y$ be two topological spaces and let $f : X \to Y$ be a map from $X$ to $Y$. We say that $f$ is *continuous* if $f^{-1}(A)$ is open (in $X$) whenever $A$ is open (in $Y$).

**Remark** Continuity is the single most important concept here. In this general setting, it looks a little different from the "$\epsilon$–$\delta$" definition, but this latter works only for metric spaces, which we shall come to shortly.

**Definition 14** A map $f : X \to Y$ is a *homeomorphism* if it is a continuous bijective map such that its inverse $f^{-1}$ is also continuous.

**Remark** Homeomorphisms are the natural maps for topological spaces, in the sense that two homeomorphic spaces are "indistinguishable" from the point of view of topology. Topological invariants are properties of topological spaces which are preserved under homeomorphisms.

**Definition 15** Let $B \subseteq A$. Then one can define the *relative topology* of $B$ by saying that a subset $C \subseteq B$ is open if and only if there exists an open set $D$ of $A$ such that $C = D \cap B$.

**Definition 16** A subset $B \subseteq A$ equipped with the relative topology is called a *subspace* of the topological space $A$.

**Remark** Thus, if for subsets of the real line, we consider $A = [0, 3], B = [0, 2]$, then $C = (1, 2]$ is open in $B$, in the relative topology induced by the usual topology of $\mathbb{R}$.

**Definition 17** Given two topological spaces $X$ and $Y$, we can define a *product topological space* $Z = X \times Y$, where the set is the Cartesian product of the two sets $X$ and $Y$, and sets of the form $A \times B$, where $A$ is open in $X$ and $B$ is open in $Y$, form a basis for the topology.

**Remark** Note that the open sets of $X \times Y$ are not always of this product form $(A \times B)$.

**Definition 18** Suppose there is a partition of $X$ into disjoint subsets $A_\alpha, \alpha \in \mathcal{I}$, for some index set $\mathcal{I}$, or equivalently, there is defined on $X$ an equivalence relation $\sim$. Then one can define the *quotient topology* on the set of equivalence classes $\{A_\alpha, \alpha \in \mathcal{I}\}$, usually denoted as the quotient space $X/\sim\, = Y$, as follows. Consider the map $\pi : X \to Y$, called the canonical projection, which maps the element $x \in X$ to its equivalence class $[x]$. Then a subset $U \subseteq Y$ is open if and only if $\pi^{-1}(U)$ is open.

**Proposition 1** *Let $\mathcal{T}$ be the quotient topology on the quotient space $Y$. Suppose $\mathcal{T}'$ is another*

*topology on Y such that the canonical projection is continuous, then* $\mathcal{T}' \subseteq \mathcal{T}$.

**Definition 19** An (*open*) *cover* $\{U_\alpha : \alpha \in \mathcal{I}\}$ for $X$ is a collection of open sets $U_\alpha \subseteq X$ such that their union equals $X$. A subcover of this cover is then a subset of the collection which is itself a cover for $X$.

**Definition 20** A topological space $X$ is said to be *compact* if every cover contains a finite subcover.

**Remark** So for a compact space, however one chooses to cover it, it is always sufficient to use a finite number of open subsets. This is one of the essential differences between an open interval (not compact) and a closed interval (compact). The former is in fact homeomorphic to the entire real line.

**Definition 21** A topological space $X$ is said to be *connected* if it cannot be written as the union of two nonempty disjoint open sets.

**Remark** A useful equivalent definition is that any continuous map from $X$ to the two-point set {0, 1}, equipped with the discrete topology, cannot be surjective.

**Definition 22** Given two points $x$, $y$ in a topological space $X$, a *path* from $x$ to $y$ is a continuous map $f : [0,1] \to X$ such that $f(0) = x, f(1) = y$. We also say that such a path joins $x$ and $y$.

**Definition 23** A topological space $X$ is *path-connected* if every two points in $X$ can be joined by a path lying entirely in $X$.

**Proposition 2** *A path-connected space is connected.*

**Proposition 3** *A connected open subspace of* $\mathbb{R}^n$ *is path-connected.*

**Definition 24** Given a topological space $X$, define an equivalence relation by saying that $x \sim y$ if and only if $x$ and $y$ belong to the same connected subspace of $X$. Then the equivalence classes are called (*connected*) *components* of $X$.

**Examples**

(i) The Lie group O(3) of $3 \times 3$ orthogonal matrices has two connected components. The identity connected component is SO(3) and is a subgroup.
(ii) The proper orthochronous Lorentz transformations of Minkowski space form the identity component of the group of Lorentz transformations.

## Metric Spaces

A special class of topological spaces plays an important role: metric spaces.

**Definition 25** A *metric space* is a set $X$ together with a function $d : X \times X \to \mathbb{R}$ satisfying

(i) $d(x,y) \geq 0$,
(ii) $d(x,y) = 0 \Leftrightarrow x = y$,
(iii) $d(x,z) \leq d(x,y) + d(y,z)$ ("triangle inequality").

**Remarks**

(i) The function $d$ is called the metric, or distance function, between the two points.
(ii) This concept of metric is what is generally known as "Euclidean" metric in mathematical physics. The distinguishing feature is the positive definiteness (and the triangle inequality). One can, and does, introduce indefinite metrics (for example, the Minkowski metric) with various signatures. But these metrics are not usually used to induce topologies in the spaces concerned.

**Definition 26** Given a metric space $X$ and a point $x \in X$, we define the *open ball* centred at $x$ with radius $r$ (a positive real number) as

$$B_r(x) = \{y \in X : d(x,y) < r\}$$

Given a metric space $X$, we can immediately define a topology on it by taking all the open balls in $X$ as a basis. We say that this is the topology induced by the given metric. Then we can recover our usual "$\epsilon$–$\delta$" definition of continuity.

**Proposition 4** *Let* $f : X \to Y$ *be a map from the metric space X to the metric space Y. Then f is continuous* (*with respect to the corresponding induced topologies*) *at* $x \in X$ *if and only if given any* $\epsilon > 0, \exists \delta > 0$ *such that* $d(x,x') < \delta$ *implies* $d(f(x,), f(x')) < \epsilon$.

Note that we do not bother to give two different symbols to the two metrics, as it is clear which spaces are involved. The proof is easily seen by taking the relevant balls as neighborhoods. Equally easy is the following:

**Proposition 5** *A metric space is Hausdorff.*

**Definition 27** A map $f : X \to Y$ of metric spaces is *uniformly continuous* if given any $\epsilon > 0$ there exists $\delta > 0$ such that for any $x_1, x_2 \in X, d(x_1, x_2) < \delta$ implies $d(f(x_1), f(x_2)) < \epsilon$.

**Remark** Note the difference between continuity and uniform continuity: the latter is stronger and requires the same $\delta$ for the whole space.

**Definition 28** Two metrics $d_1$ and $d_2$ defined on $X$ are *equivalent* if there exist positive constants $a$ and $b$ such that for any two points $x, y \in X$ we have

$$ad_1(x,y) \leq d_2(x,y) \leq bd_1(x,y)$$

**Remark** This is clearly an equivalence relation. Two equivalent metrics induce the same topology.

**Examples**

(i) Given a set $X$, we can define the discrete metric as follows: $d_0(x, y) = 1$ whenever $x \neq y$. This induces the discrete topology on $X$. This is quite a convenient way of describing the discrete topology.

(ii) In $\mathbb{R}$, the usual metric is $d(x, y) = |x - y|$, and the usual topology is the one induced by this.

(iii) More generally, in $\mathbb{R}^n$, we can define a metric for every $p \geq 1$ by

$$d_p(x, y) = \left\{ \sum_{k=1}^{n} |x_k - y_k|^p \right\}^{1/p}$$

where $x = (x_1, x_2, \ldots, x_n), y = (y_1, y_2, \ldots, y_n)$. In particular, for $p = 2$ we have the usual Euclidean metric, but the other cases are also useful. To continue the series, one can define

$$d_\infty = \max_{1<k<n} \{|x_k - y_k|\}$$

All these metrics induce the same topology on $\mathbb{R}^n$.

(iv) In a vector space $V$, say over the real or the complex field, a function $\|\cdot\| : V \to \mathbb{R}^+$ is called a *norm* if it satisfies the following axioms:
(a) $\|x\| = 0$ if and only if $x = 0$,
(b) $\|\alpha x\| = |\alpha| \|x\|$, and
(c) $\|x + y\| \leq \|x\| + \|y\|$.

Then it is easy to see that a metric can be defined using the norm

$$d(x, y) = \|x - y\|$$

In many cases, for example, the metrics defined in example (iii) above, one can define the norm of a vector as just the distance of it from the origin. One obvious exception is the discrete metric.

A slightly more general concept is found to be useful for spaces of functions and operators: that of seminorms. A *seminorm* is one which satisfies the last two of the conditions, but not necessarily the first, for a norm, as listed above.

**Definition 29** Given a metric space $X$, a sequence of points $\{x_1, x_2, \ldots\}$ is called a *Cauchy sequence* if, given any $\epsilon > 0$, there exists a positive integer $N$ such that for any $k, \ell > N$ we have $d(x_k, x_\ell) < \epsilon$.

**Definition 30** Given a sequence of points $\{x_1, x_2, \ldots\}$ in a metric space $X$, a point $x \in X$ is called a *limit* of the sequence if given any $\epsilon > 0$, there exists a positive integer $N$ such that for any $n > N$ we have $d(x, x_n) < \epsilon$. We say that the sequence *converges* to $x$.

**Definition 31** A metric space $X$ is *complete* if every Cauchy sequence in $X$ converges to a limit in it.

**Examples**

(i) The closed interval $[0, 1]$ on the real line is complete, whereas the open interval $(0, 1)$ is not. For example, the Cauchy sequence $\{1/n, n = 2, 3, \ldots\}$ has no limit in this open interval. (Considered as a sequence on the real line, it has of course the limit point 0.)

(ii) The spaces $\mathbb{R}^n$ are complete.

(iii) The Hilbert space $\ell^2$ consisting of all sequences of real numbers $\{x_1, x_2, \ldots\}$ such that $\sum_1^\infty x_k^2$ converges is complete with respect to the obvious metric which is a generalization to infinite dimension of $d_2$ above. For arbitrary $p \geq 1$, one can similarly define $\ell^p$, which are also complete and are hence Banach spaces.

**Remarks** Completeness is not a topological invariant. For example, the open interval $(-1, 1)$ and the whole real line are homeomorphic (with respect to the usual topologies) but the former is not complete while the latter is. The homeomorphism can conveniently be given in terms of the trigonometric function tangent.

**Definition 32** A subset $B$ of the metric space $X$ is *bounded* if there exists a ball of radius $R$ $(R > 0)$ which contains it entirely.

**Theorem 1** (Heine–Borel) *Any closed bounded subset of $\mathbb{R}^n$ is compact.*

**Remark** The converse is also true. We have thus a nice characterization of compact subsets of $\mathbb{R}^n$ as being closed and bounded.

**Proposition 6** *Any bounded sequence in $\mathbb{R}^n$ has a convergent subsequence.*

**Definition 33** Consider a sequence $\{f_n\}$ of real-valued functions on a subset A (usually an interval) of $\mathbb{R}$. We say that $\{f_n\}$ *converges pointwise* in $A$ if the sequence of real numbers $\{f_n(x)\}$ converges for every $x \in A$. We can then define a function $f : A \to \mathbb{R}$ by $f(x) = \lim_{n\to\infty} f_n(x)$, and write $f_n \to f$.

**Definition 34** A sequence of functions $f_n : A \to \mathbb{R}, A \subseteq \mathbb{R}$ is said to *converge uniformly* to a function $f : A \to \mathbb{R}$ if given any $\epsilon > 0$, there exists a positive integer $N$ such that, for all $x$, $|f_n(x) - f(x)| < \epsilon$ whenever $n > N$.

**Theorem 2** *Let $f_n : (a, b) \to \mathbb{R}$ be a sequence of functions continuous at the point $c \in (a, b)$, and suppose $f_n$ converges uniformly to $f$ on $(a, b)$. Then $f$ is continuous at $c$.*

**Remark and Example** The pointwise limit of continuous functions need not be continuous, as can be shown by the following example: $f_n(x) = x^n, x \in [0, 1]$. We see that the limit function $f$ is not continuous:

$$f(x) = \begin{cases} 0 & x \neq 1 \\ 1 & x = 1 \end{cases}$$

**Definition 35** Let $X$ be a metric space. A map $f: X \to X$ is a *contraction* if there exists $c < 1$ such that $d(f(x), f(y)) \leq cd(x, y)$ for all $x, y \in X$.

**Theorem 3** (Banach) *If $X$ is a complete metric space and $f$ is a contraction in $X$, then $f$ has a unique fixed point $x \in X$, that is, $f(x) = x$.*

## Some Function and Operator Spaces

The spaces of functions and operators can be equipped with different topologies, given by various concepts of convergence and of norms (or sometimes seminorms), very often with different such concepts for the same space. As we saw earlier, a norm in a vector space gives rise to a metric, and hence to a topology. Similarly with the concept of convergence for sequences of functions and operators, as one then knows what the limit points, and hence closed sets, are.

But before we do that, let us introduce, in a slightly different context, a topology which is in some sense the natural one for the space of continuous maps from one space to another.

**Definition 36** Consider a family $F$ of maps from a topological space $X$ to a topological space $Y$, and define $W(K, U) = \{f : f \in F, f(K) \subseteq U\}$. Then the family of all sets of the form $W(K, U)$ with $K$ compact (in $X$) and $U$ open (in $Y$) form a sub-basis for the *compact open topology* for $F$.

Consider a topological space $X$ and sequences of functions $(f_n)$ on it. Let $D \subseteq X$. We can then define pointwise convergence and uniform convergence exactly as for functions on subsets of the real line.

**Definition 37** Let $X$, $D$ and $(f_n)$ as above.

(i) The functions $f_n$ *converge pointwise* on $D$ to a function $f$ if the sequence of numbers $f_n(x) \to f(x), \forall x \in D$.
(ii) The functions $f_n$ *converge uniformly* on $D$ to a function $f$ if given $\epsilon > 0$, there exists $N$ such that for all $n > N$ we have $|f_n(x) - f(x)| < \epsilon, \forall x \in D$.

Next we consider the Lebesgue spaces $L^p$, that is, functions $f$ defined on subsets of $\mathbb{R}^n$, such that $|f(x)|^p$ is Lebesgue integrable, for real numbers $p \geq 1$. To define these spaces, we tacitly take equivalence classes of functions which are equal almost everywhere (that is, up to a null set), but very often we can take representatives of these classes and just deal with genuine functions instead. Note that of all $L^p$, only $L^2$ is a Hilbert space.

**Definition 38** In the space $L^p$, we define its norm by

$$\|f\| = \left( \int |f(x)|^p \, dx \right)^{1/p}$$

Now we turn to general normed spaces, and operators on them.

**Definition 39** Convergence in the norm is also called strong convergence. In other words, a sequence $(x_n)$ in a normed space $X$ is said to *converge strongly* to $x$ if

$$\lim_{n \to \infty} \|x_n - x\| = 0$$

**Definition 40** A sequence $(x_n)$ in a normed space $X$ is said to *converge weakly* to $x$ if

$$\lim_{n \to \infty} f(x_n) = f(x)$$

for all bounded linear functionals $f$.

Consider the space $B(X, Y)$ of bounded linear operators $T$ from $X$ to $Y$. We can make this into a normed space by defining the following norm:

$$\|T\| = \sup_{x \in X, \|x\| = 1} \|Tx\|$$

Then we can define three different concepts of convergence on $B(X, Y)$. There are in fact more in current use in functional analysis.

**Definition 41** Let $X$ and $Y$ be normed spaces and let $(T_n)$ be a sequence of operators $T_n \in B(X, Y)$.

(i) $(T_n)$ is *uniformly convergent* if it converges in the norm.
(ii) $(T_n)$ is *strongly convergent* if $(T_n x)$ converges strongly for every $x \in X$.
(iii) $(T_n)$ is *weakly convergent* if $(T_n x)$ converges weakly for every $x \in X$.

**Remark** Clearly we have: uniform convergence $\Longrightarrow$ strong convergence $\Longrightarrow$ weak convergence, and the limits are the same in all three cases. However, the converses are in general not true.

## Homotopy Groups

The most elementary and obvious property of a topological space $X$ is the number of connected components it has. The next such property, in a certain sense, is the number of holes $X$ has. There

are higher analogues of these, called the *homotopy groups*, which are topological invariants, that is, they are invariant under homeomorphisms. They play important roles in many topological considerations in field theory and other topics of mathematical physics. The articles Topological Defects and Their Homotopy Classification and Electric-Magnetic Duality contain some examples.

**Definition 42** Given a topological space $X$, the zeroth homotopy set, denoted $\pi_0(X)$, is the set of connected components of $X$. One sometimes writes $\pi_0(X) = 0$ if $X$ is connected.

To define the fundamental group of $X$, or $\pi_1(X)$, we shall need the concept of closed loops, which we shall find useful in other ways too. For simplicity, we shall consider based loops (that is, loops passing through a fixed point in $X$). It seems that in most applications, these are the relevant ones. One could consider loops of various smoothness (when $X$ is a manifold), but in view of applications to quantum field theory, we shall consider continuous loops, which are also the ones relevant for topology.

**Definition 43** Given a topological space $X$ and a point $x_0 \in X$, a (*closed*) (*based*) *loop* is a continuous function of the parametrized circle to $X$:

$$\xi : [0, 2\pi] \to X$$

satisfying $\xi(0) = \xi(2\pi) = x_0$.

**Definition 44** Given a connected topological space $X$ and a point $x_0 \in X$, the space of all closed based loops is called the (parametrized based) *loop space* of $X$, denoted $\Omega X$.

**Remarks**

(i) The loop space $\Omega X$ inherits the relative compact–open topology from the space of continuous maps from the closed interval $[0, 2\pi]$ to $X$. It also has a natural base point: the constant function mapping all of $[0, 2\pi]$ to $x_0$. Hence it is easy to iterate the construction and define $\Omega^k X, k \geq 1$.

(ii) Here we have chosen to parametrize the circle by $[0, 2\pi]$, as is more natural if we think in terms of the phase angle. We could easily have chosen the unit interval [0,1] instead. This would perhaps harmonize better with our previous definition of paths and the definitions of homotopies below.

**Proposition 7** *The fundamental group of a topological space $X$, denoted $\pi_1(X)$, consists of classes of closed loops in $X$ which cannot be continuously deformed into one another while preserving the base point.*

**Definition 45** A space $X$ is called *simply connected* if $\pi_1(X)$ is trivial.

To define the higher homotopy groups, let us go into a little detail about homotopy.

**Definition 46** Given two topological spaces $X$ and $Y$, and maps

$$p, q : X \to Y$$

we say that $h$ is a *homotopy* between the maps $p, q$ if

$$h : X \times I \to Y$$

is a continuous map such that $h(x, 0) = p(x)$, $h(x, 1) = q(x)$, where $I$ is the unit interval $[0, 1]$. In this case, we write $p \simeq q$.

**Definition 47** A map $f : X \to Y$ is a *homotopy equivalence* if there exists a map $g : Y \to X$ such that $g \circ f \simeq \mathrm{id}_X$ and $f \circ g \simeq \mathrm{id}_Y$.

**Remark** This is an equivalence relation.

**Definition 48** For a topological space $X$ with base point $x_0$, we define $\pi_n(X), n \geq 0$ as the set of homotopy equivalence classes of based maps from the $n$-sphere $S^n$ to $X$.

**Remark** This coincides with the previous definitions for $\pi_0$ and $\pi_1$.

There is a very nice relation between homotopy classes and loop spaces.

**Proposition 8** $\pi_n(X) = \pi_{n-1}(\Omega X) = \cdots = \pi_0(\Omega^n X)$.

**Remarks**

(i) When we consider the gauge group $G$ in a Yang–Mills theory, its fundamental group classifies the monopoles that can occur in the theory.

(ii) For $n \geq 1, \pi_n(X)$ is a group, the group action coming from the joining of two loops together to form a new loop. On the other hand, $\pi_0(X)$ in general is not a group. However, when $X$ is a Lie group, then $\pi_0(X)$ inherits a group structure from $X$, because it can be identified with the quotient group of $X$ by its identity-connected component. For example, the two components of O(3) can be identified with the two elements of the group $\mathbb{Z}_2$, the component where the determinant equals 1 corresponding to 0 in $\mathbb{Z}_2$ and the component where the determinant equals $-1$ corresponding to 1 in $\mathbb{Z}_2$.

(iii) For $n \geq 2$, the group $\pi_n(X)$ is always abelian.

(iv) Examples of nonabelian $\pi_1$ are the fundamental groups of some Riemann surfaces.

(v) Since $\pi_1$ is not necessarily abelian, much of the direct-sum notation we use for the homotopy

groups should more correctly be written multiplicatively. However, in most literature in mathematical physics, the additive notation seems to be preferred.

**Examples**

(i) $\pi_n(X \times Y) = \pi_n(X) + \pi_n(Y)$, $n \geq 1$.
(ii) For the spheres, we have the following results:

$$\pi_i(S^n) = \begin{cases} 0 & \text{if } i > n \\ \mathbb{Z} & \text{if } i = n \end{cases}$$
$$\pi_i(S^1) = 0 \qquad \text{if } i > 1$$
$$\pi_{n+1}(S^n) = \mathbb{Z}_2 \qquad \text{if } n \geq 3$$
$$\pi_{n+2}(S^n) = \mathbb{Z}_2 \qquad \text{if } n \geq 2$$
$$\pi_6(S^3) = \mathbb{Z}_{12}$$

(iii) From the theory of sphere bundles, we can deduce:

$$\pi_i(S^2) = \pi_{i-1}(S^1) + \pi_i(S^3) \quad \text{if } i \geq 2$$
$$\pi_i(S^4) = \pi_{i-1}(S^3) + \pi_i(S^7) \quad \text{if } i \geq 2$$
$$\pi_i(S^8) = \pi_{i-1}(S^7) + \pi_i(S^{15}) \quad \text{if } i \geq 2$$

and the first of these relations give the following more succinct result:

$$\pi_i(S^3) = \pi_i(S^2) \quad \text{if } i \geq 3$$

(iv) A result of Serre says that all the homotopy groups of spheres are in fact finite except $\pi_n(S^n)$ and $\pi_{4n-1}(S^{2n}), n \geq 1$.

**Definition 49** Given a connected space $X$, a map $\pi : B \to X$ is called a *covering* if (i) $\pi(B) = X$, and (ii) for each $x \in X$, there exists an open connected neighborhood $V$ of $x$ such that each component of $\pi^{-1}(V)$ is open in $B$, and $\pi$ restricted to each component is a homeomorphism. The space $B$ is called a *covering space*.

**Examples**

(i) The real line $\mathbb{R}$ is a covering of the group U(1).
(ii) The group SU(2) is a double cover of the group SO(3).
(iii) The group SL(2, $\mathbb{C}$) is a double cover of the Lorentz group SO(1, 3).
(iv) The group SU(2, 2) is a 4-fold cover of the conformal group in four dimensions. This local isomorphism is of great importance in twistor theory.

**Remarks**

(i) By considering closed loops in $X$ and their coverings in $B$ it is easily seen that the fundamental group $\pi_1(X)$ acts on the coverings of $X$. If we further assume that the action is transitive, then we have the following nice result: coverings of $X$ are in 1–1 correspondence with normal subgroups of $\pi_1(X)$.
(ii) Given a connected space $X$, there always exists a unique connected simply connected covering space $\widetilde{X}$, called the universal covering space. Furthermore, $\widetilde{X}$ covers all the other covering spaces of $X$. For the higher homotopy groups, one has

$$\pi_n(X) = \pi_n(\widetilde{X}), \quad n \geq 2$$

One very important class of homotopy groups are those of Lie groups. To simplify matters, we shall consider only connected groups, that is, $\pi_0(G) = 0$. Also we shall deal mainly with the classical groups, and in particular, the orthogonal and unitary groups.

**Proposition 9** *Suppose that G is a connected Lie group.*

(i) *If G is compact and semi-simple, then* $\pi_1(G)$ *is finite. This implies that* $\widetilde{G}$ *is still compact.*
(ii) $\pi_2(G) = 0$.
(iii) *For G compact, simple, and nonabelian,* $\pi_3(G) = \mathbb{Z}$.
(iv) *For G compact, simply connected, and simple,* $\pi_4(G) = 0$ or $\mathbb{Z}_2$.

**Examples**

(i) $\pi_1(\mathrm{SU}(n)) = 0$.
(ii) $\pi_1(\mathrm{SO}(n)) = \mathbb{Z}_2$.
(iii) Since the unitary groups U($n$) are topologically the product of SU($n$) with a circle $S^1$, their homotopy groups are easily computed using the product formula. We remind ourselves that U(1) is topologically a circle and SU(2) topologically $S^3$.
(iv) For $i \geq 2$, we have:

$$\pi_i(\mathrm{SO}(3)) = \pi_i(\mathrm{SU}(2))$$
$$\pi_i(\mathrm{SO}(5)) = \pi_i(\mathrm{Sp}(2))$$
$$\pi_i(\mathrm{SO}(6)) = \pi_i(\mathrm{SU}(4))$$

Just for interest, and to show the richness of the subject, some isomorphisms for homotopy groups are shown in Table 1 and some homotopy groups for low SU($n$) and SO($n$) are listed in Table 2.

**Table 1** Some isomorphisms for homotopy groups

| *Isomorphism* | *Range* |
|---|---|
| $\pi_i(\mathrm{SO}(n)) \cong \pi_i(\mathrm{SO}(m))$ | $n, m \geq i+2$ |
| $\pi_i(\mathrm{SU}(n)) \cong \pi_i(\mathrm{SU}(m))$ | $n, m \geq \frac{1}{2}(i+1)$ |
| $\pi_i(\mathrm{Sp}(n)) \cong \pi_i(\mathrm{Sp}(m))$ | $n, m \geq \frac{1}{4}(i-1)$ |
| $\pi_i(G_2) \cong \pi_i(\mathrm{SO}(7))$ | $2 \leq i \leq 5$ |
| $\pi_i(F_4) \cong \pi_i(\mathrm{SO}(9))$ | $2 \leq i \leq 6$ |
| $\pi_i(\mathrm{SO}(9)) \cong \pi_i(\mathrm{SO}(7))$ | $i \leq 13$ |

**Table 2** Some homotopy groups for low SU($n$) and SO($n$)

| | $\pi_4$ | $\pi_5$ | $\pi_6$ | $\pi_7$ | $\pi_8$ | $\pi_9$ | $\pi_{10}$ |
|---|---|---|---|---|---|---|---|
| SU(2) | $\mathbb{Z}_2$ | $\mathbb{Z}_2$ | $\mathbb{Z}_{12}$ | $\mathbb{Z}_2$ | $\mathbb{Z}_2$ | $\mathbb{Z}_3$ | $\mathbb{Z}_{15}$ |
| SU(3) | 0 | $\mathbb{Z}$ | $\mathbb{Z}_6$ | 0 | $\mathbb{Z}_{12}$ | $\mathbb{Z}_3$ | $\mathbb{Z}_{30}$ |
| SU(4) | 0 | $\mathbb{Z}$ | 0 | $\mathbb{Z}$ | $\mathbb{Z}_{24}$ | $\mathbb{Z}_2$ | $\mathbb{Z}_{120}+\mathbb{Z}_2$ |
| SU(5) | 0 | $\mathbb{Z}$ | 0 | $\mathbb{Z}$ | 0 | $\mathbb{Z}$ | $\mathbb{Z}_{120}$ |
| SU(6) | 0 | $\mathbb{Z}$ | 0 | $\mathbb{Z}$ | 0 | $\mathbb{Z}$ | $\mathbb{Z}_3$ |
| SO(5) | $\mathbb{Z}_2$ | $\mathbb{Z}_2$ | 0 | $\mathbb{Z}$ | 0 | 0 | $\mathbb{Z}_{120}$ |
| SO(6) | 0 | $\mathbb{Z}$ | 0 | $\mathbb{Z}$ | $\mathbb{Z}_{24}$ | $\mathbb{Z}_2$ | $\mathbb{Z}_{120}+\mathbb{Z}_2$ |
| SO(7) | 0 | 0 | 0 | $\mathbb{Z}$ | $\mathbb{Z}_2+\mathbb{Z}_2$ | $\mathbb{Z}_2+\mathbb{Z}_2$ | $\mathbb{Z}_{24}$ |
| SO(8) | 0 | 0 | 0 | $\mathbb{Z}+\mathbb{Z}$ | $\mathbb{Z}_2+\mathbb{Z}_2+\mathbb{Z}_2$ | $\mathbb{Z}_2+\mathbb{Z}_2+\mathbb{Z}_2$ | $\mathbb{Z}_{24}+\mathbb{Z}_{24}$ |
| SO(9) | 0 | 0 | 0 | $\mathbb{Z}$ | $\mathbb{Z}_2+\mathbb{Z}_2$ | $\mathbb{Z}_2+\mathbb{Z}_2$ | $\mathbb{Z}_{24}$ |
| SO(10) | 0 | 0 | 0 | $\mathbb{Z}$ | $\mathbb{Z}_2$ | $\mathbb{Z}+\mathbb{Z}_2$ | $\mathbb{Z}_{12}$ |

## Appendix: A Mathematician's Basic Toolkit

The following is a drastically condensed list, most of which is what a mathematics undergraduate learns in the first few weeks. The rest is included for easy reference. These notations and concepts are used universally in mathematical writing. We have not endeavored to arrange the material in a logical order. Furthermore, given structures such as sets, groups, etc., one can usually define "substructures" such as subsets, subgroups, etc., in a straightforward manner. We shall therefore not spell this out.

### Sets

| | |
|---|---|
| $A \cup B = \{x : x \in A \text{ or } x \in B\}$ | union |
| $A \cap B = \{x : x \in A \text{ and } x \in B\}$ | intersection |
| $A \backslash B = \{x : x \in A \text{ and } x \notin B\}$ | complement |
| $A \times B = \{(x, y) : x \in A, y \in B\}$ | Cartesian product |

### Maps

1. A map or mapping $f : A \to B$ is an assignment of an element $f(x)$ of $B$ for every $x \in A$.
2. A map $f : A \to B$ is injective if $f(x) = f(y) \Longrightarrow x = y$. This is sometimes called a 1–1 map, a term to be avoided.
3. A map $f : A \to B$ is surjective if for every $y \in B$ there exists an $x \in A$ such that $y = f(x)$. This is sometimes called an "onto" map.
4. A map $f : A \to B$ is bijective if it is both surjective and injective. This is also sometimes called a 1–1 map, a term to be equally avoided.
5. For any map $f : A \to B$ and any subset $C \subseteq B$, the inverse image $f^{-1}(C) = \{x : f(x) \in C\} \subseteq A$ is always defined, although, of course, it can be empty. On the other hand, the map $f^{-1}$ is defined if and only if $f$ is bijective.
6. A map from a set to either the real or complex numbers is usually called a function.
7. A map between vector spaces, and more particularly normed spaces (including Hilbert spaces), is called an operator. Most often, one considers linear operators.
8. An operator from a vector space to its field of scalars is called a functional. Again, one considers almost exclusively linear functionals.

### Relations

1. A relation $\sim$ on a set $A$ is a subset $R \subseteq A \times A$. We say that $x \sim y$ if $(x, y) \in R$.
2. We shall only be interested in equivalence relations. An equivalence relation $\sim$ is one satisfying, for all $x, y, z \in A$:
   (a) $x \sim x$ ("reflexive"),
   (b) $x \sim y \Longrightarrow y \sim x$ ("symmetric"),
   (c) $x \sim y, y \sim z \Longrightarrow x \sim z$ ("transitive").
3. If $\sim$ is an equivalence relation in $A$, then for each $x \in A$, we can define its equivalence class:

   $$[x] = \{y \in A : y \sim x\}$$

   It can be shown that equivalence classes are nonempty, any two equivalence classes are either equal or disjoint, and they together partition the set $A$. Subgroup equivalence classes are called cosets.
4. An element of an equivalence class is called a representative.

### Groups

A group is a set G with a map, called multiplication or group law

$$\begin{aligned} G \times G &\longrightarrow G \\ (x, y) &\longmapsto xy \end{aligned}$$

satisfying

1. $(xy)z = x(yz), \forall x, y, z \in G$ ("associative");
2. there exists a neutral element (or identity) 1 such that $1x = x1 = x, \forall x \in G$; and
3. every element $x \in G$ has an inverse $x^{-1}$, that is, $xx^{-1} = x^{-1}x = 1$.

A map such as the multiplication in the definition is an example of a binary operation. Note that we have denoted the group law as multiplication here. It is usual to denote it additively if the group is abelian, that is, if $xy = yx, \forall x, y \in G$. In this case, we may write the condition as $x + y = y + x$, and call the identity element 0.

### Rings

A ring is a set $R$ equipped with two binary operations, $x + y$ called addition, and $xy$ called multiplication, such that

1. $R$ is an abelian group under addition;
2. the multiplication is associative; and
3. $(x + y)z = xz + yz, x(y + z) = xy + xz, \forall x, y, z \in R$ ("distributive").

If the multiplication is commutative ($xy = yx$) then the ring is said to be commutative. A ring may contain a multiplicative identity, in which case it is called a ring with unit element.

An ideal $I$ of $R$ is a subring of $R$, satisfying in addition

$$r \in R, a \in I \implies ra \in I, ar \in I$$

One can define in an obvious fashion a left-ideal and a right- ideal. The above definition will then be for a two-sided ideal.

### Modules

Given a ring $R$, an $R$-module is an abelian group $M$, together with an operation, $M \times R \to M$, denoted multiplicatively, satisfying, for $x, y \in M, r, s \in R$,

1. $(x + y)r = xr + yr$,
2. $x(r + s) = xr + xs$,
3. $x(rs) = (xr)s$, and
4. $x1 = x$

The term right $R$-module is sometimes used, to distinguish it from obviously defined left $R$-modules.

### Fields

A field $F$ is a commutative ring in which every nonzero element is invertible.

The additive identity 0 is never invertible, unless $0 = 1$, so it is usual to assume that a field has at least two elements, 0 and 1.

The most common fields we come across are, of course, the number fields: the rationals, the reals, and the complex numbers.

### Vector Spaces

A vector space, or sometimes linear space, $V$, over a field $F$, is an abelian group, written additively, with a map $F \times V \to V$ such that, for $x, y \in V, \alpha, \beta \in F$,

1. $\alpha(x + y) = \alpha x + \alpha y$ ("linearity"),
2. $(\alpha + \beta)x = \alpha x + \beta x$,
3. $(\alpha\beta)x = \alpha(\beta x)$, and
4. $1x = x$.

A vector space is then a right (or left) $F$-module. The elements of $V$ are called vectors, and those of $F$ scalars.

### Algebras

An algebra $A$ over a field $F$ is a ring which is a vector space over $F$, such that

$$\alpha(ab) = (\alpha a)b = a(\alpha b), \quad \alpha \in F, \ a, b \in A$$

Note that in some older literature, particularly the Russian school, an algebra of operators is called a ring of operators.

## Abelian and Nonabelian Gauge Theories Using Differential Forms

**A C Hirshfeld**, Universität Dortmund, Dortmund, Germany

### Introduction

Quantum electrodynamics is the theory of the electromagnetic interactions of photons and electrons. When attempting to generalize this theory to other interactions it turns out to be necessary to identify its essential components. The essential properties of electrodynamics are contained in its formulation as an "abelian gauge theory." The generalization to include other interactions is then reduced to incorporating the structure of nonabelian groups. This becomes particularly clear when we formulate the theory in the language of differential forms.

Here we first present the formulation of electrodynamics using differential forms. The electromagnetic fields are introduced via the Lorentz force equation. They are recognized as the components of a differential 2-form. This form fulfills two differential conditions, which are equivalent to Maxwell's equations. These are expressed with the help of a differential operator and its Hermitian conjugate, the codifferential operator. We consider the effects of charge conservation and introduce electromagnetic potentials, which are defined up to gauge transformations. We finally consider Weyl's argument for the existence of the electromagnetic interaction as a consequence of the local phase invariance of the electron wave function.

We then go on to present the nonabelian generalization. The gauge bosons appear in a theory with fermions by requiring invariance of the theory with respect to local gauge transformations. When the fermions group into symmetry multiplets this gives rise to a gauge group SU($N$) involving $N^2-1$ gauge bosons mediating the interaction, where $N$ is the dimension of the Lie algebra. The interaction arises through the necessity of replacing the usual derivatives by covariant derivatives, which transform in a natural way in order to preserve the gauge invariance. The covariant derivatives involve the gauge potentials, whose transformation properties are dictated by those of the covariant derivative. Whereas for an abelian gauge theory such as electromagnetism scalar-valued $p$-forms are sufficient (actually only $p=1,2$), a nonabelian gauge theory involves the use of Lie-algebra-valued $p$-forms. These are introduced and used to construct the Yang–Mills action, which involves the field strength tensor which is determined from the gauge potentials. This action leads to the Yang–Mills equations for the gauge potentials, which are the nonabelian generalizations of the Maxwell equations.

### Relativistic Kinematics

The trajectory of a mass point is described as $x^\mu(\tau)$, where $\tau$ is the invariant proper time interval:

$$d\tau^2 = dt^2 - d\boldsymbol{x}\cdot d\boldsymbol{x} = dt^2(1-\boldsymbol{v}^2) \qquad [1]$$

with $\boldsymbol{v} = d\boldsymbol{x}/dt$. With the abbreviation $\gamma = (1-\boldsymbol{v}^2)^{-1/2}$ this yields $d\tau = (1/\gamma)dt$.

The 4-velocity of a point is defined as $u^\mu = dx^\mu/d\tau = \gamma(dx^\mu/dt)$. The quantity

$$u^2 = g_{\mu\nu}u^\mu u^\nu = \frac{dx^\mu dx_\mu}{d\tau^2} = 1 \qquad [2]$$

is a relativistic invariant. Here

$$g_{\mu\nu} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \qquad [3]$$

is the metric of Minkowski space.

The 4-momentum of a particle is $p^\mu = m_0 u^\mu = (m_0\gamma, m_0\gamma\boldsymbol{v})$, and $p^\mu p_\mu = m_0^2$. The 4-force is

$$f^\mu = \frac{dp^\mu}{d\tau} = \gamma\frac{dp^\mu}{dt} = \gamma\left(\frac{dp^0}{dt}, \boldsymbol{f}\right) \qquad [4]$$

with the 3-force

$$\boldsymbol{f} = \frac{d(m_0\gamma\boldsymbol{v})}{dt} \qquad [5]$$

Differentiate $p^2 = m_0^2$ with respect to $\tau$, this yields

$$2p^{\mu}f_{\mu} = 2m_0\gamma^2\left(\frac{dp^0}{dt} - \boldsymbol{f}\cdot\boldsymbol{v}\right) = 0 \qquad [6]$$

or

$$\frac{dp^0}{dt} = \boldsymbol{f}\cdot\boldsymbol{v} = \boldsymbol{f}\cdot\frac{d\boldsymbol{x}}{dt} \qquad [7]$$

This says that

$$dp^0 = \boldsymbol{f}\cdot d\boldsymbol{x} = dW \qquad [8]$$

where $W$ is the work done and $p^0$ is the energy.

For a charged particle, the Lorentz force is

$$\boldsymbol{f} = q(\boldsymbol{E} + \boldsymbol{v}\times\boldsymbol{B}) \qquad [9]$$

where $q$ is the charge of the particle, $\boldsymbol{E}$ is the electric, and $\boldsymbol{B}$ the magnetic field strength. Since $\boldsymbol{f}\cdot\boldsymbol{v} = q\boldsymbol{E}\cdot\boldsymbol{v}$, we have the four-dimensional form of the Lorentz force:

$$f^{\mu} = q\gamma(\boldsymbol{E}\cdot\boldsymbol{v}, \boldsymbol{E} + \boldsymbol{v}\times\boldsymbol{B}) \qquad [10]$$

## The Lorentz Force Equation with Differential Forms

We write the Lorentz force equation as an equation for a differential form $f = f_{\mu}dx^{\mu}$, with $f_{\mu} = g_{\mu\nu}f^{\nu}$. The velocity-dependent Lorentz force is

$$f = -qi_uF \qquad [11]$$

with

$$u = \gamma\left(\frac{\partial}{\partial t} + v^x\frac{\partial}{\partial x} + v^y\frac{\partial}{\partial y} + v^z\frac{\partial}{\partial z}\right) \qquad [12]$$

the 4-velocity and $F$ the electromagnetic field strength:

$$F = \mathcal{E}\wedge dt + \mathcal{B} \qquad [13]$$

where $\mathcal{E}$ is a 1-form in three dimensions,

$$\mathcal{E} = E_x dx + E_y dy + E_z dz \qquad [14]$$

and $\mathcal{B}$ is a 2-form in three dimensions,

$$\mathcal{B} = B_x dy\wedge dz + B_y dz\wedge dx + B_z dx\wedge dy \qquad [15]$$

The symbol $i_u$ indicates a contraction of a 2-form with a vector, which is defined as

$$i_uF(v) = F(u, v) \qquad [16]$$

for an arbitrary vector $v$. The contraction of a 2-form with a vector yields a 1-form.

It is easily seen that a 2-form can be expressed in terms of a polar vector and an axial vector: if it is to be invariant with respect to parity transformations with

$$t\to t,\quad x\to -x,\quad y\to -y,\quad z\to -z \qquad [17]$$

the fields in eqn [13] must transform as

$$\boldsymbol{E}\to -\boldsymbol{E},\quad \boldsymbol{B}\to\boldsymbol{B} \qquad [18]$$

Now we check the validity of eqn [11]. We have

$$\begin{aligned} f &= -qi_uF \\ &= q\gamma(\boldsymbol{v}\cdot\boldsymbol{E})dt - q\gamma[(E^x + (\boldsymbol{v}\times\boldsymbol{B})^x)dx \\ &\quad + (E^y + (\boldsymbol{v}\times\boldsymbol{B})^y)dy + (E^z + (\boldsymbol{v}\times\boldsymbol{B})^z)dz] \end{aligned} \qquad [19]$$

in agreement with eqn [10]. We remember to change the signs in $E_x = -E^x, B_x = -B^x$, etc.

## The Codifferential Operator

The space of $p$-forms on an $n$-dimensional manifold is an

$$\binom{n}{p} = \binom{n}{n-p} = \frac{n!}{(n-p)!p!} \qquad [20]$$

dimensional vector space. The space of $p$-forms is thus isomorphic to the space of $(n-p)$-forms. The Hodge dual operator maps the $p$-forms into the $(n-p)$-forms, and is defined by

$$\alpha\wedge *\beta = \langle\alpha,\beta\rangle dx^1\wedge\cdots\wedge dx^n \qquad [21]$$

Here $\langle\alpha,\beta\rangle$ is the scalar product of two $p$-forms:

$$\langle\alpha,\beta\rangle = \alpha_{i_1\cdots i_p}\beta^{i_1\cdots si_p} \qquad [22]$$

where $\alpha_{i_1\cdots si_p}$ are the coefficients of the form $\alpha$,

$$\alpha = \alpha_{i_1\cdots i_p}dx^{i_1}\wedge\cdots\wedge dx^{i_p} \qquad [23]$$

$\beta_{j_1\cdots sj_p}$ are the coefficients of the form $\beta$,

$$\beta = \beta_{j_1\cdots j_p}dx^{j_1}\wedge\cdots\wedge dx^{j_p} \qquad [24]$$

and

$$\beta^{i_1\cdots i_p} = g^{i_1j_1}\cdots g^{i_pj_p}\beta_{j_1\cdots j_p} \qquad [25]$$

The indices satisfy $i_1 < \cdots < i_p$ and $j_1 < \cdots < j_p$.

The basis elements are orthogonal with respect to this scalar product, and

$$\begin{aligned} &\langle dx^{i_1}\wedge\cdots\wedge dx^{i_p}, dx^{i_1}\wedge\cdots\wedge dx^{i_p}\rangle \\ &= g_{i_1i_1}\cdots g_{i_pi_p} \end{aligned} \qquad [26]$$

The Hodge dual has the property that

$$* \left( dx^{\sigma(1)} \wedge \cdots \wedge dx^{\sigma(p)} \right) = g_{\sigma(1)\sigma(1)} \cdots g_{\sigma(p)\sigma(p)} (\text{sign}\, \sigma) \times \left( dx^{\sigma(p+1)} \wedge \cdots \wedge dx^{\sigma(n)} \right) \quad [27]$$

where $\sigma$ is a permutation of the indices $(1, \ldots, n)$, $\sigma(1) < \cdots < \sigma(p)$, and $\sigma(p+1) < \cdots < \sigma(n)$. We also have

$$* \left( dx^{\sigma(p+1)} \wedge \cdots \wedge dx^{\sigma(n)} \right) = g_{\sigma(p+1)\sigma(p+1)} \cdots g_{\sigma(n)\sigma(n)} (-1)^{p(n-p)} (\text{sign}\, \sigma) \times \left( dx^{\sigma(1)} \wedge \cdots \wedge dx^{\sigma(p)} \right) \quad [28]$$

We therefore find that the application of the Hodge dual to a $p$-form twice yields

$$\begin{aligned} **\left( dx^{\sigma(1)} \wedge \cdots \wedge dx^{\sigma(p)} \right) &= g_{\sigma(1)\sigma(1)} \cdots g_{\sigma(p)\sigma(p)} (\text{sign}\, \sigma) * \left( dx^{\sigma(p+1)} \wedge \cdots \wedge dx^{\sigma(n)} \right) \\ &= g_{\sigma(1)\sigma(1)} \cdots g_{\sigma(n)\sigma(n)} (-1)^{p(n-p)} dx^{\sigma(1)} \wedge \cdots \wedge dx^{\sigma(p)} \end{aligned} \quad [29]$$

or

$$** = (-1)^{p(n-p)} (-1)^{\text{Ind}\, g} \text{Id} \quad [30]$$

where $\text{Ind}\, g$ is the number of times $(-1)$ occurs along the diagonal of $g$.

Now let $\alpha$ be a $(p-1)$-form, and $\beta$ a $p$-form. Then $d * \beta$ is an $(n-p+1)$-form, and

$$\begin{aligned} d(\alpha \wedge * \beta) &= d\alpha \wedge * \beta + (-1)^{p-1} \alpha \wedge d * \beta \\ &= d\alpha \wedge * \beta + (-1)^{(p-1)} (-1)^{(n-p+1)(p-1)} \times (-1)^{\text{Ind} g} \alpha \wedge (**) d * \beta \\ &= d\alpha \wedge * \beta + (-1)^{n(p-1)} (-1)^{\text{Ind} g} \times \alpha \wedge * (* d * \beta) \end{aligned} \quad [31]$$

We then have

$$(d\alpha, \beta) - (\alpha, d^* \beta) = \int_M d(\alpha \wedge * \beta) \quad [32]$$

with

$$d^* = -(-1)^{n(p-1)} (-1)^{\text{Ind}\, g} * d * \quad [33]$$

We are here using the scalar product of two $p$-forms

$$(\alpha, \beta) := \int_M (\alpha \wedge * \beta) \quad [34]$$

With the help of Stokes' theorem the last integral in eqn [32] may be turned into a surface term at infinity, which vanishes for $\alpha$ and $\beta$ with compact support. $d^*$ is the adjoint operator to $d$ with respect to the scalar product $( \, , \, )$. Whereas the differential operator $d$ maps $p$-forms into $(p+1)$-forms, the codifferential operator $d^*$ maps $p$-forms into $(p-1)$-forms.

The relation $d^2 = 0$ leads to

$$(d^*)^2 \propto (*d*)(*d*) \propto *d^2* = 0 \quad [35]$$

This fact plays an essential role in connection with the conservation laws.

Finally, we want to obtain a coordinate expression for $d^* \beta$. Indeed $d^* \beta = -\text{Div}\, \beta$ for

$$(\text{Div} \beta)_K = \frac{\partial \beta^j_K}{\partial x^j} \quad [36]$$

where $K$ is the multi-index of the coeffecients in $\beta = \beta_{\underline{K}} dx^K$, and $\underline{K}$ indicates that $K = (k_1, \ldots, k_p)$ is in the order $k_1 < \cdots < k_p$. We will show that $(\alpha, d^* \beta) = (\alpha, -\text{Div} \beta)$ for an arbitrary $(p-1)$-form $\alpha$. It is a fact that

$$(\alpha, d^* \beta) = (d\alpha, \beta) = \int (d\alpha)_{\underline{I}} \beta^I * 1 \quad [37]$$

Now we have the coordinate expressions

$$d\alpha = (d\alpha_{\underline{L}}) \wedge dx^L \quad [38]$$

and $(dx^L)_K = \delta^L_K$. It follows that

$$(d\alpha)_{\underline{I}} = (d\alpha_{\underline{L}} \wedge dx^L)_{\underline{I}} = \delta^{jK}_{\underline{I}} \frac{\partial \alpha_{\underline{L}}}{\partial x^j} \delta^L_K \quad [39]$$

or

$$(d\alpha)_{\underline{I}} = \delta^{j\underline{K}}_{\underline{I}} \frac{\partial \alpha_K}{\partial x^j} \quad [40]$$

Here we use

$$(\alpha \wedge \beta)_I = \delta^{KL}_I \alpha_K \beta_L \quad [41]$$

where

$$\delta^{KL}_I = \begin{cases} 1 & \text{if (KL) is an even permutation of I} \\ -1 & \text{if (KL) is an odd permutation of I} \\ 0 & \text{otherwise} \end{cases} \quad [42]$$

Use of the Leibnitz rule yields

$$\begin{aligned} \int (d\alpha)_{\underline{I}} \beta^I * 1 &= \int \delta^{j\underline{K}}_{\underline{I}} \frac{\partial \alpha_K}{\partial x^j} \beta^I * 1 \\ &= \int \frac{\partial (\delta^{j\underline{K}}_{\underline{I}} \alpha_K \beta^I)}{\partial x^j} * 1 \\ &\quad - \int \alpha_{\underline{K}} \delta^{jK}_{\underline{I}} \frac{\partial \beta^I}{\partial x^j} * 1 \end{aligned} \quad [43]$$

The first term corresponds to a surface integration and we can neglect it. We then have $\delta^{jK}_{\underline{I}}\beta^I = \beta^{jK}$ from the antisymmetry of $\beta$, so that

$$(\alpha, d^*\beta) = -\int \alpha_{\underline{K}} \frac{\partial \beta^{jK}}{\partial x^j} * 1 = (\alpha, -\mathrm{Div}\beta) \qquad [44]$$

## The Maxwell Equations

The Maxwell equations become remarkably concise when expressed in terms of differential forms, namely

$$dF = 0, \qquad d^*F = -j \qquad [45]$$

where $F$ is the field strength and $j$ is the current density. We wish to demonstrate this. We use a $(3+1)$-separation of the exterior derivative into a timelike and a spacelike part:

$$d = \boldsymbol{d} + dt \wedge \frac{\partial}{\partial t} \qquad [46]$$

We then get

$$dF = \left(\boldsymbol{d}\mathcal{E} + \frac{\partial \mathcal{B}}{\partial t}\right) \wedge dt + \boldsymbol{d}\mathcal{B} = 0 \qquad [47]$$

By comparing coefficients, we arrive at

$$\boldsymbol{d}\mathcal{E} = -\frac{\partial \mathcal{B}}{dt}, \qquad \boldsymbol{d}\mathcal{B} = 0 \qquad [48]$$

In vector notation

$$\mathrm{curl}\,\boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t}, \qquad \mathrm{div}\,\boldsymbol{B} = 0 \qquad [49]$$

the usual form of the homogeneous Maxwell equations.

By direct application of the formula [27], one finds

$$*F = -\star\mathcal{B} \wedge dt + \star\mathcal{E} \qquad [50]$$

where $\star$ means the Hodge dual in three space dimensions. One finds

$$d * F = \boldsymbol{d} \star \mathcal{E} - \left(\boldsymbol{d} \star \mathcal{B} - \frac{\partial \star \mathcal{E}}{\partial t}\right) \wedge dt \qquad [51]$$

Therefore,

$$\begin{aligned} d * F = &-(\mathrm{div}\,\boldsymbol{E}) dx \wedge dy \wedge dz \\ &+ \left((\mathrm{curl}\,\boldsymbol{B})^x - \frac{\partial E^x}{dt}\right) dy \wedge dz \wedge dt \\ &+ \left((\mathrm{curl}\,\boldsymbol{B})^y - \frac{\partial E^y}{dt}\right) dz \wedge dx \wedge dt \\ &+ \left((\mathrm{curl}\,\boldsymbol{B})^z - \frac{\partial E^z}{dt}\right) dx \wedge dy \wedge dt \end{aligned} \qquad [52]$$

We apply again the Hodge dual:

$$\begin{aligned} *d * F = &-(\mathrm{div}\,\boldsymbol{E}) dt + \left((\mathrm{curl}\,\boldsymbol{B})^x - \frac{\partial E^x}{\partial t}\right) dx \\ &+ \left((\mathrm{curl}\,\boldsymbol{B})^y - \frac{\partial E^y}{\partial t}\right) dy \\ &+ \left((\mathrm{curl}\,\boldsymbol{B})^z - \frac{\partial E^z}{\partial t}\right) dz \end{aligned} \qquad [53]$$

In Minkowski space the expression $*d*$ equals the codifferential. Therefore, the equation $d^*F = *d*F = -j$ holds, with $j$ given by $j^\mu = (\rho, \boldsymbol{J})$, which is equivalent to

$$\mathrm{div}\,\boldsymbol{E} = \rho, \qquad \mathrm{curl}\,\boldsymbol{B} - \frac{\partial \boldsymbol{E}}{\partial \boldsymbol{t}} = \boldsymbol{J} \qquad [54]$$

the inhomogeneous Maxwell equations.

## Current Conservation

The electromagnetic 4-current is

$$j^\mu = \rho_0 \boldsymbol{u}^\mu = (\rho_0\gamma, \rho_0\gamma\boldsymbol{v}) = (\rho, \boldsymbol{J}) \qquad [55]$$

where $\rho$ is the charge density and $\boldsymbol{J}$ the current density. This corresponds to a 1-form

$$j = \rho dt - J^x dx - J^y dy - J^z dz \qquad [56]$$

The Hodge dual is $*j = \sigma^3 - j^2 \wedge dt$, with the 3-form $\sigma^3 = \rho dx \wedge dy \wedge dz$, and the 2-form

$$j^2 = -J^x dy \wedge dz - J^y dz \wedge dx - J^z dx \wedge dy \qquad [57]$$

From the Maxwell equation $d^*F = -j$, it follows that

$$(d^*)^2 F = -d^* j = 0 \qquad [58]$$

that is

$$\begin{aligned} *d(*j) &= *d(\sigma^3 - j^2 \wedge dt) = *(\boldsymbol{d}\sigma^3 - \boldsymbol{d}j^2 \wedge dt) \\ &= *\left(\frac{\partial \rho}{\partial t} + \mathrm{div}\boldsymbol{J}\right) dt \wedge dx \wedge dy \wedge dz \\ &= \frac{\partial \rho}{\partial t} + \mathrm{div}\boldsymbol{J} = 0 \end{aligned} \qquad [59]$$

This is the “continuity equation.”

The total charge inside a volume $V$ is $Q = \int_V \rho dV$, therefore

$$-\frac{dQ}{dt} = -\frac{d}{dt}\int_V \rho\, dV = \int_{\partial V} \boldsymbol{J} \cdot \boldsymbol{n}\, dS \qquad [60]$$

where $\partial V$ is the surface which encloses the volume $V$, $dS$ is the surface element, and $\boldsymbol{n}$ is the normal vector to this surface. This is current conservation.

## The Gauge Potential

The "Poincaré lemma" tells us that $dF=0$ implies $F=dA$, with the 4-potential $A$:

$$A = \phi dt + \boldsymbol{A} \quad [61]$$

and the vector potential $\boldsymbol{A}=A_x dx + A_y dy + A_z dz$. From

$$\begin{aligned} F = \mathcal{E} \wedge dt + \mathcal{B} &= \left(\boldsymbol{d} + dt \wedge \frac{\partial}{\partial t}\right) A \\ &= \boldsymbol{d}\phi \wedge dt + \boldsymbol{dA} + dt \wedge \frac{\partial \boldsymbol{A}}{\partial t} \end{aligned} \quad [62]$$

it follows by comparing coefficients that

$$\mathcal{E} = \boldsymbol{d}\phi - \frac{\partial \boldsymbol{A}}{\partial t}, \qquad \mathcal{B} = \boldsymbol{dA} \quad [63]$$

In vector notation this is

$$\boldsymbol{E} = \mathrm{grad}\phi - \frac{\partial \boldsymbol{A}}{\partial t}, \qquad \boldsymbol{B} = \mathrm{curl}\,\boldsymbol{A} \quad [64]$$

The 4-potential is determined up to a gauge function $\Lambda$:

$$A' = A + d\Lambda \quad [65]$$

This gauge freedom has no influence on the observable quantities $\boldsymbol{E}$ and $\boldsymbol{B}$:

$$F' = dA' = dA + d^2\Lambda = dA = F \quad [66]$$

The Laplace operator is $\triangle = (d^* + d)^2 = dd^* + d^*d$, so when the 4-potential $A$ fulfills the condition $d^*A = 0$, we have

$$\triangle A = d^* dA = d^* F = -j \quad [67]$$

the "classical wave equation." The condition $d^*A=0$ is called the "Lorentz gauge condition." This condition can always be fulfilled by using the gauge freedom: $d^*(A + d\Lambda) = 0$ is fulfilled when $d^*d\Lambda = \triangle\Lambda = -d^*A$, where we have used the fact that $d^*\Lambda = 0$ for functions. That is to say, $d^*A = 0$ is fulfilled when $\Lambda$ is a solution of the inhomogeneous wave equation.

## Gauge Invariance

In quantum mechanics, the electron is described by a wave function which is determined up to a free phase. Indeed, at every point in space this phase can be chosen arbitrarily:

$$\begin{aligned} \psi(x) &\rightarrow \psi'(x) = \exp\{\mathrm{i}\alpha(x)\}\psi(x) \\ \bar{\psi}(x) &\rightarrow \bar{\psi}'(x) = \bar{\psi}(x)\exp\{-\mathrm{i}\alpha(x)\} \end{aligned} \quad [68]$$

with the only condition being that $\alpha(x)$ is a continuous function. The gauge transformation is of the form $g = \exp\{\mathrm{i}\alpha(x)\}$, with $g$ an element of the abelian gauge group $G = \mathrm{U}(1)$. The free action is

$$S_0 = \int \mathcal{L}_0 \, d^4x \quad [69]$$

with

$$\mathcal{L}_0 = \bar{\psi}(\mathrm{i}\gamma^\mu \partial_\mu - m)\psi \quad [70]$$

the "Lagrange density." This action is not invariant under gauge transformations:

$$\mathcal{L}_0 \rightarrow \mathcal{L}_0' = \bar{\psi}(\mathrm{i}\gamma^\mu\partial_\mu - m)\psi - (\partial_\mu\alpha)\bar{\psi}\gamma^\mu\psi \quad [71]$$

The undesired term can be compensated by the introduction of a gauge potential $\omega$ in a covariant derivative of $\psi$,

$$D\psi = (d + \omega)\psi \quad [72]$$

which has the desired transformation property $D\psi \rightarrow \exp\{\mathrm{i}\alpha\}D\psi$ when besides the transformation $\psi(x) \rightarrow \exp\{\mathrm{i}\alpha(x)\}\psi(x)$ of the matter field the gauge potential simultaneously transforms according to the gauge transformation $\omega \rightarrow \omega - \mathrm{i}d\alpha$. The new Lagrange density is

$$\mathcal{L} = \bar{\psi}(\mathrm{i}\gamma^\mu D_\mu - m)\psi = \mathcal{L}_0 + \mathrm{i}\omega_\mu\bar{\psi}(x)\gamma^\mu\psi(x) \quad [73]$$

The substitution $\partial_\mu \rightarrow D_\mu$ is known to physicists; with $\omega = -\mathrm{i}qA$ it is the ansatz of minimal coupling for taking into account electromagnetic effects: $\partial_\mu \rightarrow \partial_\mu - \mathrm{i}qA_\mu$. The Lagrange density becomes in this notation $\mathcal{L} = \mathcal{L}_0 - A_\mu J^\mu$, where $J^\mu = -q\bar{\psi}\gamma^\mu\psi$.

The Lagrange density must now be completed by a kinetic term for the gauge potential and we get the complete electromagnetic Lagrange density

$$\mathcal{L} = \mathcal{L}_0 - A_\mu J^\mu - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} \quad [74]$$

with $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$. In the action this corresponds to

$$S = S_0 - \int_M A_\mu J^\mu \mathrm{vol}^4 - \frac{1}{4}\int_M F_{\mu\nu}F^{\mu\nu}\mathrm{vol}^4 \quad [75]$$

We get the field equations for the potential $A$ by demanding that the variation of the action vanishes:

$$\delta S[A] = -\int_M \delta A_\mu J^\mu \mathrm{vol}^4 - \frac{1}{4}\delta\int_M F_{\mu\nu}F^{\mu\nu}\mathrm{vol}^4 \quad [76]$$

We write now

$$\int_M \delta A_\mu J^\mu \mathrm{vol}^4 = (\delta A, j) \quad [77]$$

and

$$\begin{aligned}\frac{1}{4}\delta\int_M F_{\mu\nu}F^{\mu\nu}\mathrm{vol}^4 \\ =\frac{1}{2}\delta\int_M F\wedge *F=\frac{1}{2}\delta(F,F) \\ =(\delta dA,F)=(d\delta A,F)=(\delta A,d^*F)\end{aligned} \quad [78]$$

where we have exchanged the action of $\delta$ and $d$. Since this holds for arbitrary variations $\delta A$ we find

$$d^*F=-j \quad [79]$$

the inhomogeneous Maxwell equation.

## Nonabelian Gauge Theories

In SU($N$) gauge theory the elementary particles are taken to be members of symmetry multiplets. For example, in electroweak theory the left-handed electron and the neutrino are members of an SU(2) doublet:

$$\psi=\begin{pmatrix}e^-\\ \nu\end{pmatrix} \quad [80]$$

A gauge transformation is

$$\psi'(x)=g^{-1}(x)\psi(x),\qquad \bar{\psi}'(x)=\bar{\psi}(x)g(x) \quad [81]$$

with

$$g(x)=\exp\{\Lambda(x)\} \quad [82]$$

where $g(x)$ is an element of the Lie group SU(2) and $\Lambda$ is an element of the Lie algebra su(2). The Lie algebra is a vector space, and its elements may be expanded in terms of a basis:

$$\Lambda(x)=\Lambda^a(x)T_a \quad [83]$$

For su(2) the basis elements are traceless and anti-Hermitian (see below), they are conventionally expressed in terms of the Pauli matrices,

$$T_a=\frac{\sigma_a}{2\mathrm{i}} \quad [84]$$

with

$$\sigma_1=\begin{pmatrix}0&1\\1&0\end{pmatrix},\qquad \sigma_2=\begin{pmatrix}0&-\mathrm{i}\\ \mathrm{i}&0\end{pmatrix} \\ \sigma_3=\begin{pmatrix}1&0\\0&-1\end{pmatrix} \quad [85]$$

They are conventionally normalized according to

$$\mathrm{tr}(T_aT_b)=-\tfrac{1}{2}\delta_{ab} \quad [86]$$

The Dirac Lagrangian is not invariant with respect to local gauge transformations:

$$\begin{aligned}\mathcal{L}_0=\bar{\psi}(\mathrm{i}\gamma^\mu\partial_\mu-m)\psi\to\mathcal{L}_0' \\ =\mathcal{L}_0+\mathrm{i}\bar{\psi}\gamma^\mu(g\partial_\mu g^{-1})\psi\end{aligned} \quad [87]$$

We introduce the gauge potential

$$\omega_\mu(x)=\omega_\mu^a(x)T_a \quad [88]$$

with a gauge transformation

$$\omega_\mu\to\omega_\mu'=g^{-1}\omega_\mu g+g^{-1}\partial_\mu g \quad [89]$$

The Lagrange density is modified through a covariant derivative:

$$\partial_\mu\to D_\mu=\partial_\mu+\omega_\mu \quad [90]$$

The covariant derivative $D_\mu$ transforms according to

$$D_\mu\to D_\mu{}'=g^{-1}D_\mu g \quad [91]$$

and thus the modified Lagrange density

$$\mathcal{L}=\bar{\psi}(\mathrm{i}\gamma^\mu D_\mu-m)\psi=\mathcal{L}_0+\mathrm{i}\bar{\psi}\gamma^\mu\omega_\mu\psi \quad [92]$$

is invariant with respect to local gauge transformations.

The extra term in the Langrange density is conventionally written

$$-J_a^\mu A_\mu^a \quad [93]$$

with

$$A_\mu^a=-\mathrm{i}q\omega_\mu^a \quad [94]$$

and

$$J_a^\mu=\bar{\psi}\gamma^\mu T_a\psi \quad [95]$$

In mathematical terminology $\omega$ is called a connection. The quantity $A$ is the physicist's gauge potential. The connection is anti-Hermitian and the gauge potential Hermitian. The gauge potential also includes the coupling constant $q$. We will refer to both $\omega$ and $A$ as the gauge potential, where the relation between them is given by eqn [94].

We can write the gauge potential as $A=A_\mu^a dx^\mu T_a$ or, in the SU(2) case, as

$$A_\mu=A_\mu^1T_1+A_\mu^2T_2+A_\mu^3T_3 \quad [96]$$

where we see explicitly that it involves three vector fields, which couple to the electroweak currents [95] with the single coupling constant $q$, and which will become after symmetry breaking the three vector bosons $W_+, W_-, Z_0$ of the electroweak gauge theory. Actually, a mix of the neutral gauge boson and the photon will combine to yield the $Z_0$ boson, while the orthogonal mixture gives rise to the electromagnetic interaction, in an $\mathrm{SU}(2)\times\mathrm{U}(1)$ theory. At this stage,

the gauge bosons are all massless, their masses are generated by the "Higgs' mechanism."

## Lie-Algebra-Valued $p$-Forms

To describe nonabelian fields, we need Lie-algebra-valued $p$-forms:

$$\phi = T_a \phi^a \qquad [97]$$

where $T_a$ is a generator of the Lie algebra, the index $a$ runs over the number of generators of the Lie algebra, and the $\phi^a$ are the usual scalar-valued $p$-forms. The composition in a Lie algebra is a Lie bracket, which is defined for two Lie-algebra-valued $p$-forms by

$$[\phi, \psi] := [T_a, T_b]\phi^a \wedge \psi^b \qquad [98]$$

The Lie bracket in the algebra is

$$[T_a, T_b] = f^c_{ab} T_c \qquad [99]$$

where $f^a_{bc}$ are the structure constants. It follows from this that

$$[\psi, \phi] = [T_a, T_b]\psi^a \wedge \phi^b = -[T_b, T_a]\psi^a \wedge \phi^b \qquad [100]$$

or

$$[\psi, \phi] = (-1)^{pq+1}[\phi, \psi] \qquad [101]$$

when $\phi$ is a $p$-form and $\psi$ is a $q$-form. In the special case that $T_a$ is a matrix, also the product $T_a T_b$ is defined, and from this the product of two Lie-algebra-valued $p$-forms

$$\phi \wedge \psi = T_a \phi^a \wedge T_b \psi^b = T_a T_b \phi^a \wedge \psi^b \qquad [102]$$

Now the Lie bracket is a commutator:

$$[T_a, T_b] = T_a T_b - T_b T_a \qquad [103]$$

and

$$\begin{aligned}[\phi, \psi] &= [T_a, T_b]\phi^a \wedge \psi^b \\ &= T_a\phi^a \wedge T_b\psi^b - (-1)^{pq} T_b\psi^b \wedge T_a\phi^a \\ &= \phi \wedge \psi - (-1)^{pq}\psi \wedge \phi \end{aligned} \qquad [104]$$

From this relation it follows that for $\phi$ and $\psi$ odd $p$-forms

$$[\phi, \psi] = \phi \wedge \psi + \psi \wedge \phi \qquad [105]$$

For $\phi$ an odd $p$-form

$$[\phi, \phi] = \phi \wedge \phi + \phi \wedge \phi = 2(\phi \wedge \phi) \qquad [106]$$

## The Gauge Potential and the Field Strength

The generalization of the abelian relationship between the gauge potential and the field strength, $F = dA$, is

$$\theta = d\omega + \tfrac{1}{2}[\omega, \omega] = d\theta + \omega \wedge \omega \qquad [107]$$

where because $\omega$ is a 1-form we can use eqn [106]. The mathematician refers to $\theta$ as the curvature. The physicist writes, in analogy to eqn [94],

$$F = -\mathrm{i}\, q\theta = \tfrac{1}{2} F^a_{\mu\nu} dx^\mu \wedge dx^\nu T_a \qquad [108]$$

One obtains for the components

$$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu - \mathrm{i} q f^a_{bc} A^b_\mu A^c_\nu \qquad [109]$$

A generalization of the gauge transformation of $A$, that is, $A' = A + d\Lambda$, is eqn [89]:

$$\omega' = g^{-1}\omega g + g^{-1} dg \qquad [110]$$

A quantity $\phi$ with the transformation property

$$\phi' = g^{-1}\phi g \qquad [111]$$

is called a "tensorial" quantity. The gauge potential $\omega$ is according to this definition nontensorial. Nevertheless the field strength is tensorial. Indeed

$$\begin{aligned}\theta' = {} & d(g^{-1}\omega g) + (dg^{-1}) \wedge dg \\ & + \tfrac{1}{2}[g^{-1}\omega g + g^{-1}dg, g^{-1}\omega g + g^{-1}dg] \\ = {} & (dg^{-1}) \wedge \omega g + g^{-1} d\omega g - g^{-1}\omega \wedge dg + (dg^{-1}) \wedge dg \\ & + \tfrac{1}{2} g^{-1}[\omega, \omega] g + \tfrac{1}{2}[g^{-1}\omega g, g^{-1}dg] \\ & + \tfrac{1}{2}[g^{-1}dg, g^{-1}\omega g] + \tfrac{1}{2}[g^{-1}dg, g^{-1}dg] \\ = {} & g^{-1}\theta g + (dg^{-1}) \wedge \omega g - g^{-1}\omega \wedge dg + (dg^{-1}) \wedge dg \\ & + g^{-1}\omega \wedge dg + g^{-1}dg \wedge g^{-1}\omega g + g^{-1}dg \wedge g^{-1}dg \\ = {} & g^{-1}\theta g \end{aligned} \qquad [112]$$

where we have used the derivation of the relation $g^{-1}g = \mathrm{Id}$ to get

$$dg^{-1} = -g^{-1} dg\, g^{-1} \qquad [113]$$

In the abelian case, we had $dF = 0$. The nonabelian analog is

$$\begin{aligned} d\theta &= d\omega \wedge \omega - \omega \wedge d\omega \\ &= (\theta - \omega \wedge \omega) \wedge \omega - \omega \wedge (\theta - \omega \wedge \omega) \\ &= \theta \wedge \omega - \omega \wedge \theta \end{aligned} \qquad [114]$$

or

$$d\theta + \omega \wedge \theta - \theta \wedge \omega = 0 \qquad [115]$$

the Bianchi identity. It can also be written as

$$d\theta + \omega \wedge \theta - \theta \wedge \omega = d\theta + [\omega, \theta] = 0 \qquad [116]$$

because from eqn [104]

$$\omega \wedge \theta + (-1)^{2 \cdot 1} \theta \wedge \omega = [\omega, \theta] \qquad [117]$$

The covariant derivative $D$ is defined as

$$D\phi := d\phi + [\omega, \phi] \qquad [118]$$

for $\phi$ a tensorial quantity. The covariant derivative takes tensorial $p$-forms into tensorial $(p+1)$-forms:

$$\begin{aligned} D'\phi' &= d(g^{-1}\phi g) + [g^{-1}\omega g + g^{-1}dg, g^{-1}\phi g] \\ &= dg^{-1} \wedge \phi g + g^{-1} d\phi g + (-1)^p g^{-1} \phi \wedge dg \\ &\quad + [g^{-1}\omega g, g^{-1}\phi g] + [g^{-1}dg, g^{-1}\phi g] \\ &= g^{-1} D\phi g + dg^{-1} \wedge \phi g + (-1)^p g^{-1} \phi \wedge dg \\ &\quad + g^{-1} dg g^{-1} \wedge \phi g - (-1)^p g^{-1} \phi \wedge dg \\ &= g^{-1} D\phi g \end{aligned} \qquad [119]$$

We have thereby verified the transformation property of eqn [91].

## The Gauge Group

From the gauge transformation $\psi' = g\psi$ the requirement $|\psi'|^2 = |\psi|^2$ leads to $g^\dagger g = 1$. That means that $g$ belongs to the unitary Lie group $G = \mathrm{U}(n)$, whose elements fulfill $g^\dagger = \bar{g}^{\mathrm{T}} = g^{-1}$. For elements of the Lie algebra $\mathcal{G} = \mathrm{u}(n)$ this implies

$$\left(\mathrm{e}^X\right)^\dagger = \mathrm{e}^{\bar{X}^{\mathrm{T}}} = \mathrm{e}^{-X} \qquad [120]$$

or

$$X^\dagger = \bar{X}^{\mathrm{T}} = -X \qquad [121]$$

where $\bar{X}$ is complex conjugation and $X^{\mathrm{T}}$ means transposition.

For elements of the Lie algebra we can define a scalar product (the Killing metric)

$$\langle X, Y \rangle := -\mathrm{tr}\,(XY) = -X^\alpha{}_\beta X^\beta{}_\alpha \qquad [122]$$

The scalar product is real:

$$\langle \bar{X}, \bar{Y} \rangle = -\bar{X}^\beta{}_\alpha \bar{Y}^\alpha{}_\beta = -X^\alpha{}_\beta X^\beta{}_\alpha = \langle X, Y \rangle \qquad [123]$$

symmetric:

$$\langle X, Y \rangle = -\mathrm{tr}(X, Y) = -\mathrm{tr}(Y, X) = \langle Y, X \rangle \qquad [124]$$

and positive definite:

$$\langle X, X \rangle = -X^\alpha{}_\beta X^\beta{}_\alpha = X^\alpha{}_\beta \bar{X}^\alpha{}_\beta = |X^\alpha{}_\beta|^2 \qquad [125]$$

The scalar product is invariant under the action of $G$ on $\mathcal{G}$: for $g \in G$

$$\begin{aligned} \langle gXg^{-1}, gYg^{-1} \rangle &= -\mathrm{tr}\,(gXYg^{-1}) \\ &= -\mathrm{tr}(X, Y) = \langle X, Y \rangle \end{aligned} \qquad [126]$$

or for $X, Y, Z \in \mathcal{G}$

$$\langle \mathrm{e}^{tX} Y \mathrm{e}^{-tX}, \mathrm{e}^{tX} Z \mathrm{e}^{-tX} \rangle = \langle Y, Z \rangle \qquad [127]$$

We take the derivative of this equation with respect to $t$ at the value $t = 0$ and get:

$$\langle [X, Y], Z \rangle + \langle Y, [X, Z] \rangle = 0 \qquad [128]$$

We define an action of the algebra $\mathcal{G}$ on itself: $ad(X): \mathcal{G} \to \mathcal{G}$

$$ad(X)Y = [X, Y] \qquad [129]$$

We can then formulate our conclusion as follows: the action of $\mathcal{G}$ on itself is anti-Hermitian:

$$\langle ad(X)Y, Z \rangle = -\langle Y, ad(X)Z \rangle \qquad [130]$$

or

$$[ad(X)]^\dagger = -ad(X) \qquad [131]$$

From $g^\dagger g = 1$ we have $|\det(g)|^2 = 1$. For the gauge group $G = \mathrm{SU}(N)$ we require in addition $\det(g) = 1$. Since

$$\det(g) = \det(\exp(X)) = \exp(\mathrm{tr}(X)) \qquad [132]$$

the elements $X \in \mathrm{su}(N)$ must be traceless. A basis of the vector space of traceless, anti-Hermitian $(2 \times 2)$ matrices is given by the Pauli matrices, eqn [85].

## The Yang–Mills Action

The SU(2) Yang–Mills action is, in analogy to the abelian case,

$$\begin{aligned} S &= -\frac{1}{4q^2} \int_M F^a_{\mu\nu} F^{a\mu\nu} \mathrm{vol}^4 = \frac{1}{2q^2} \int_M \mathrm{tr}(F_{\mu\nu} F^{\mu\nu}) \mathrm{vol}^4 \\ &= \frac{1}{2q^2} \int_M \mathrm{tr}(F \wedge * F) \end{aligned} \qquad [133]$$

We have included the trace in our definition of the scalar product:

$$(\phi, \psi) := -\int_M \mathrm{tr} < \phi_I \psi^I > \mathrm{vol}^n = -\int_M \mathrm{tr}(\phi \wedge * \psi) \qquad [134]$$

We then write eqn [133] as

$$S[\omega] = \tfrac{1}{2} (\theta, \theta) \qquad [135]$$

taking into account the relation between $\theta$ and the field strength $F$, and indicating the dependence on

the gauge potential. Since $\theta$ is tensorial the action is invariant.

Now we calculate the variation von $S[\omega]$ with respect to a variation of the gauge potential:

$$\begin{aligned}\delta S[\omega] &= \frac{d}{dt}S[\omega(t)]|_{t=0} = \frac{1}{2}\delta(\theta,\theta) \\ &= \frac{1}{2}((\delta\theta,\theta)+(\theta,\delta\theta)) \\ &= (\delta\theta,\theta) = \left(\delta\left(d\omega+\frac{1}{2}[\omega,\omega]\right),\theta\right) \\ &= \left(\delta d\omega+\frac{1}{2}[\delta\omega,\omega]+\frac{1}{2}[\omega,\delta\omega],\theta\right) \\ &= (d\delta\omega+[\omega,\delta\omega],\theta)\end{aligned} \quad [136]$$

where we have exchanged the order of $\delta$ and $d$. We remark that although $\omega$ is not a tensorial section, $\delta\omega$ is: for $\omega'_1 = g^{-1}\omega_1 g + g^{-1}dg$ and $\omega'_2 = g^{-1}\omega_2 g + g^{-1}dg$ is

$$\delta\omega = \omega'_1 - \omega'_2 = g^{-1}(\omega_1-\omega_2)g \quad [137]$$

The quantity $\theta$ is in any case tensorial. Therefore, the covariant derivative is defined, and we have

$$D\delta\omega = d\delta\omega + [\omega,\delta\omega] \quad [138]$$

and

$$D\theta = d\theta + [\omega,\theta] \quad [139]$$

In general, the action of the covariant derivative on tensorial quantities can be written as $D = d + ad(\omega)$, where $ad(X)$ is the representation of the Lie algebra on itself introduced in the previous section. We now have

$$\delta S[\omega] = (D\delta\omega,\theta) = (\delta\omega, D^*\theta) = 0 \quad [140]$$

for an arbitrary variation $\delta\omega$. Therefore, $D^*\theta = 0$.

We have obtained

$$D^*\theta = 0 \quad [141]$$

the "Yang–Mills equations," and

$$D\theta = 0 \quad [142]$$

the "Bianchi identites." These are the generalizations of the Maxwell equations $d^*F = 0$ and $dF = 0$ in the absence of external sources. For the general case of interacting fermions, we write out the full action, in analogy to eqn [74], and obtain, in analogy to eqns [79] and [58],

$$D^*\theta = -J, \qquad D^*J = 0 \quad [143]$$

We shall now derive, again for the pure gauge sector, coordinate expressions for the Yang–Mills equations. Consider the expression

$$\begin{aligned}\delta S[\omega] &= (D\delta\omega,\theta) = (\delta\omega, D^*\theta) \\ &= (d\delta\omega + [\omega,\delta\omega],\theta)\end{aligned} \quad [144]$$

The first term in the last expression is

$$(d\delta\omega,\theta) = (\delta\omega, d^*\theta) = -\mathrm{tr}\int_M \delta\omega_\nu\{d^*\theta\}^\nu \mathrm{vol}^4 \quad [145]$$

The second term can be computed using

$$\begin{aligned}[][\omega,\delta\omega]_{\mu\nu} &= \{\omega\wedge\delta\omega + \delta\omega\wedge\omega\}(\partial_\mu,\partial_\nu) \\ &= \omega_\mu\delta\omega_\nu - \omega_\nu\delta\omega_\mu + \delta\omega_\mu\omega_\nu - \delta\omega_\nu\omega_\mu\end{aligned} \quad [146]$$

and hence

$$[\omega,\delta\omega]_{\mu\nu}\theta^{\mu\nu} = 2[\omega_\mu,\delta\omega_\nu]\theta^{\mu\nu} \quad [147]$$

because $\theta$ is antisymmetric, $\theta^{\mu\nu} = -\theta^{\nu\mu}$. Thus,

$$\begin{aligned}([\omega,\delta\omega],\theta) &= -\int_M \mathrm{tr}([\omega,\delta\omega]\wedge *\theta) \\ &= -\frac{1}{2}\int_M \mathrm{tr}([\omega,\delta\omega]_{\mu\nu}\theta^{\mu\nu})\mathrm{vol}^4 \\ &= -\int_M \mathrm{tr}([\omega_\mu,\delta\omega_\nu]\theta^{\mu\nu})\mathrm{vol}^4 \\ &= \int_M \langle[\omega_\mu,\delta\omega_\nu],\theta^{\mu\nu}\rangle\mathrm{vol}^4\end{aligned} \quad [148]$$

where $\langle\,,\rangle$ is the scalar product in $\mathcal{G}$. From eqn [128] this equals

$$\begin{aligned}&-\int_M \langle\delta\omega_\nu,[\omega_\mu,\theta^{\mu\nu}]\rangle\mathrm{vol}^4 \\ &\quad = \int_M \mathrm{tr}(\delta\omega_\nu[\omega_\mu,\theta^{\mu\nu}])\mathrm{vol}^4\end{aligned} \quad [149]$$

Combining this with eqn [144] gives

$$\begin{aligned}(\delta\omega, D^*\theta) &= -\int_M \mathrm{tr}(\delta\omega_\nu\{(d^*\theta)^\nu - [\omega_\mu,\theta^{\mu\nu}]\})\mathrm{vol}^4 \\ &= (\delta\omega, \{(d^*\theta)^\nu - [\omega_\mu,\theta^{\mu\nu}]\})\end{aligned} \quad [150]$$

We can now insert the coordinate expression for

$$(d\theta)^\nu = -\partial_\mu\theta^{\mu\nu} \quad [151]$$

Finally, the coordinate expressions of the Yang–Mills equations $D^*\theta = 0$ are

$$(D^*\theta)^\nu = -\{\partial_\mu\theta^{\mu\nu} + [\omega_\mu,\theta^{\mu\nu}]\} = 0 \quad [152]$$

## The Analogy with Electromagnetism

The Yang–Mills equation and the Bianchi identity in the absence of external sources are

$$\partial_\nu F^{\mu\nu} - \mathrm{i}q[A_\nu, F^{\mu\nu}] = 0 \quad [153]$$

and

$$\begin{aligned}&\partial_\mu F_{\nu\tau} + \partial_\tau F_{\mu\nu} + \partial_\nu F_{\tau\mu} - \mathrm{i}q\{[A_\mu, F_{\nu\tau}] \\ &\quad + [A_\tau, F_{\mu\nu}] + [A_\nu, F_{\tau\mu}]\} = 0\end{aligned} \quad [154]$$

We shall write these equations in terms of the fields

$$F^{i0} = E^i, \quad i = 1,2,3 \qquad [155]$$

$$F^{12} = B^3, \qquad F^{31} = B^2, \qquad F^{12} = B^3 \qquad [156]$$

where the **E** and **B** vectors may be thought of as "electric" and "magnetic" fields, even though they have Lie-algebra indices, $F^{i0} = (F^a)^{i0} T_a$, etc. In the context of the SU(3) theory, they are referred to as the "chromoelectric" and "chromomagnetic" fields, respectively.

The Yang–Mills equations with $\mu = 0$ are

$$\partial_i F^{i0} - \mathrm{i}q[A_i, F^{i0}] = 0 \qquad [157]$$

with $i = 1,2,3$ a spatial index. In vector notation this is

$$\operatorname{div} \boldsymbol{E} = \mathrm{i}q(\boldsymbol{A} \cdot \boldsymbol{E} - \boldsymbol{E} \cdot \boldsymbol{A}) \qquad [158]$$

This is the analog of Gauss's equation. Even though we started out without external sources, $\mathrm{i}q(\boldsymbol{A} \cdot \boldsymbol{E} - \boldsymbol{E} \cdot \boldsymbol{A})$ plays the role of a "charge density." The Yang–Mills field $\boldsymbol{E}$ and the potential $\boldsymbol{A}$ combine to act as a source for the Yang–Mills field. This is an essential feature of nonabelian gauge theories in which they differ from the abelian case, due to the fact that the commutator $[\boldsymbol{A}, \boldsymbol{E}]$ is nonvanishing.

Now consider the Yang–Mills equations with a spatial index $\mu = i$:

$$\partial_0 F^{i0} + \partial_j F^{ij} - \mathrm{i}q[A_0, F^{i0}] - \mathrm{i}q[A_j F^{ij}] = 0 \qquad [159]$$

In vector notation this is

$$\operatorname{curl} \boldsymbol{B} = \frac{\partial \boldsymbol{E}}{\partial t} - \mathrm{i}q(A_0 \boldsymbol{E} - \boldsymbol{E} A_0) + \mathrm{i}q(\boldsymbol{A} \times \boldsymbol{B} + \boldsymbol{B} \times \boldsymbol{A}) \qquad [160]$$

replacing the Ampere–Maxwell law. Note that there are two extra contributions to the "current" other than the displacement current.

The analogs of the laws of Faraday and of the absence of magnetic monopoles are derived similarly from the Bianchi identities. The results are

$$\operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = \mathrm{i}q\{(\boldsymbol{A} \times \boldsymbol{E} + \boldsymbol{E} \times \boldsymbol{A}) + (A_0 \boldsymbol{B} - \boldsymbol{B} A_0)\} \qquad [161]$$

and

$$\operatorname{div} \boldsymbol{B} = \mathrm{i}q(\boldsymbol{A} \cdot \boldsymbol{B} - \boldsymbol{B} \cdot \boldsymbol{A}) \qquad [162]$$

## Further Remarks

The foundations of the mathematics of differential forms were laid down by Poincaré (1953). They were applied to the description of electrodynamics already by Cartan (1923). A modern presentation of differential forms and the manifolds on which they are defined is given in Abraham *et al.* (1983). A recent treatment of electrodynamics in this approach is Hehl and Obukhov (2003). Weyl's argument is in his paper of 1929.

Nonabelian gauge theories today explain the electromagnetic, the strong and weak nuclear interactions. The original paper is that of Yang and Mills (1954). Glashow, Salam, and Weinberg (1980) saw the way to apply it to the weak interactions by using spontaneous symmetry breaking to generate the masses through the use of the Higgs' (1964) mechanism. t'Hooft and Veltman (1972) showed that the resulting quantum field theory was renormalizable. The strong interactions were recognized as the nonabelian gauge theory with gauge group SU(3) by Gell-Mann (1972). For a modern treatment which puts nonabelian gauge theories in the context of differential geometry, see Frankel (1987).

# Abelian Higgs Vortices

**J M Speight**, University of Leeds, Leeds, UK

## Introduction

For the purpose of this article, vortices are topological solitons arising in field theories in $(2+1)$-dimensional spacetime when a complex-valued field $\phi$ is allowed to acquire winding at infinity, meaning that the phase of $\phi(t, \boldsymbol{x})$, as $\boldsymbol{x}$ traverses a large circle in the spatial plane, changes by $2\pi n$, where $n$ is a nonzero integer. Such winding cannot be removed by any continuous deformation of $\phi$ (hence "topological") and traps a considerable amount of energy which tends to coalesce into smooth, stable lumps with highly particle-like characteristics (hence "solitons"). Clearly, the universe is $(3+1)$ dimensional. Nonetheless, planar field theories are of physical interest for two main reasons. First, the theory may arise by dimensional reduction of a $(3+1)$-dimensional model under the assumption of translation invariance in one direction. Vortices are then transverse slices through straight tube-like objects variously interpreted as magnetic flux tubes in a superconductor or cosmic strings. Second, a crucial ingredient of the standard model of particle physics is spontaneous breaking of gauge symmetry by a Higgs field. As well as endowing the fundamental gauge bosons and chiral fermions with mass, this mechanism can potentially generate various types of topological solitons (monopoles, strings, and domain walls) whose structure and interactions one would like to understand. Vortices in $(2+1)$ dimensions are interesting in this regard because they arise in the simplest field theory exhibiting the Higgs mechanism, the abelian Higgs model (AHM). They are thus a useful theoretical laboratory in which to test ideas which may ultimately find application in more realistic theories. This article describes the properties of abelian Higgs vortices and explains how, using a mixture of numerical and analytical techniques, a good understanding of their dynamical interactions has been obtained.

## The Abelian Higgs Model

Throughout this article spacetime will be $\mathbb{R}^{2+1}$ endowed with the Minkowski metric with signature $(+,-,-)$, and Cartesian coordinates $x^\mu, \mu = 0,1,2$, with $x^0 = t$ (the speed of light $c = 1$). A spacetime point will be denoted $x$, its spatial part by $\boldsymbol{x} = (x^1, x^2)$. Latin indices $j, k, \ldots$ range over 1, 2, and repeated indices (Latin or Greek) are summed over. We sometimes use polar coordinates in the spatial plane, $\boldsymbol{x} = r(\cos\theta, \sin\theta)$, and sometimes a complex coordinate $z = x^1 + \mathrm{i}x^2 = r\mathrm{e}^{\mathrm{i}\theta}$. Occasionally, it is convenient to think of $\mathbb{R}^{2+1}$ as a subspace of $\mathbb{R}^{3+1}$ and denote by $\boldsymbol{k}$ the unit vector in the (fictitious) third spatial direction. The complex scalar Higgs field is denoted $\phi$, and the electromagnetic gauge potential $A_\mu$, best thought of as the components of a 1-form $A = A_\mu \,\mathrm{d}x^\mu$. $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the field strength tensor which, in $\mathbb{R}^{2+1}$, has only three independent components, identified with the magnetic field $B = F_{12}$ and electric field $(E_1, E_2) = (F_{01}, F_{02})$. The gauge-covariant derivative is $D_\mu\phi = \partial_\mu\phi - \mathrm{i}eA_\mu\phi$, $e$ being the electric charge of the Higgs. Under a U(1) gauge transformation,

$$\phi \mapsto \mathrm{e}^{\mathrm{i}\Lambda}\phi, \qquad A_\mu \mapsto A_\mu + \mathrm{e}^{-1}\partial_\mu\Lambda \qquad [1]$$

$\Lambda : \mathbb{R}^{2+1} \to \mathbb{R}$ being any smooth function, $F_{\mu\nu}$ and $|\phi|$ remain invariant, while $D_\mu\phi \mapsto \mathrm{e}^{\mathrm{i}\Lambda}D_\mu\phi$. Only gauge-invariant quantities are physically observable (classically).

With these conventions, the AHM has Lagrangian density

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{\alpha}{2}D_\mu\phi\overline{D^\mu\phi} - \frac{\lambda}{8}(\nu^2 - |\phi|^2)^2 \qquad [2]$$

which is manifestly gauge invariant. By rescaling $\phi, A_\mu, x$ and the unit of action, we can (and henceforth will) assume that $e = \nu = \alpha = 1$. The only parameter which cannot be scaled away is $\lambda > 0$. Its value greatly influences the model's behavior.

The field equations, obtained by demanding that $\phi(x), A_\mu(x)$ be a local extremal of the action $S = \int \mathcal{L} d^3x$, are

$$\begin{aligned} D_\mu D^\mu\phi + \frac{\lambda}{2}(1 - |\phi|^2)\phi = 0 \\ \partial^\mu F_{\mu\nu} + \frac{\mathrm{i}}{2}(\phi\overline{D_\nu\phi} - \bar{\phi}D_\nu\phi) = 0 \end{aligned} \qquad [3]$$

This is a coupled set of nonlinear second-order PDEs. Of particular interest are solutions which have finite total energy. Energy is not a Lorentz-invariant quantity. To define it we must choose an inertial frame and, having broken Lorentz invariance, it is convenient to work in a temporal gauge, for which $A_0 \equiv 0$ (which may be obtained by a gauge transformation with $\Lambda(t, \boldsymbol{x}) = \int_0^t A_0(t', \boldsymbol{x})\,\mathrm{d}t'$, after which only time-independent gauge transformations are permitted). The potential energy of a field is then

$$\begin{aligned} E &= \frac{1}{2}\int \left(B^2 + D_i\phi\overline{D_i\phi} + \frac{\lambda}{4}(1 - |\phi|^2)^2\right)\mathrm{d}x^1\mathrm{d}x^2 \\ &= E_{\mathrm{mag}} + E_{\mathrm{grad}} + E_{\mathrm{self}} \end{aligned} \qquad [4]$$

while its kinetic energy is

$$E_{\text{kin}} = \frac{1}{2}\int\left(|\partial_0 \boldsymbol{A}|^2 + \partial_0\phi\overline{\partial_0\phi}\right)\mathrm{d}x^1\mathrm{d}x^2 \qquad [5]$$

If $\phi, \boldsymbol{A}$ satisfy the field equations then the total energy $E_{\text{tot}} = E_{\text{kin}} + E$ is independent of $t$. By Derrick's theorem, static solutions have $E_{\text{mag}} \equiv E_{\text{self}}$ (Manton and Sutcliffe 2004, pp. 82–87).

Configurations with finite energy have quantized total magnetic flux. To see this, note that $E$ finite implies $|\phi| \to 1$ as $r \to \infty$, so $\phi \sim e^{i\chi(r,\theta)}$ at large $r$ for some real (in general, multivalued) function $\chi$. The winding number of $\phi$ is its winding around a circle of large radius $R$, that is, the integer $n = (\chi(R, 2\pi) - \chi(R, 0))/2\pi$. Although the phase of $\phi$ is clearly gauge dependent, $n$ is not, because to change this, a gauge transformation $e^{i\Lambda} : \mathbb{R}^2 \to U(1)$ would itself need nonzero winding around the circle, contradicting smoothness of $e^{i\Lambda}$. The model is invariant under spatial reflexions, under which $n \mapsto -n$, so we will assume (unless noted otherwise) that $n \geq 0$. Finiteness of $E$ also implies that $D\phi = \mathrm{d}\phi - iA\phi \to 0$, so $A \sim -i\mathrm{d}\phi/\phi \sim \mathrm{d}\chi$ as $r \to \infty$ (note $\phi \neq 0$ for large $r$). Hence, the total magnetic flux is

$$\int_{\mathbb{R}^2} B\,\mathrm{d}^2\boldsymbol{x} = \lim_{R\to\infty}\oint_{S_R} A = \lim_{R\to\infty}\int_0^{2\pi}\partial_\theta\chi\,\mathrm{d}\theta = 2\pi n \qquad [6]$$

where $S_R = \{\boldsymbol{x} : |\boldsymbol{x}| = R\}$ and we have used Stokes's theorem. The above argument uses only generic properties of $E$, namely that finite $E_{\text{self}}$ requires $|\phi|$ to assume a nonzero constant value as $r \to \infty$. So flux quantization is a robust feature of this type of model. As presented, the argument is somewhat formal, but it can be made mathematically rigorous at the cost of gauge-fixing technicalities (Manton and Sutcliffe 2004, pp. 164–166). Note that if $n \neq 0$ then, by continuity, $\phi(\boldsymbol{x})$ must vanish at some $\boldsymbol{x} \in \mathbb{R}^2$, and one expects a lump of energy density to be associated with each such $\boldsymbol{x}$ since $\phi = 0$ maximizes the integrand of $E_{\text{self}}$.

## Radially Symmetric Vortices

The model supports static solutions within the radially symmetric ansatz $\phi = \sigma(r)e^{in\theta}, A = a(r)\,\mathrm{d}\theta$, which reduces the field equations to a coupled pair of nonlinear ODEs:

$$\begin{aligned}\frac{\mathrm{d}^2\sigma}{\mathrm{d}r^2} + \frac{1}{r}\frac{\mathrm{d}\sigma}{\mathrm{d}r} - \frac{1}{r^2}(n-a)^2\sigma + \frac{\lambda}{2}(1-\sigma^2)\sigma = 0\\ \frac{\mathrm{d}^2 a}{\mathrm{d}r^2} - \frac{1}{r}\frac{\mathrm{d}a}{\mathrm{d}r} + (n-a)\sigma^2 = 0\end{aligned} \qquad [7]$$

Finite energy requires $\lim_{r\to\infty}\sigma(r) = 1$, $\lim_{r\to\infty}a(r) = n$ while smoothness requires $\sigma(r) \sim \text{const}_1 r^n, a(r) \sim \text{const}_2 r^2$ as $r \to 0$. It is known that solutions to this system, which we shall call $n$-vortices, exist for all $n, \lambda$, though no explicit formulas for them are known. They may be found numerically, and are depicted in Figure 1. Note that $\sigma$ and $a$ always rise monotonically to their vacuum values, and $B$ always falls monotonically to 0, as $r$ increases. These solutions have their magnetic flux concentrated in a single, symmetric lump, a flux tube in the $\mathbb{R}^{3+1}$ picture. In contrast, the total energy density (integrand of $E$ in [4]) is nonmonotonic for $n \geq 2$, being peaked on a ring whose radius grows with $n$. This is a common feature of planar solitons.

The large $r$ asymptotics of $n$-vortices are well understood. For $\lambda \leq 4$ one may linearize [7] about $\sigma = 1, a = n$, yielding

$$\sigma(r) \sim 1 + \frac{q_n}{2\pi}K_0(\sqrt{\lambda}r) \qquad [8]$$

$$a(r) \sim n + \frac{m_n}{2\pi}rK_1(r) \qquad [9]$$

where $q_n, m_n$ are unknown constants and $K_\alpha$ denotes the modified Bessel's function. For $\lambda > 4$ linearization is no longer well justified, and the asymptotic behaviour of $\sigma$ (though not $a$) is quite different (Manton and Sutcliffe 2004, pp. 174–175). We shall not consider this rather extreme regime further. Note that

$$K_\alpha(r) \sim \sqrt{\frac{\pi}{2r}}e^{-r} \quad \text{as } r \to \infty \qquad [10]$$

for all $\alpha$, so both $\sigma$ and $a$ approach their vacuum values exponentially fast, but with different decay lengths: $1/\sqrt{\lambda}$ for $\sigma$, 1 for $a$. This can be seen in **Figure 1a**. The constants $q_n$ and $m_n$ depend on $\lambda$ and must be inferred by comparing the numerical solutions with [8], [9]; $q = q_1$ and $m = m_1$ will receive a physical interpretation shortly.

The 1-vortex (henceforth just "vortex") is stable for all $\lambda$, but $n$-vortices with $n \geq 2$ are unstable to break up into $n$ separate vortices if $\lambda > 1$. We shall say that the AHM is type I if $\lambda < 1$, type II if $\lambda > 1$, and critically coupled if $\lambda = 1$, based on this distinction. Let $E_n$ denote the energy of an $n$-vortex. **Figure 2** shows the energy per vortex $E_n/n$ plotted against $n$ for $\lambda = 0.5, 1$, and 2. It decreases with $n$ for $\lambda = 0.5$, indicating that it is energetically favorable for isolated vortices to coalesce into higher winding lumps. For $\lambda = 2$, by contrast, $E_n/n$ increases with $n$ indicating that it is energetically favorable for $n$-vortices to fission into their constituent vortex parts. The case $\lambda = 1$ balances between these behaviors: $E_n/n$ is independent of $n$. In fact, the energy of a collection of vortices is independent of their positions in this case.

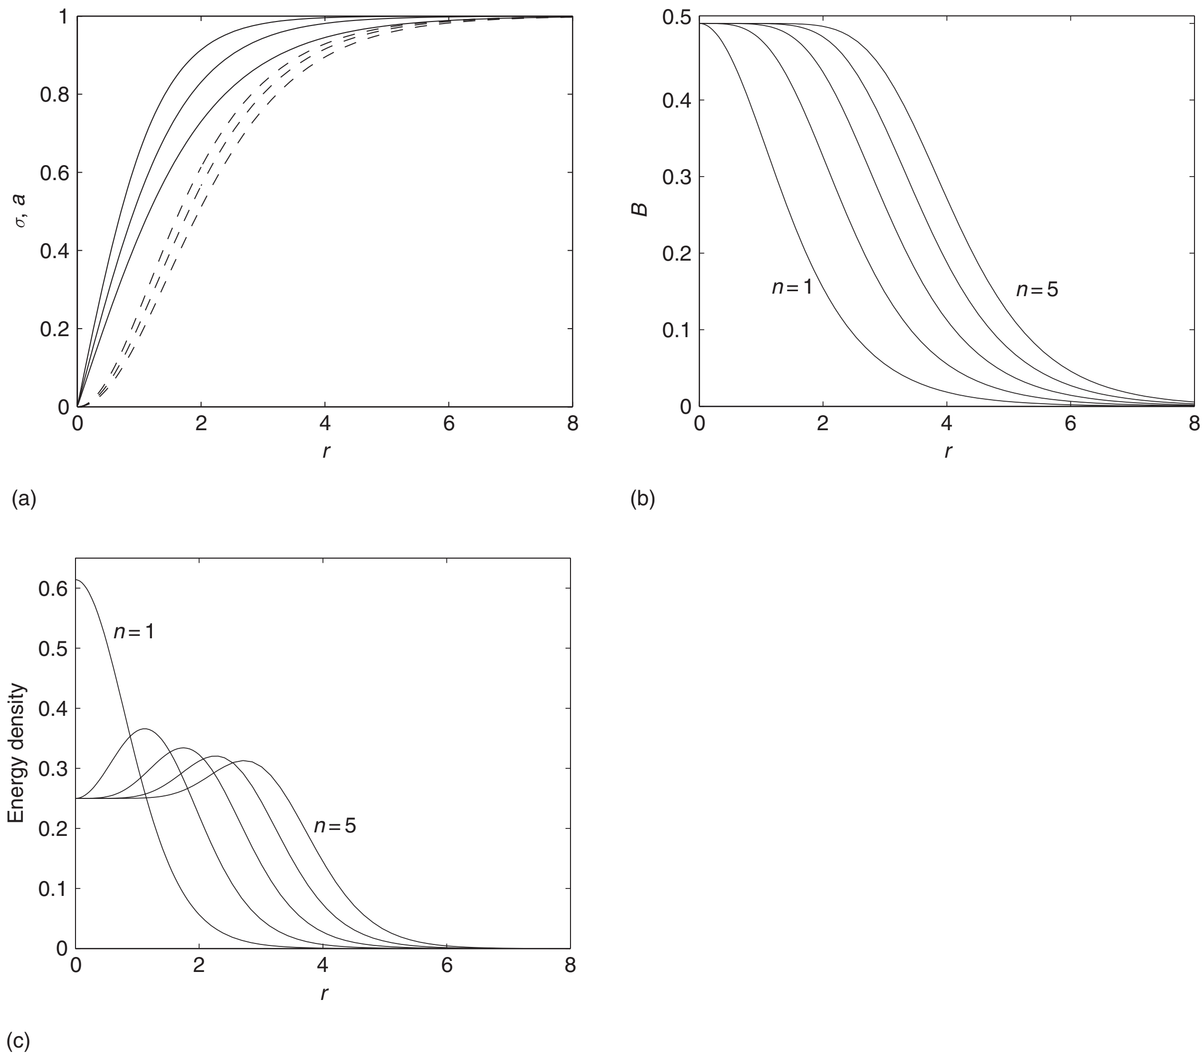

**Figure 1** Static, radially symmetric *n*-vortices: (a) the 1-vortex profile functions $\sigma(r)$ (solid curve) and $a(r)$ (dashed curve) for $\lambda = 2, 1$, and 1/2, left to right; (b) the magnetic field $B$; and (c) the energy density of *n*-vortices, $n = 1$ to 5, left to right, for $\lambda = 1$.

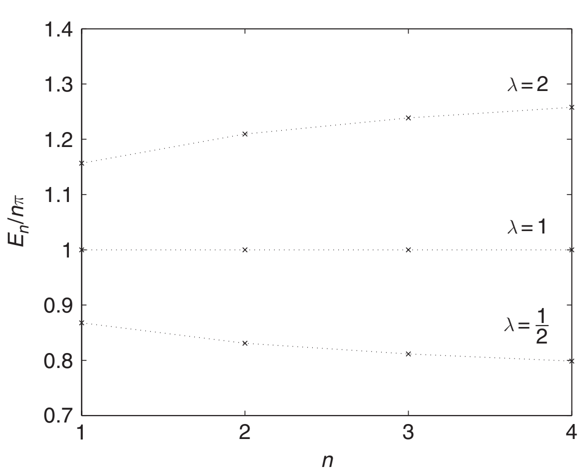

**Figure 2** The energy per unit winding $E_n/n$ of radially symmetric *n*-vortices for $\lambda = 1/2, 1$, and 2.

## Interaction Energy

A precise understanding of the type I/II dichotomy can be obtained using the 2-vortex interaction energy $E_{\text{int}}(s)$ introduced by Jacobs and Rebbi. This is defined to be the minimum of $E$ over all $n = 2$ configurations for which $\phi(\boldsymbol{x}) = 0$ at some pair of points $\boldsymbol{x}_1, \boldsymbol{x}_2$ distance $s$ apart. One interprets $\boldsymbol{x}_1, \boldsymbol{x}_2$ as the vortex positions. $E_{\text{int}}$ can only depend on their separation $s = |\boldsymbol{x}_1 - \boldsymbol{x}_2|$, by translation and rotation invariance. Figure 3 presents graphs of $E_{\text{int}}(s)$ generated by a lattice minimization algorithm. For $\lambda < 1$, vortices uniformly attract one another, so a vortex pair has least energy when coincident. For $\lambda > 1$, vortices uniformly repel, always lowering their energy by moving further apart. The graph for $\lambda = 1$ would be a horizontal line, $E_{\text{int}}(s) = 2\pi$.

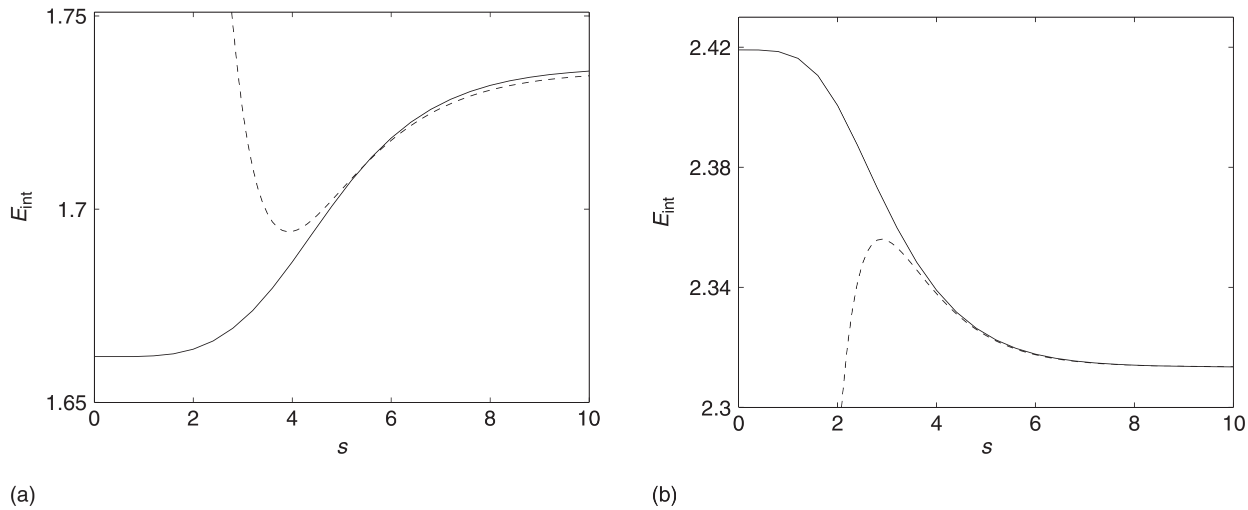

**Figure 3** The 2-vortex interaction energy $E_{\text{int}}(s)$ as a function of vortex separation (solid curve), in comparison with its asymptotic form $E_{\text{int}}^{\infty}(s)$ (dashed curve) for (a) $\lambda = 1/2$ and (b) $\lambda = 2$.

The large $s$ behavior of $E_{\text{int}}(s)$ is known, and can be understood in two ways (Manton and Sutcliffe 2004, pp. 177–181). Speight, adapting ideas of Manton on asymptotic monopole interactions, observed that, in the real $\phi$ gauge ($\phi \mapsto e^{-i\theta}\phi$, $A \mapsto A - d\theta$), the difference between the vortex and the vacuum $\phi = 1, A = 0$ at large $r$,

$$\psi = \phi - 1 \sim \frac{q}{2\pi} K_0(\sqrt{\lambda}\, r) \qquad [11]$$

$$(A_0, \boldsymbol{A}) \sim \frac{m}{2\pi}(0, \boldsymbol{k} \times \nabla K_0(r)) \qquad [12]$$

is identical to the solution of a linear Klein–Gordon–Proca theory,

$$(\partial_\mu \partial^\mu + \lambda)\psi = \kappa, \qquad (\partial_\mu \partial^\mu + 1)A_\nu = j_\nu \qquad [13]$$

in the presence of a composite point source,

$$\kappa = q\delta(\boldsymbol{x}), \qquad (j_0, \boldsymbol{j}) = m(0, \boldsymbol{k} \times \nabla \delta(\boldsymbol{x})) \qquad [14]$$

located at the vortex position. Viewed from afar, therefore, a vortex looks like a point particle carrying both a scalar monopole charge $q$ and a magnetic dipole moment $m$, a "point vortex," inducing a real scalar field of mass $\sqrt{\lambda}$ (the Higgs particle) and a vector boson field of mass 1 (the "photon"). If physics is to be model independent, therefore, the interaction energy of a pair of well-separated vortices should approach that of the corresponding pair of point vortices as the separation grows. Computing the latter is an easy exercise in classical linear field theory, yielding

$$E_{\text{int}}(s) \sim E_{\text{int}}^{\infty}(s) = 2E_1 - \frac{q^2}{2\pi} K_0(\sqrt{\lambda} s) + \frac{m^2}{2\pi} K_0(s) \qquad [15]$$

Bettencourt and Rivers obtained the same formula by a more direct superposition ansatz approach, though they did not give the constants $q$, $m$ a physical interpretation.

The force between a well-separated vortex pair, $-E_{\text{int}}{}'(s)$, consists of the mutual attraction of identical scalar monopoles, of range $1/\sqrt{\lambda}$, and the mutual repulsion of identical magnetic dipoles, of range 1. If $\lambda < 1$, scalar attraction dominates at large $s$ so vortices attract. If $\lambda > 1$, magnetic repulsion dominates and they repel. If $\lambda = 1$ then $q \equiv m$, as we shall see, so the forces cancel exactly. Figure 3 shows both $E_{\text{int}}$ and $E_{\text{int}}^{\infty}$ for $\lambda = 0.5, 2$. The agreement is good for $s$ large, but breaks down for $s < 4$, as one expects. Vortices are not point particles, as in the linear model, and when they lie close together the overlap of their cores produces significant effects.

The same method predicts the interaction energy between an $n_1$-vortex and an $n_2$-vortex at large separation. We just replace $2E_1$ by $E_{n_1} + E_{n_2}$, $q^2$ by $q_{n_1} q_{n_2}$, and $m^2$ by $m_{n_1} m_{n_2}$. In particular, an antivortex ((−1)-vortex) has $E_{-1} = E_1, q_{-1} = q_1 = q$, and $m_{-1} = -m_1 = -m$, so the interaction energy for a vortex–antivortex pair is

$$E_{\text{int}}^{v\bar{v}}(s) \sim 2E_1 - \frac{q^2}{2\pi} K_0(\sqrt{\lambda} r) - \frac{m^2}{2\pi} K_0(r) \qquad [16]$$

which is uniformly attractive. It would be pleasing if $q_n, m_n$ could be deduced easily from $q$, $m$. One might guess $q_n = |n|q, m_n = nm$, in analogy with monopoles. Unfortunately, this is false: $q_n, m_n$ grow approximately exponentially with $|n|$.

## Vortex Scattering

The AHM being Lorentz invariant, one can obtain time-dependent solutions wherein a single $n$-vortex travels at constant velocity, with speed $0 < v < 1$ and $E_{\text{tot}} = (1 - v^2)^{-1/2} E_n$, by Lorentz boosting the static solutions described above. Of more dynamical interest are solutions in which two or more vortices undergo relative motion. The simplest problem is vortex scattering. Two vortices, initially well separated, are propelled towards one another. In the center-of-mass (COM) frame they have, as $t \to -\infty$, equal speed $v$, and approach one another along parallel lines distance $b$ (the impact parameter) apart, see Figure 4. If $b = 0$, they approach head-on. Assuming they do not capture one another, they interact and, as $t \to \infty$, recede along parallel straight lines having been deflected through an angle $\Theta$ (the scattering angle). If scattering is elastic, the exit lines also lie $b$ apart and each vortex travels at speed $v$ as $t \to \infty$. The dependence of $\Theta$ on $v$, $b$, and $\lambda$ has been studied through lattice simulations by several authors, perhaps most comprehensively by Myers, Rebbi, and Strilka (1992). We shall now describe their results.

Note first that vortex scattering is actually inelastic: vortices recede with speed $< v$ because some of their initial kinetic energy is dispersed by the collision as small-amplitude traveling waves ("radiation"). This energy loss can be as high as 80% in very fast collisions at small $b$. At small $v$ the energy loss is tiny, but can still have important consequences for type I vortices: if $v$ is very small, they start with only just enough energy to escape their mutual attraction. In undergoing a small $b$ collision they can lose enough of this energy to become trapped in an oscillating bound state. In this case they do not truly scatter and $\Theta$ is ill-defined. Myers *et al.* find that $v \geq 0.2$ suffices to avoid

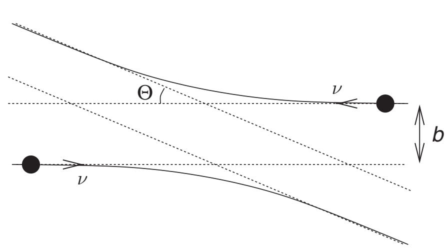

**Figure 4** The geometry of vortex scattering.

capture when $\lambda = 1/2$. Since type I vortices attract, one might expect $\Theta$ to be always negative, indicating that the vortices deflect towards one another. In fact, as Figure 5a shows, this happens only for small $v$ and large $b$. Another naive expectation is that $\Theta = 0$ or $\Theta = 180°$ when $b = 0$ (either vortices pass through one another or ricochet backwards in a head-on collision). In fact $\Theta = 90°$, the only other possibility allowed by reflexion symmetry of the initial data. Figure 6 depicts snapshots of such a scattering process at modest $v$. The vortices deform each other as they get close until, at the moment of coincidence, they are close to the static 2-vortex ring. They then break apart along a line perpendicular to their line of approach. One may consider them to have exchanged half-vortices, so that each emergent vortex is a mixture of the incoming vortices. This rather surprising phenomenon was actually predicted by Ruback in advance of any numerical simulations and turns out to be a generic feature of planar topological solitons.

Consider now the type II case ($\lambda = 2$, Figure 5b). Here, $\Theta > 0$ for all $v$, $b$ as one expects of particles that repel each other. Head-on scattering is more interesting now since two regimes emerge: for $v > v_{\text{crit}} \approx 0.3$, one has the surprising 90° scattering already described, while for $v < v_{\text{crit}}$ the vortices bounce backwards, $\Theta = 180°$. This is easily explained. In order to undergo 90° head-on scattering, the vortices must become coincident (otherwise reflexion symmetry is violated), hence must have initial energy at least $E_2$. For $v < v_{\text{crit}}$, where

$$\frac{2E_1}{\sqrt{1 - {v_{\text{crit}}}^2}} = E_2 \qquad [17]$$

they have too little energy, so come to a halt before coincidence, then recede from one another. The solution $v_{\text{crit}}$ of [17] depends on $\lambda$ and is plotted in Figure 7. For $v$ slightly above $v_{\text{crit}}$, we see that, in contrast to the type I case, $\Theta(b)$ is not monotonic: maximum deflection occurs at nonzero $b$.

The point vortex formalism yields a simple model of type II vortex scattering which is remarkably successful at small $v$. One writes down the Lagrangian for two identical (nonrelativistic) point particles of mass $E_1$ moving along trajectories $\boldsymbol{x}_1(t), \boldsymbol{x}_2(t)$ under the influence of the repulsive potential $E_{\text{int}}^{\infty}$,

$$L = \tfrac{1}{2} E_1 (|\dot{\boldsymbol{x}}_1|^2 + |\dot{\boldsymbol{x}}_2|^2) - E_{\text{int}}^{\infty}(|\boldsymbol{x}_1 - \boldsymbol{x}_2|) \qquad [18]$$

Energy and angular momentum conservation reduce $\Theta(v, b)$ to an integral over one variable ($s = |\boldsymbol{x}_1 - \boldsymbol{x}_2|$) which is easily computed numerically. To illustrate, Figure 5b shows the result for $\lambda = 2, v = 0.1$ in comparison with the lattice simulations of

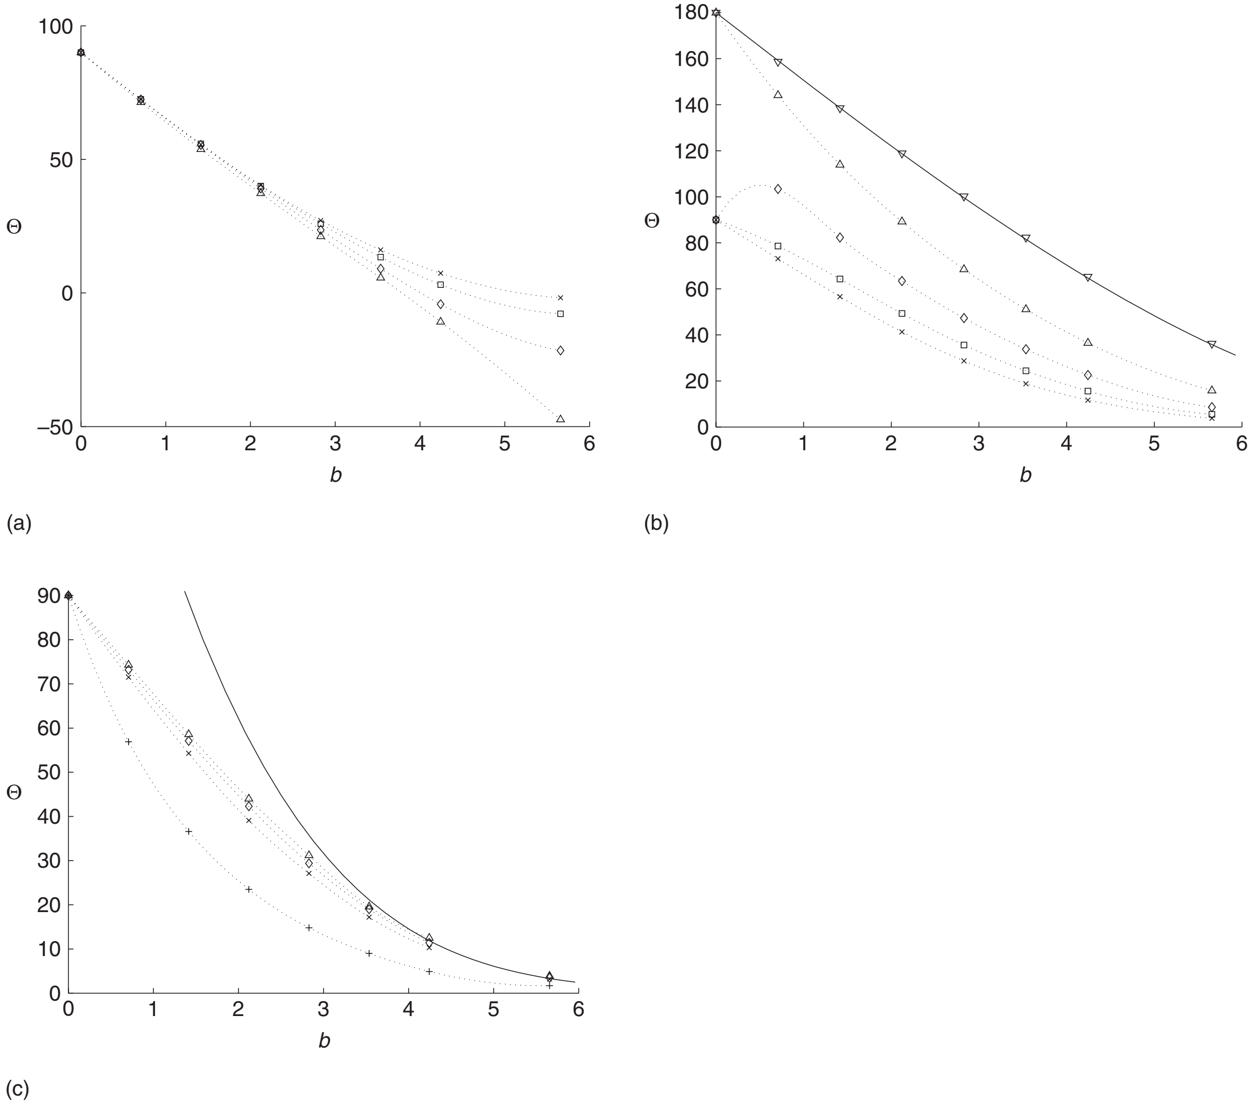

**Figure 5** The 2-vortex scattering angle $\Theta$ as a function of impact parameter $b$ for $v = 0.1$ ($\bigtriangledown$), $v = 0.2$ ($\bigtriangleup$), $v = 0.3$ ($\Diamond$), $v = 0.4$ ($\approx$), $v = 0.5$ ($\times$), and $v = 0.9$ ($+$), as computed by Myers *et al.* (1992): (a) $\lambda = 1/2$; (b) $\lambda = 2$; (c) $\lambda = 1$. The dotted curves are merely guides to the eye. The solid curves in (b), (c) were computed using the point vortex model. Note that Myers *et al.* use different normalizations, so $b = \sqrt{2} b_{MRS}$ and $\lambda = \lambda_{MRS}/2$.

Myers *et al.* The agreement is almost perfect. For large $v$ the approximation breaks down not only because relativistic corrections become significant, but also because small $b$ collisions then probe the small $|\boldsymbol{x}_1 - \boldsymbol{x}_2|$ region where vortex core overlap effects become important. For the same reason, the point vortex model is less useful for type I scattering. Here there is no repulsion to keep the vortices well separated, so its validity is restricted to the small $v$, large $b$ regime.

Critical coupling is theoretically the most interesting regime, where most analytic progress has been made. Since $E_{\text{int}} \equiv E_{\text{int}}^{\infty} \equiv 0$, one might expect vortex scattering to be trivial ($\Theta(v, b) \equiv 0$), but this is quite wrong, as shown in **Figure 5c**. In particular, $\Theta(v, 0) = 90°$ for all $v$, just as in the large $v$ type I and type II cases. The point is that scalar attraction and magnetic repulsion of vortices are mediated by fields with different Lorentz transformation properties. While they cancel for static vortices, there is no reason to expect them to cancel for vortices in relative motion.

## Critical Coupling

The AHM with $\lambda = 1$ has many remarkable properties, at which we have so far only hinted. These all stem from Bogomol'nyi's crucial observation (Manton and Sutcliffe 2004, pp. 197–202) that the potential energy in this case can be rewritten as

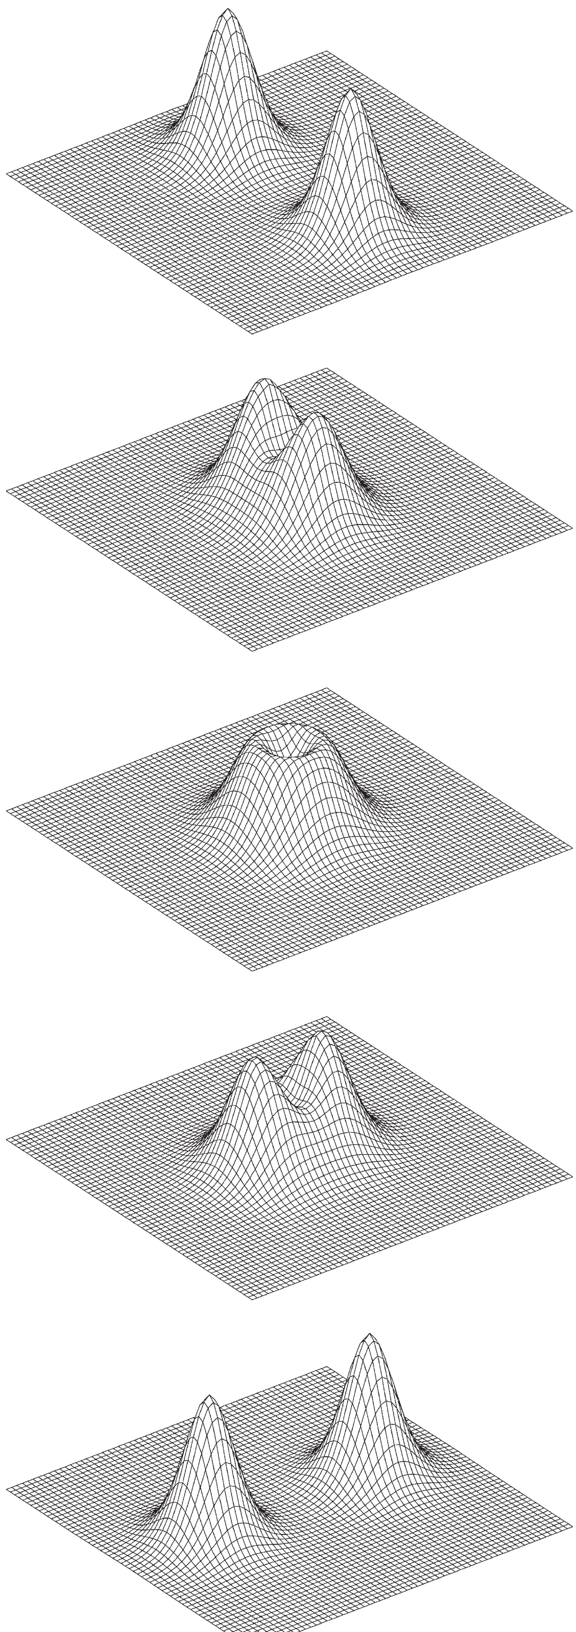

**Figure 6** Snapshots of the energy density during a head-on collision of vortices. This 90° scattering phenomenon is a generic feature of planar topological soliton dynamics.

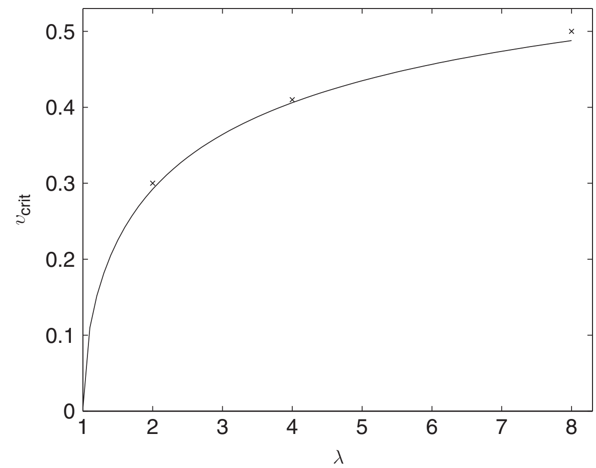

**Figure 7** The critical velocity for 90° head-on scattering of type II vortices $v_{\mathrm{crit}}$ as a function of $\lambda$, as predicted by equation [17] (solid curve), in comparison with the results of Myers *et al.* (1992), (crosses).

$$E = \frac{1}{2}\int\left\{\left(B - \frac{1}{2}(1-|\phi|^2)\right)^2 + |D_1\phi + \mathrm{i}D_2\phi|^2 + B\right\}\mathrm{d}^2\boldsymbol{x} - \mathrm{i}\int_{\mathbb{R}^2}\mathrm{d}(\bar{\phi}D\phi) \qquad [19]$$

The last integral vanishes by Stokes's theorem, so $E \geq \pi n$ by flux quantization [6], and $E = \pi n$ if and only if

$$(D_1 + \mathrm{i}D_2)\phi = 0 \qquad [20]$$

$$\tfrac{1}{2}(1 - |\phi|^2) = B \qquad [21]$$

Note that system [20], [21] is first order, in contrast to the second-order field equations [3]. No explicit solutions of [20], [21] are known. However, Taubes has proved that for each unordered list $[z_1, z_2, \ldots, z_n]$ of $n$ points in $\mathbb{C}$, not necessarily distinct, there exists a solution of [20], [21], unique up to gauge transformations, with $\phi(z_1) = \phi(z_2) = \cdots = \phi(z_n) = 0$ and $\phi$ nonvanishing elsewhere, the zero at $z_r$ having the same multiplicity as $z_r$ has in the list. Note that the list is unordered: a solution is uniquely determined by the positions and multiplicities of the zeroes of $\phi$, but the order in which we label these is irrelevant. The solution minimizes $E$ within the class $\mathcal{C}_n$ of winding $n$ configurations, so is automatically a stable static solution of the model.

Equation [20] applied to the symmetric $n$-vortex, $\phi = \sigma(r)\,\mathrm{e}^{\mathrm{i}n\theta}, A = a(r)\,\mathrm{d}\theta$ implies $a(r) = n - r\sigma'(r)/\sigma(r)$. Comparing with [8], [9], it follows that $q_n = m_n$ when $\lambda = 1$ as previously claimed, since $K_1 = -K_0'$. Tong has conjectured, based on a string duality argument, that $q_1 = -2\pi 8^{1/4}$. This is consistent with current numerics but has no direct derivation so far.

Taubes's theorem shows that this $n$-vortex is just one point, corresponding to the list $[0, 0, \ldots, 0]$, in a $2n$-dimensional space of static multivortex solutions called the moduli space $\mathsf{M}_n$. This space may be visualized as the flat, finite-dimensional valley bottom in $\mathcal{C}_n$ on which $E$ attains its minimum value, $\pi n$. Points in $\mathsf{M}_n$ are in one-to-one correspondence with distinct unordered lists $[z_1, z_2, \ldots, z_n]$, which are themselves in one-to-one correspondence with points in $\mathbb{C}^n$, as follows. To each list, we assign the unique monic polynomial whose roots are $z_r$,

$$\begin{aligned} p(z) &= (z - z_1)(z - z_2) \cdots (z - z_n) \\ &= a_0 + a_1 z + \cdots + a_{n-1} z^{n-1} + z^n \end{aligned} \qquad [22]$$

This polynomial is uniquely determined by its coefficients $(a_0, a_1, \ldots, a_{n-1}) \in \mathbb{C}^n$, which give good global coordinates on $\mathsf{M}_n \cong \mathbb{C}^n$. The zeros $z_r$ of $\phi$ may be used as local coordinates on $\mathsf{M}_n$, away from $\Delta$, the subset of $\mathsf{M}_n$ on which two or more of the zeros $z_r$ coincide, but are not good global coordinates.

Let $(\phi, \boldsymbol{A})_{\boldsymbol{a}}$ denote the static solution corresponding to $\boldsymbol{a} \in \mathbb{C}^n$. If the zeros $z_r$ are all at least $s$ apart, Taubes showed the solution is just a linear superposition of 1-vortices located at $z_r$, up to corrections exponentially small in $s$. Imagine these constituent vortices are pushed with small initial velocities. Then $(\phi(t), \boldsymbol{A}(t))$ must remain close to the valley bottom $\mathsf{M}_n$, since departing from it costs kinetic energy, of which there is little. Manton has suggested, therefore, that the dynamics is well approximated by the constrained variational problem wherein $(\phi(t), \boldsymbol{A}(t)) = (\phi, \boldsymbol{A})_{\boldsymbol{a}(t)} \in \mathsf{M}_n$ for all $t$. Since the action $S = \int \mathcal{L}\, d^3x = \int (E_{\text{kin}} - E)\, dt$, and $E = \pi n$, constant, on $\mathsf{M}_n$, this constrained problem amounts to Lagrangian mechanics on configuration space $\mathsf{M}_n$ with Lagrangian $L = E_{\text{kin}}|_{\mathsf{M}_n}$. Now $E_{\text{kin}}$ is real, positive, and quadratic in time derivatives of $\phi$, $\boldsymbol{A}$, so

$$L = \tfrac{1}{2} \gamma_{rs}(\boldsymbol{a}) \dot{a}_r \dot{\bar{a}}_s \qquad [23]$$

$\gamma_{rs}$ forming the entries of a positive-definite $n \times n$ Hermitian matrix ($\gamma_{sr} \equiv \overline{\gamma_{rs}}$). Since $(\phi, \boldsymbol{A})_{\boldsymbol{a}}$ is not known explicitly, neither are $\gamma_{rs}(\boldsymbol{a})$. Observe, however, that $L$ is the Lagrangian for geodesic motion in $\mathsf{M}_n$ with respect to the Riemannian metric

$$\gamma = \gamma_{rs}(\boldsymbol{a})\, da_r\, d\bar{a}_s \qquad [24]$$

Manton originally proposed this geodesic approximation for monopoles, but it is now standard for all topological solitons of Bogomol'nyi type (where one has a moduli space of static multisolitons saturating a topological lower bound on $E$). Note that geodesics are independent of initial speed, which agrees with Myers *et al*: **Figure 5c** shows that $\Theta(v, b)$ is approximately independent of $v$ for $v \leq 0.5$. Further, Stuart (1994) has proved that, for initial speeds of order $\epsilon$, small, the fields stay (pointwise) $\epsilon^2$ close to their geodesic approximant for times of order $\epsilon^{-1}$.

On symmetry grounds, two vortex dynamics in the COM frame reduces to geodesic motion in $\mathsf{M}_2^0 \cong \mathbb{C}$, the subspace of centered 2-vortices ($a_1 = 0$, so $z_1 = -z_2$), with induced metric

$$\gamma^0 = G(|a_0|)\, da_0\, d\bar{a}_0 \qquad [25]$$

$G$ being some positive function. Note that $a_0 = z_1 z_2$, so the intervortex distance $|z_1 - z_2| = 2|z_1| = 2|a_0|^{1/2}$. The line $a_0 = \beta \in \mathbb{R}$, traversed with $\beta$ increasing, say, is geodesic in $\mathsf{M}_2^0$. The vortex positions (roots of $z^2 + a_0$) are $\pm\sqrt{|\beta|}$ for $\beta \leq 0$ and $\pm i\sqrt{\beta}$ for $\beta > 0$. This describes perfectly the 90° scattering phenomenon: two vortices approach head-on along the $x^1$ axis, coincide to form a 2-vortex ring, then break apart along the $x^2$ axis, as in **Figure 6**. This behavior occurs because $a_0 = z_1 z_2$, rather than $z_1 - z_2$, is the correct global coordinate on $\mathsf{M}_2^0$, since vortices are classically indistinguishable.

Samols found a useful formula (Manton and Sutcliffe 2004, pp. 205–215) for $\gamma$ in terms of the behavior of $|\phi_{\boldsymbol{a}}|$ close to its zeros, using which he devised an efficient numerical scheme to evaluate $G(|a_0|)$, and computed $\Theta(b)$ in detail, finding excellent agreement with lattice simulations at low speeds. He also studied the quantum scattering of vortices, approximating the quantum state by a wave function $\Psi$ on $\mathsf{M}_n$ evolving according to the natural Schrödinger equation for quantum geodesic motion,

$$i\hbar \frac{\partial \Psi}{\partial t} = -\tfrac{1}{2} \hbar^2 \Delta_\gamma \Psi \qquad [26]$$

where $\Delta_\gamma$ is the Laplace–Beltrami operator on $(\mathsf{M}_n, \gamma)$. This technique, introduced for monopoles by Gibbons and Manton, is now standard for solitons of Bogomol'nyi type.

By analyzing the forces between moving point vortices at $\lambda = 1$, Manton and Speight (2003) showed that, as the vortex separations become uniformly large, the metric on $\mathsf{M}_n$ approaches

$$\begin{aligned} \gamma^\infty = \pi \sum_r \Bigg[ & dz_r\, d\bar{z}_r - \frac{q^2}{4\pi} \sum_{s \neq r} K_0(|z_r - z_s|) \\ & \times (dz_r - dz_s)(d\bar{z}_r - d\bar{z}_s) \Bigg] \end{aligned} \qquad [27]$$

This formula can also be obtained by a method of matched asymptotic expansions. We can use [27] to study 2-vortex scattering for large $b$, when the

vortices remain well separated. (Note that $\gamma^\infty$ is not positive definite if any $|z_r - z_s|$ becomes too small.) The results are good, provided $v \le 0.5$ and $b \ge 3$ (see Figure 5c).

## Other Developments

The (critically coupled) AHM on a compact physical space $\Sigma$ is of considerable theoretical and physical interest. Bradlow showed that $\mathsf{M}_n(\Sigma)$ is empty unless $V = \text{Area}(\Sigma) \ge 4\pi n$, so there is a limit to how many vortices a space of finite area can accommodate (Manton and Sutcliffe 2004, pp. 227–230). Manton has analyzed the thermodynamics of a gas of vortices by studying the statistical mechanics of geodesic flow on $\mathsf{M}_n(\Sigma)$. In this context, spatial compactness is a technical device to allow nonzero vortex density $n/V$ for finite $n$, without confining the fields to a finite box, which would destroy the Bogomol'nyi properties. In the limit of interest, $n, V \to \infty$ with $n/V$ fixed, the thermodynamical properties turn out to depend on $\Sigma$ only through $V$, so $\Sigma = S^2$ and $\Sigma = T^2$ give equivalent results, for example. The equation of state of the gas is ($P$ = pressure, $T$ = temperature)

$$P = \frac{nT}{V - 4\pi n} \qquad [28]$$

which is similar, at low density $n/V$, to that of a gas of hard disks of area $2\pi$. The crucial step in deriving [28] is to find the volume of $\mathsf{M}_n(\Sigma)$ which, despite there being no formula for $\gamma$, may be computed exactly by remarkable indirect arguments (Manton and Sutcliffe 2004, pp. 231–234).

The static AHM coincides with the Ginzburg–Landau model of superconductivity, which has precisely the same type I/II classification. Here the "Higgs" field represents the wave function of a condensate of Cooper pairs, usually (but not always) electrons. There has been a parallel development of the static model by condensed matter theorists, therefore; see Fossheim and Sudbo (2004), for example. In fact the vortex was actually first discovered by Abrikosov in the condensed matter context. One important difference is that type I superconductors do not support vortex solutions in an external magnetic field $B_{\text{ext}}$ because the critical $|B_{\text{ext}}|$ required to create a single vortex is greater than the critical $|B_{\text{ext}}|$ required to destroy the condensate completely ($\phi \equiv 0$). Type II superconductors do support vortices, and there are such superconductors with $\lambda \approx 1$, but the vortex dynamics we have described is not relevant to these systems. In this context there is an obvious preferred reference frame (the rest frame of the superconductor) so it is unsurprising that the Lorentz-invariant AHM is inappropriate. Insofar as vortices move at all, they seem to obey a first-order (in time) dynamical system, in contrast to the second-order AHM. Manton has devised a first-order system which may have relevance to superconductivity, by replacing $E_{\text{kin}}$ with a Chern–Simons–Schrödinger functional (Manton and Sutcliffe 2004, pp. 193–197). Rather than attracting or repelling, vortices now tend to orbit one another at constant separation. There is again a moduli space approximation to slow vortex dynamics for $\lambda \approx 1$, but it has a Hamiltonian-mechanical rather than Riemannian-geometric flavor.

Finally, an interesting simplification of the AHM, which arises, for example, as a phenomenological model of liquid helium-4, is obtained if we discard the gauge field $A_\mu$, or equivalently set the electric charge of $\phi$ to $e = 0$. There is now no type I/II classification, since $\lambda$ may be absorbed by rescaling. The resulting model, which has only global U(1) phase symmetry, supports $n$-vortices $\phi = \sigma(r)e^{in\theta}$ for all $n$, but these are not exponentially spatially localized,

$$\sigma(r) = 1 - \frac{n^2}{\lambda r^2} - \frac{n^2(8 + n^2)}{2\lambda^2 r^4} + O(r^{-6}) \qquad [29]$$

and cannot have finite $E$ by Derrick's theorem. They are unstable for $|n| > 1$, and 1-vortices uniformly repel one another. They can be given an interesting first-order dynamics (the Gross–Pitaevski equation).

# Adiabatic Piston

**Ch Gruber**, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland
**A Lesne**, Université P.-M. Curie, Paris VI, Paris, France

## Introduction

### Macroscopic Problem

The "adiabatic piston" is an old problem of thermodynamics which has had a long and controversial history. It is the simplest example concerning the time evolution of an adiabatic wall, that is, a wall which does not conduct heat. The system consists of a gas in a cylinder divided by an adiabatic wall (the piston). Initially, the piston is held fixed by a clamp and the two gases are in thermal equilibrium characterized by $(p^\pm, T^\pm, N^\pm)$, where the index $-/+$ refers to the gas on the left/right side of the piston and $(p, T, N)$ denote the pressure, the temperature, and the number of particles (Figure 1). Since the piston is adiabatic, the whole system remains in equilibrium even if $T^- \neq T^+$. At time $t = 0$, the clamp is removed and the piston is let free to move without any friction in the cylinder. The question is to find the final state, that is, the final position $X_\mathrm{f}$ of the piston and the parameters $(p_\mathrm{f}^\pm, T_\mathrm{f}^\pm)$ of the gases.

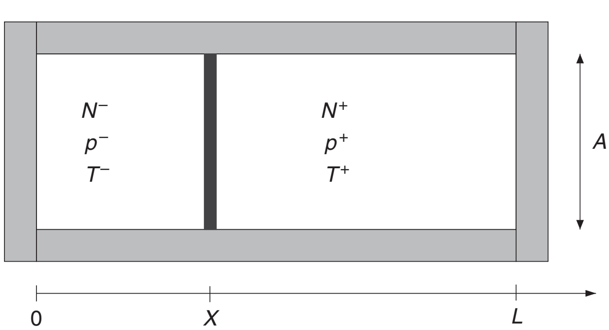

**Figure 1** The adiabatic piston problem.

In the late 1950s, using the two laws of equilibrium thermodynamics (i.e., thermostatics), Landau and Lifshitz concluded that the adiabatic piston will evolve toward a final state where $p^-/T^- = p^+/T^+$. Later, Callen (1963) and others realized that the maximum entropy condition implies that the system will reach mechanical equilibrium where the pressures are equal $p_\mathrm{f}^- = p_\mathrm{f}^+$; however, nothing could be said concerning the final position $X_\mathrm{f}$ or the final temperatures $T_\mathrm{f}^\pm$ which should depend explicitly on the viscosity of the fluids. It thus became a controversial problem since one was forced to accept that the two laws of thermostatics are not sufficient to predict the final state as soon as adiabatic movable walls are involved (see early references in Gruber (1999)).

Experimentally, the adiabatic piston was used already before 1924 to measure the ratio $c_p/c_v$ of the specific heats of gases. In 2000, new measurements have shown that one has to distinguish between two regimes, corresponding to weak damping or strong damping, with very different properties, for example, for weak damping the frequency of oscillations corresponds to adiabatic oscillations, whereas for strong damping it corresponds to isothermal oscillations.

### Microscopic Problem

The "adiabatic piston" was first considered from a microscopic point of view by Lebowitz who introduced in 1959 a simple model to study heat conduction. In this model, the gas consists of point particles of mass $m$ making purely elastic collisions on the wall of the cylinder and on the piston. Furthermore, the gas is very dilute so that the

equation of state $p = nk_BT$ is satisfied at equilibrium, where $n$ is the density of particles in the gas and $k_B$ the Boltzmann constant. The adiabatic piston is taken as a heavy particle of mass $M \gg m$ without any internal degree of freedom. Using this same model Feynman (1965) gave a qualitative analysis in *Lectures in Physics*. He argued intuitively but correctly that the system should converge first toward a state of mechanical equilibrium where $p^- = p^+$ and then very slowly toward thermal equilibrium. This approach toward thermal equilibrium is associated with the "wiggles" of the piston induced by the random collisions with the atoms of the gas. Of course, this stochastic behavior is not part of thermodynamics and the evolution beyond the mechanical equilibrium cannot appear in the macroscopical framework assuming that the piston does not conduct heat.

From a microscopical point of view, one is confronted with two different problems: the approach toward mechanical equilibrium in the absence of any *a priori* friction (where the entropy of both gases should increase) and, on a different timescale, the approach toward thermal equilibrium (where the entropy of one gas should decrease but the total entropy increase).

The conceptual difficulties of the problem beyond mechanical equilibrium come from the following intuitive reasoning. When the piston moves toward the hotter gas, the atoms of the hotter gas gain energy, whereas those of the cooler gas lose energy. When the piston moves toward the cooler side, it is the opposite. Since on an average the hotter side should cool down and the cold side should warm up, we are led to conclude that on an average the piston should move toward the colder side. On the other hand, from $p = nk_BT$, the piston should move toward the warmer side to maintain pressure balance.

In 1996, Crosignani, Di Porto, and Segev introduced a kinetic model to obtain equations describing the adiabatic approach toward mechanical equilibrium. Starting with the microscopical model introduced by Lebowitz, Gruber, Piasecki, and Frachebourg, later joined by Lesne and Pache, initiated in 1998 a systematic investigation of the adiabatic piston within the framework of statistical mechanics, together with a large number of numerical simulations. This analysis was based on the fact that $m/M$ is a very small parameter to investigate expansions in powers of $m/M$ (see Gruber and Piasecki (1999) and Gruber *et al.* (2003) and reference therein). An approach using dynamical system methods was then developed by Lebowitz *et al.* (2000) and Chernov *et al.* (2002). An extension to hard-disk particles was analyzed at the same time by Kestemont *et al.* (2000). Recently, several other authors have contributed to this subject.

The general picture which emerges from all the investigations is the following. For an infinite cylinder, starting with mechanical equilibrium $p^- = p^+ = p$, the piston evolves to a stationary stochastic state with nonzero velocity toward the warmer side

$$\langle V \rangle = \frac{m}{M}\sqrt{\frac{\pi k_B}{8m}}\left(\sqrt{T^+} - \sqrt{T^-}\right) + o\left(\frac{m}{M}\right) \qquad [1]$$

with relaxation time

$$\tau = \frac{M}{A}\sqrt{\frac{\pi k_B}{8m}}\frac{1}{p}\left(\frac{1}{\sqrt{T^-}} + \frac{1}{\sqrt{T^+}}\right)^{-1} \qquad [2]$$

where $M/A$ is the mass per unit area of the piston. In this state the piston has a temperature $T_P = \sqrt{T^+T^-}$ and there is a heat flux

$$j_Q = \left(\sqrt{T^-} - \sqrt{T^+}\right)\frac{m}{M}\sqrt{\frac{8k_B}{m\pi}}p + o\left(\frac{m}{M}\right) \quad (p^- = p^+ = p) \qquad [3]$$

For a finite cylinder and $p^+ \neq p^-$, the evolution proceeds in four different stages. The first two are deterministic and adiabatic. They correspond to the thermodynamic evolution of the (macroscopic) adiabatic piston. The last two stages, which go beyond thermodynamics, are stochastic with heat transfer across the piston. More precisely:

1. In the first stage whose duration is the time needed for the shock wave to bounce back on the piston, the evolution corresponds to the case of the infinite cylinder (with $p^- \neq p^+$). If $R = Nm/M > 10$, the piston will be able to reach and maintain a constant velocity

$$V = (p^- - p^+)\sqrt{\frac{\pi k_B}{8m}}\frac{\sqrt{T^-T^+}}{p^+\sqrt{T^-} + p^-\sqrt{T^+}} + \mathcal{O}\left(\frac{m}{M}\right) \quad \text{for } |p^- - p^+| \ll 1 \qquad [4]$$

2. In the second stage the evolution toward mechanical equilibrium is either weakly or strongly damped depending on $R$. If $R < 1$, the evolution is very weakly damped, the dynamics takes place on a timescale $t' = \sqrt{R}t$, and the effect of the collisions on the piston is to introduce an external potential $\phi(X) = c_1/X^2 + c_2/(L - X)^2$. On the other hand, if $R > 4$, the evolution is strongly damped (with two oscillations only) and depends neither on $M$ nor on $R$.

3. After mechanical equilibrium has been reached, the third stage is a stochastic approach toward thermal equilibrium associated with heat transfer across the piston. This evolution is very slow and exhibits a scaling property with respect to $t' = mt/M$.
4. After thermal equilibrium has been reached ($T^- = T^+$, $p^- = p^+$), in a fourth stage the gas will evolve very slowly toward a state with Maxwellian distribution of velocities, induced by the collision with the stochastic piston.

The general conclusion is thus that a wall which is adiabatic when fixed will become a heat conductor under a stochastic motion. However, it should be stressed that the time required to reach thermal equilibrium will be several orders of magnitude larger than the age of the universe for a macroscopical piston and such a wall could not reasonably be called a heat conductor. However, for mesoscopic systems, the effect of stochasticity may lead to very interesting properties, as shown by Van den Broeck *et al.* (2004) in their investigations of Brownian (or biological) motors.

## Microscopical Model

The system consists of two fluids separated by an "adiabatic" piston inside a cylinder with $x$-axis, length $L$, and area $A$. The fluids are made of $N^{\pm}$ identical light particles of mass $m$. The piston is a heavy flat disk, without any internal degree of freedom, of mass $M \gg m$, orthogonal to the $x$-axis, and velocity parallel to this $x$-axis. If the piston is fixed at some position $X_0$, and if the two fluids are in thermal equilibrium characterized by $(p_0^{\pm}, T_0^{\pm}, N^{\pm})$, then they will remain in equilibrium forever even if $T_0^+ \neq T_0^-$: it is thus an "adiabatic piston" in the sense of thermodynamics. At a certain time $t = 0$, the piston is let free to move and the problem is to study the time evolution. To define the dynamics, we consider that the system is purely Hamiltonian, that is, the particles and the piston move without any friction according to the laws of mechanics. In particular, the collisions between the particles and the walls of the cylinder, or the piston, are purely elastic and the total energy of the system is conserved. In most studies, one considers that the particles are point particles making purely elastic collisions. Since the piston is bound to move only in the $x$-direction, the velocity components of the particles in the transverse directions play no role in this problem. Moreover, since there is no coupling between the components in the $x$- and transverse directions, one can simplify the model further by assuming that all probability distributions are independent of the transverse coordinates. We are thus led to a formally one-dimensional problem (except for normalizations). Therefore, in this review, we consider that the particles are noninteracting and all velocities are parallel to the $x$-axis. From the collision law, if $v$ and $V$ denote the velocities of a particle and the piston before a collision, then under the collision on the piston:

$$\begin{aligned} v \to v' &= 2V - v + \alpha(v - V) \\ V \to V' &= V + \alpha(v - V) \end{aligned} \qquad [5]$$

where

$$\alpha = \frac{2m}{M + m} \qquad [6]$$

Similarly, under a collision of a particle with the boundary at $x = 0$ or $x = L$:

$$v \to v' = -v \qquad [7]$$

Let us mention that more general models have also been considered, for example, the case where the two fluids are made of point particles with different masses $m^{\pm}$, or two-dimensional models where the particles are hard disks. However, no significant differences appear in these more general models and we restrict this article to the simplest case.

One can study different situations: $L = \infty$, $L$ finite, and $L \to \infty$. Furthermore, taking first $M$ and $A$ finite, one can investigate several limits.

1. Thermodynamic limit for the piston only. In this limit, $L$ is fixed (finite or infinite) and $A \to \infty, M \to \infty$, keeping constant the initial densities $n^{\pm}$ of the fluid and the parameter

$$\gamma = \frac{2mA}{M + m} = \alpha A \sim 2m\,\frac{A}{M} \qquad [8]$$

   If $L$ is finite, this means that $N^{\pm} \to \infty$ while keeping constant the parameters

$$R^{\pm} = \frac{mN^{\pm}}{M} = \frac{M_{\text{gas}}^{\pm}}{M} \qquad [9]$$

2. Thermodynamic limit for the whole system, where $L \to \infty$ and $A \sim L^2, N^{\pm} \sim L^3$. In this limit, space and time variables are rescaled according to $x' = x/L$ and $t' = t/L$. This limit can be considered as a limiting case of (1) where $R^{\pm} \sim \sqrt{A} \to \infty$ (and time is scaled).
3. Continuum limit where $L$ and $M$ are fixed and $N^{\pm} \to \infty, m \to 0$ keeping $M_{\text{gas}}^{\pm}$ constant, that is, $R^{\pm} = cte$.

The case $L$ infinite and the limit (1) have been investigated using statistical mechanics (Liouville or

Boltzmann's equations). On the other hand, the limit (2) has been studied using dynamical system methods, reducing first the system to a billiard in an $(N^+ + N^- + 1)$-dimensional polyhedron. The limit (3) has been introduced to derive hydrodynamical equations for the fluids.

In this article, we present the approach based on statistical mechanics. Although not as rigorous as (2) on a mathematical level, it yields more informations on the approach toward mechanical and thermal equilibrium. Moreover, it indicates what are the open problems which should be mathematically solved. In all investigations, advantage is taken of the fact that $m/M$ is very small and one introduces the small parameter

$$\epsilon = \sqrt{m/M} \ll 1 \qquad [10]$$

Let us note that $\epsilon$ measures the ratio of thermal velocities for the piston and a fluid particle, whereas $\alpha \sim \epsilon^2$ measures the ratio of velocity changes during a collision.

## Starting Point: Exact Equations

Using the statistical point of view, the time evolution is given by Liouville's equation for the probability distribution on the whole phase space for $(N^+ + N^- + 1)$ particles, with $L, A, N^{\pm}$, and $M$ finite. Initially $(t \le 0)$, the piston is fixed at $(X_0, V_0 = 0)$ and the fluids are in thermal equilibrium with homogeneous densities $n_0^{\pm}$, velocity distributions $\varphi_0^{\pm}(v) = \varphi_0^{\pm}(-v)$, and temperatures

$$T_0^{\pm} = m \int_{-\infty}^{\infty} \mathrm{d}v \, n_0^{\pm} \varphi_0^{\pm}(v) v^2 \qquad [11]$$

Integrating out the irrelevant degrees of freedom, the Liouville's equation yields the equations for the distribution $\rho^{\pm}(x, v; t)$ of the right and left particles:

$$\partial_t \rho^{\pm}(x, v; t) + v \partial_x \rho^{\pm}(x, v; t) = I^{\pm}(x, v; t) \qquad [12]$$

The collision term $I^{\pm}(x, v; t)$ is a functional of $\rho_{\pm,P}(X, v; X, V; t)$, the two-point correlation function for a right (resp. left) particle at $(x = X, v)$ and the piston at $(X, V)$. Similarly, one obtains for the velocity distribution of the piston:

$$\begin{aligned} \partial_t \Phi(V; t) = & A \int_{-\infty}^{\infty} (V - v)\big[\theta(V - v)\rho^-_{\mathrm{surf}}(v'; V'; t) \\ & + \theta(v - V)\rho^-_{\mathrm{surf}}(v; V; t)\big]\mathrm{d}v \\ & - A \int_{-\infty}^{\infty} (V - v)\big[\theta(v - V)\rho^+_{\mathrm{surf}}(v'; V'; t) \\ & + \theta(V - v)\rho^+_{\mathrm{surf}}(v; V; t)\big]\mathrm{d}v \end{aligned} \qquad [13]$$

where $(v', V')$ are given by eqn [5] and

$$\rho^{\pm}_{\mathrm{surf}}(v; V; t) = \int_{-\infty}^{\infty} \mathrm{d}X \rho_{\pm,P}(X, v; X, V; t) \qquad [14]$$

We thus have to solve eqns [12]–[13] with initial conditions

$$\begin{aligned} \rho^-(x, v; t = 0) &= n_0^- \varphi_0^-(v)\theta(x)\theta(X_0 - x) \\ \rho^+(x, v; t = 0) &= n_0^+ \varphi_0^+(v)\theta(L - x)\theta(x - X_0) \\ \Phi(V; t = 0) &= \delta(V) \end{aligned} \qquad [15]$$

Using the fact that $\alpha = 2m/(M + m) \ll 1$, we can rewrite eqn [13] as a formal series in powers of $\alpha$:

$$\partial_t \Phi(V; t) = \gamma \sum_{k=1}^{\infty} \frac{(-1)^k \alpha^{k-1}}{k!} \left(\frac{\partial}{\partial V}\right)^k \tilde{F}_{k+1}(V; t) \qquad [16]$$

$$\begin{aligned} \tilde{F}_k(V; t) = & \int_V^{\infty} (v - V)^k \rho^-_{\mathrm{surf}}(v; V; t)\mathrm{d}v \\ & - \int_{-\infty}^{V} (v - V)^k \rho^+_{\mathrm{surf}}(v; V; t)\mathrm{d}v \end{aligned} \qquad [17]$$

from which one obtains the equations for the moments of the piston velocity:

$$\frac{1}{\gamma}\frac{\mathrm{d}\langle V^n \rangle}{\mathrm{d}t} = \sum_{k=1}^{n} \alpha^{k-1} \frac{n!}{k!(n-k)!} \int_{-\infty}^{\infty} \mathrm{d}V \, V^{n-k} \tilde{F}_{k+1}(V; t) \qquad [18]$$

However, we do not know the two-point correlation functions.

If the length of the cylinder is infinite, the condition $M \gg m$ implies that the probability for a particle to make more than one collision on the piston is negligible. Alternatively, one could choose initial distributions $\varphi_0^{\pm}(v)$ which are zero for $|v| < v_{\min}$, where $v_{\min}$ is taken such that the probability of a recollision is strictly zero. Therefore, if $L = \infty$, one can consider that before a collision on the piston the particles are distributed with $\varphi_0^{\pm}(v)$ for all $t$, and the two-point correlation functions factorize, that is,

$$\begin{aligned} \rho^-_{\mathrm{surf}}(v; V; t) &= \rho^-_{\mathrm{surf}}(v; t)\Phi(V; t), \quad \text{if } v > V \\ \rho^+_{\mathrm{surf}}(v; V; t) &= \rho^+_{\mathrm{surf}}(v; t)\Phi(V; t), \quad \text{if } v < V \end{aligned} \qquad [19]$$

where for $L = \infty$, $\rho^{\pm}_{\mathrm{surf}}(v; t) = n_0^{\pm}\varphi_0^{\pm}(v)$ and thus the conditions to obtain eqn [18] are satisfied.

If $L$ is finite, one can show that the factorization property (eqn [19]) is an exact relation in the thermodynamic limit for the piston $(A \to \infty, M/A = cte)$. For finite $L$ and finite $A$, we introduce

**Assumption 1** (Factorization condition). Before a collision the two-point correlation functions have the factorization property (eqn [19]) to first order in $\alpha$.

Under the factorization condition, we have

$$\tilde{F}_k(V;t) = F_k(V;t)\Phi(V;t) \qquad [20]$$

with

$$\begin{aligned} F_k(V;t) &= \int_V^{\infty} \mathrm{d}v(v-V)^k \rho^{-}_{\mathrm{surf}}(v;t) \\ &\quad - \int_{-\infty}^{V} \mathrm{d}v(v-V)^k \rho^{+}_{\mathrm{surf}}(v;t) \\ &= F_k^{-}(V;t) - F_k^{+}(V;t) \end{aligned} \qquad [21]$$

and from eqn [18]

$$\left(\frac{M}{A}\right)\frac{\mathrm{d}}{\mathrm{d}t}\langle V\rangle = M\alpha\langle F_2(V;t)\rangle_\Phi \qquad [22]$$

$$\left(\frac{M}{A}\right)\frac{\mathrm{d}}{\mathrm{d}t}\langle V^2\rangle = M\alpha[\langle VF_2(V;t)\rangle_\Phi + \alpha\langle F_3(V;t)\rangle_\Phi] \qquad [23]$$

Introducing $\bar{V} = \langle V\rangle_\Phi$ then from eqns [12] and [20], it follows that the (kinetic) energies satisfy

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\langle E^{\pm}\rangle}{A}\right) &= \pm M\alpha\Big[\langle F_2^{\pm}(V;t)\rangle_\Phi \bar{V} \\ &\quad + \langle (V-\bar{V})F_2^{\pm}(V;t)\rangle_\Phi \\ &\quad + \frac{\alpha}{2}\langle F_3^{\pm}(V;t)\rangle_\Phi\Big] \end{aligned} \qquad [24]$$

which implies conservation of energy.

From the first law of thermodynamics,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\langle E^{\pm}\rangle}{A}\right) = \frac{1}{A}\left[P_W^{P\to\pm} + P_Q^{P\to\pm}\right] \qquad [25]$$

where $P_W^{P\to\pm}$ and $P_Q^{P\to\pm}$ denote the work- and heat-power transmitted by the piston to the fluid, we conclude from eqns [22] and [25] that the heat flux is

$$\begin{aligned} \frac{1}{A}P_Q^{P\to\pm} &= \pm M\alpha\Big[\langle (V-\bar{V})F_2^{\pm}(V;t)\rangle_\Phi \\ &\quad + \frac{\alpha}{2}\langle F_3^{\pm}(V;t)\rangle_\Phi\Big] \end{aligned} \qquad [26]$$

Since $\alpha \ll 1$, it is interesting to introduce the irreducible moments

$$\Delta_r = \langle (V-\bar{V})^r\rangle_\Phi \qquad [27]$$

and the expansion around $\bar{V} = \langle V\rangle_t$,

$$F_n^{\pm}(V;t) = \sum_{r=0}^{\infty}\frac{1}{r!}F_n^{(r,\pm)}(\bar{V})(V-\bar{V})^r \qquad [28]$$

from which one obtains equations for $\mathrm{d}\Delta_r/\mathrm{d}t$. In particular, using the identities

$$F_3^{(r+1,\pm)} = -3F_2^{(r,\pm)}, \qquad F_2^{(r+2,\pm)} = 2F_0^{(r,\pm)} \qquad [29]$$

in [22] and [24], we have

$$\begin{aligned} \langle F_2^{\pm}(V;t)\rangle_\Phi &= F_2^{\pm}(\bar{V};t) \\ &\quad + \sum_{r\geq 0}\frac{2}{(2+r)!}F_0^{(r,\pm)}\Delta_{2+r} \end{aligned} \qquad [30]$$

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\langle E^{\pm}\rangle}{A}\right) &= \pm M\alpha\Big[\langle F_2^{\pm}(V;t)\rangle_\Phi \bar{V} \\ &\quad + \frac{\alpha}{2}F_3^{\pm}(\bar{V};t) + \frac{1}{2}\sum_{r\geq 2}\frac{1}{r!}(2r-3\alpha) \\ &\quad \times F_2^{(r-1,\pm)}(\bar{V};t)\Delta_r\Big] \end{aligned} \qquad [31]$$

Depending on the questions or approximations one wants to study, either the distribution $\Phi(V;t)$ or the moments $\langle V^n\rangle_t$ will be the interesting objects. Finally, with the condition [19], one can take eqn [12] for $x \neq X_t$ and impose the boundary conditions at $x = X_t$:

$$\begin{aligned} \rho^{-}(X_t,v;t) &= \rho^{-}(X_t,v';t), \quad \text{if } v < V_t \\ \rho^{+}(X_t,v;t) &= \rho^{+}(X_t,v';t), \quad \text{if } v > V_t \end{aligned} \qquad [32]$$

and similarly for $x = 0$ and $x = L$ with $v' = -v$.

Let us note that this factorization condition is of the same nature as the molecular chaos assumption introduced in kinetic theory, and with this condition eqn [13] yields the Boltzmann equation for this model.

In the following, to obtain explicit results as a function of the initial temperatures $T_0^{\pm}$, we take Maxwellian distributions $\varphi_0^{\pm}(v)$ and initial conditions $(p_0^{\pm}, T_0^{\pm}, n_0^{\pm})$ such that the velocity of the piston remains small (i.e., $|\langle V\rangle_t| \ll |\langle v^{\pm}\rangle_0|$).

## Distribution $\Phi(V;t)$ for the Infinite Cylinder ($L = \infty$)

To lowest order in $\epsilon = \sqrt{m/M}$, and assuming $|1 - p^{+}/p^{-}|$ is of order $\epsilon$, one obtains from eqn [16] the usual Fokker–Planck equation whose solution gives

$$\Phi_0(V;t) = \frac{1}{\sqrt{2\pi}}\frac{1}{\Delta(t)}\exp-\left(\frac{(V-\bar{V}(t))^2}{2\Delta^2(t)}\right) \qquad [33]$$

with

$$\bar{V}(t) = (p^- - p^+)\sqrt{\frac{\pi k_B}{8m}}\left[\frac{p^+}{\sqrt{T^+}} + \frac{p^-}{\sqrt{T^-}}\right]^{-1}(1 - e^{-\lambda t})$$
$$\lambda = \frac{A}{M}\sqrt{\frac{8m}{\pi k_B}}\left[\frac{p^+}{\sqrt{T^+}} + \frac{p^-}{\sqrt{T^-}}\right] \quad [34]$$
$$\Delta^2(t) = \frac{k_B}{M}\sqrt{T^- T^+}\,\frac{p^+\sqrt{T^+} + p^-\sqrt{T^-}}{p^+\sqrt{T^-} + p^-\sqrt{T^+}}(1 - e^{-2\lambda t})$$

where we have dropped the index "zero" on the variable $T^\pm, n^\pm$ and used the equation of state $p^\pm = n^\pm k_B T^\pm$.

In conclusion, in the thermodynamic limit for the piston ($M \to \infty, M/A$ fixed), eqn [33] shows that the evolution is deterministic, that is, $\Phi(V;t) = \delta(V - \bar{V}(t))$, where the velocity $\bar{V}(t)$ of the piston tends exponentially fast toward stationary value $V_{stat} = \bar{V}(\infty)$ with relaxation time $\tau = \lambda^{-1}$.

Let us note that for $p^+ = p^-$, we have $\bar{V}(t) \equiv 0$ and the evolution [33] is identical to the Ornstein–Uhlenbeck process of thermalization of the Brownian particle starting with zero velocity and friction coefficient $\lambda$. The analysis of [16] to first order in $\epsilon$ yields then

$$\Phi(V;t) = \left[1 + \epsilon\sum_{k=0}^{3} a_k(t)(V - \bar{V}(t))^k\right]\Phi_0(V;t) \quad [35]$$

where $a_k(t)$ can be explicitly calculated and $a_0(t) = -\Delta^2(t)a_2(t)$ because of the normalization condition. Moreover, $a_2(t) \sim (p^- - p^+)$, that is, $a_2(t) = 0$ if $p^- = p^+$. From [35], one obtains

$$\begin{aligned}\langle V\rangle_t = &\sqrt{\frac{\pi k_B}{8m}}\frac{\sqrt{T^- T^+}}{p^+\sqrt{T^-} + p^-\sqrt{T^+}} \\ &\times \Big\{(p^- - p^+)(1 - e^{-\lambda t}) \\ &+ (p^- - p^+)^2\frac{\pi}{8}\frac{(p^- T^+ - p^+ T^-)}{(p^+\sqrt{T^-} + p^-\sqrt{T^+})^2} \\ &\times (1 - 2\lambda t e^{-\lambda t} - e^{-2\lambda t}) \\ &+ \frac{m}{M}\frac{1}{\sqrt{T^- T^+}}(p^- T^+ - p^+ T^-) \\ &\times \left(\frac{p^+\sqrt{T^+} + p^-\sqrt{T^-}}{p^+\sqrt{T^-} + p^-\sqrt{T^+}}\right)(1 - e^{-\lambda t})^2\Big\}\end{aligned} \quad [36]$$

and

$$\langle V^2\rangle_t - \langle V\rangle_t^2 = \Delta^2(t)\left[1 + \sqrt{\frac{m}{M}}2\Delta^2(t)a_2(t)\right] \quad [37]$$

From eqn [36], we now conclude that for equal pressures $p^- = p^+$, the piston will evolve stochastically to a stationary state with nonzero velocity toward the warmer side

$$\left.\begin{aligned}\langle V\rangle_{stat} &= \frac{m}{M}\sqrt{\frac{\pi k_B}{8m}}(\sqrt{T^+} - \sqrt{T^-}) \\ \langle V^2\rangle_{stat} - \langle V\rangle_{stat}^2 &= \frac{k_B}{M}\sqrt{T^- T^+}\end{aligned}\right\} \text{ if } p^- = p^+ \quad [38]$$

Let us remark that we have established eqn [35] under the condition that $|1 - p^+/p^-| = \mathcal{O}(\epsilon)$, but as we see in the next section, the stationary value $V_{stat}$ obtained from eqn [36] remains valid whenever $|(1 - p^+/p^-)(1 - \sqrt{T^+/T^-})| \ll 1$.

## Moments $\langle V^n\rangle_t$: Thermodynamic Limit for the Piston

### General Equations: Adiabatic Evolution

In the thermodynamic limit $M \to \infty$, $\alpha \to 0$, $\gamma = \alpha A$ is fixed and eqn [16] reduces to

$$\partial_t\Phi(V;t) = -\gamma\frac{\partial}{\partial V}\tilde{F}_2(V;t) \quad [39]$$

Integrating [39] with initial condition $\Phi(V;t=0) = \delta(V)$ yields

$$\Phi(V,t) = \delta(V - \bar{V}(t)), \text{ that is, } \langle V^n\rangle_t = \langle V\rangle_t^n \quad [40]$$

where

$$\frac{d}{dt}V(t) = \gamma F_2(V(t);t), \quad V(t=0) = 0 \quad [41]$$

Moreover,

$$\tilde{F}_2(V;t) = F_2(V;t)\Phi(V;t) \quad [42]$$

and

$$\begin{aligned}\rho_{\pm,P}(X, v; X, V; t) = \rho^\pm(x, v; t)\delta(X - X(t)) \\ \times \delta(V - V(t))\end{aligned} \quad [43]$$

where $dX(t)/dt = V(t), X(t=0) = X_0$.

In conclusion, as already mentioned, in this limit the factorization condition (eqn [19]) is an exact relation. Let us note that $\rho^\pm_{surf}(v;t) = \rho^\pm_{surf}(2V - v;t)$ if $v > V(t)$ (on the right) or $v < V(t)$ (on the left). Let us also remark that $2mF_2^\pm(V(t);t)$ represents the effective pressure from the right/left exerted on the piston. Moreover, since for any distribution $\rho^\pm_{surf}(v;t)$, the functions $F_2^-(V;t)$ and $-F_2^+(V;t)$ are monotonically decreasing, we can introduce the decomposition

$$p^\pm_{surf} = 2mF_2^\pm(V;t) = \hat{p}^\pm \pm \left(\frac{M}{A}\right)\lambda^\pm(V;t)V \quad [44]$$

where the static pressure at the surface is $\hat{p}^\pm(t) = p^\pm_{surf}(V=0;t)$ and the friction coefficients

$\lambda^{\pm}(V;t)$ are strictly positive. The evolution [41] is thus of the form

$$\frac{d}{dt}V(t) = \frac{A}{M}(\hat{p}^- - \hat{p}^+) - \lambda(V)V \qquad [45]$$

It involves the difference of static pressure and the friction coefficient $\lambda(V) = \lambda^-(V) + \lambda^+(V)$. Finally, from eqn [12], we obtain the evolution of the (kinetic) energy per unit area for the fluids in the left and right compartments:

$$\frac{d}{dt}\left(\frac{<E^{\pm}>}{A}\right) = \pm 2mF_2^{\pm}(V;t)V \qquad [46]$$

Therefore, from [40] and [46], and the first law of thermodynamics, we recover the conclusions obtained in the previous section, that is, in the thermodynamic limit for the piston, the evolution (eqns [41], [12], and [35]) is deterministic and adiabatic (i.e., in [46] only work and no heat is involved).

### Infinite Cylinder ($L = \infty, M = \infty$)

As already discussed, for $L = \infty$ we can neglect the recollisions. Therefore, in $F_2^{\pm}$ the distribution $\rho^{\pm}(v;t)$ can be replaced by $n_0^{\pm}\varphi_0^{\pm}(v)$ and $F_2^{\pm}(V)$ is independent of $t$. In this case, the evolution of the piston is simply given by the ordinary differential equation

$$\frac{d}{dt}V(t) = \frac{A}{M}2mF_2(V), \quad V(t=0) = 0 \qquad [47]$$

where $F_2(V)$ is a strictly decreasing function of $V$. If $p_0^+ = p_0^-$, then $V(t) = 0$, that is, the piston remains at rest and the two fluids remain in their original thermal equilibrium. If $p_0^+ \neq p_0^-$, that is, $n_0^+ k_B T_0^+ \neq n_0^- k_B T_0^-$, the piston will evolve monotonically to a stationary state with constant velocity $V_{stat}$ solution of $F_2(V_{stat}) = 0$. From [34], it follows that $V_{stat}$ is a function of $n_0^+/n_0^-, T_0^-, T_0^+$ but does not depend on the value $M/A$. Moreover, the approach to this stationary state is exponentially fast with relaxation time $\tau_0 = 1/\lambda(V=0)$. For Maxwellian distributions $\varphi_0^{\pm}(v)$, $V_{stat}$ is a solution of

$$k_B\left(n_0^- T_0^- - n_0^+ T_0^+\right) - V_{stat}\sqrt{\frac{8k_B m}{\pi}}\left(n_0^-\sqrt{T_0^-} - n_0^+\sqrt{T_0^+}\right) + V_{stat}^2 m\left(n_0^- - n_0^+\right) + \mathcal{O}\left(V_{stat}^3\right) = 0 \qquad [48]$$

Moreover,

$$\tau_0^{-1} = \frac{A}{M}\sqrt{\frac{8k_B m}{\pi}}\left(n_0^-\sqrt{T_0^-} + n_0^+\sqrt{T_0^+}\right) \qquad [49]$$

which implies that the relaxation time will be very small either if $M/A \ll 1$, or if $n_0^{\pm} = \xi\,\tilde{n}_0^{\pm}$ with $\xi \gg 1$. In this case, the piston acquires almost immediately its final velocity $V_{stat}$ and one can solve eqn [12] to obtain the evolution of the fluids.

### Finite Cylinder ($L < \infty$, $M = \infty$)

For finite $L$, introducing the average temperature in the fluids

$$T_{av}^{\pm} = \frac{2\langle E^{\pm}\rangle_t}{k_B N^{\pm}} \qquad [50]$$

we have to solve [41] and [46], that is,

$$\begin{aligned} \frac{d}{dt}V(t) &= \frac{A}{M}2m\left[F_2^-(V;t) - F_2^+(V;t)\right] \\ k_B\frac{d}{dt}T_{av}^{\pm} &= \pm 4m\frac{A}{N^{\pm}}F_2^{\pm}(V;t)V \end{aligned} \qquad [51]$$

where $F_2^{\pm}(V;t)$ is a functional of $\rho_{surf}^{\pm}(v;t)$ which we decompose as

$$F_2^{\pm}(V;t) = \hat{n}^{\pm}(t)k_B\hat{T}^{\pm}(t) \pm \left(\frac{M}{A}\right)\lambda^{\pm}(V;t)V \qquad [52]$$

with

$$\begin{aligned} \hat{n}^-(t) &= \int_0^{\infty} dv\rho_{surf}^-(v;t) \\ \hat{n}^+(t) &= \int_{-\infty}^{0} dv\rho_{surf}^+(v;t) \end{aligned} \qquad [53]$$

and

$$\hat{n}^{\pm}k_B\hat{T}^{\pm} = \hat{p}^{\pm} \qquad [54]$$

For a time interval $\tau_1 = L\sqrt{m/k_B T}$ which is the time for the shock wave to bounce back, the piston will evolve as already discussed. In particular, if $R^{\pm}$ is sufficiently large, then after a time $\tau_0 = \mathcal{O}((R^{\pm})^{-1})$ the piston will reach the velocity $\bar{V}$ given by $F_2(\bar{V}, t) = 0$ (eqn [47]). For $t > \tau_1$, $F_2^{\pm}(V;t)$ depends explicitly on time. For $R^{\pm}$ sufficiently large, we can expect that for all $t$ the velocity $V(t)$ will be a functional of $\rho_{surf}^{\pm}(v;t)$ given by $F_2[V(t); \rho_{surf}^{\pm}(.;t)] = 0$, and thus the problem is to solve eqn [12] with the boundary condition (eqn [32]). Since $V(t)$ so defined is independent of $M/A$, the evolution will be independent of $M/A$ if $R^{\pm}$ is sufficiently large. This conclusion, which we cannot prove rigorously, will be confirmed by numerical simulations.

To give a qualitative discussion of the evolution for arbitrary values of $R^{\pm}$, we shall use the following assumption already introduced in the experimental measurement of $c_p/c_v$.

**Assumption 2** (Average assumption). The surface coefficients $\hat{n}^{\pm}(t)$ and $\hat{T}^{\pm}(t)$ (eqns [52]–[53]) coincide to order 1 in $\alpha$ with the average value of the density and temperature in the fluids, that is,

$$\hat{n}^- = \frac{N^-}{AX(t)}, \quad \hat{n}^+ = \frac{N^+}{A(L - X(t))}$$
$$\hat{T}^{\pm} = T^{\pm}_{\mathrm{av}}(t) \qquad [55]$$

We still need an expression for the friction coefficients. From

$$F_2^{\pm}(V;t) = \hat{p}^{\pm}(t) - 4mVF_1^{\pm}(V=0;t) + mV^2\hat{n}^{\pm}(t) + \mathcal{O}(V^3) \qquad [56]$$

then, assuming that to first order in $\alpha$, $F_1^{\pm}(V=0;t)$ is the same function of $\hat{T}^{\pm}(t)$ as for Maxwellian distributions, we have

$$\lambda^{\pm}(V) = \left(\frac{A}{M}\right)m\hat{n}^{\pm}\left[\sqrt{\frac{8k_{\mathrm{B}}\hat{T}^{\pm}}{m\pi}} \pm V\right] + \mathcal{O}(V^2) \qquad [57]$$

Therefore, choosing initial condition such that $V(t)$ is small for all time, eqn [51] yields

$$\sqrt{\hat{T}^-}X - \sqrt{\hat{T}^+}(L-X) = C = \sqrt{\hat{T}_0^-}X_0 - \sqrt{\hat{T}_0^+}(L-X_0) \qquad [58]$$

We thus obtain the equilibrium point for the adiabatic evolution ($M=\infty$):

$$\left(\frac{N^-}{A}\right)T_{\mathrm{f}}^- = \frac{2E_0}{Ak_{\mathrm{B}}}\frac{X_{\mathrm{f}}}{L} \qquad [59]$$

$$\left(\frac{N^+}{A}\right)T_{\mathrm{f}}^+ = \frac{2E_0}{Ak_{\mathrm{B}}}\left(1 - \frac{X_{\mathrm{f}}}{L}\right) \qquad [60]$$

where

$$\frac{2E_0}{Ak_{\mathrm{B}}} = \left(\frac{N^-}{A}\right)T_0^- + \left(\frac{N^+}{A}\right)T_0^+ \qquad [61]$$

and

$$\sqrt{\left(\frac{A}{N^-}\right)X_{\mathrm{f}}^3} - \sqrt{\left(\frac{A}{N^+}\right)(L-X_{\mathrm{f}})^3} = \sqrt{\frac{AL}{2E_0k_{\mathrm{B}}}}C \qquad [62]$$

Solving [58]–[62] gives the equilibrium state $(X_{\mathrm{f}}, T_{\mathrm{f}}^{\pm})$, which is a state of mechanical equilibrium $p_{\mathrm{f}}^- = p_{\mathrm{f}}^+$, but not thermal equilibrium $T_{\mathrm{f}}^- \neq T_{\mathrm{f}}^+$. Moreover, this equilibrium state does not depend on $M$. Having obtained the equilibrium point, we can then investigate the evolution close to the equilibrium point. Linearizing eqn [51] around $(X_{\mathrm{f}}, T_{\mathrm{f}}^{\pm})$ yields

$$\frac{\mathrm{d}}{\mathrm{d}t}V = k_{\mathrm{B}}\left[\left(\frac{N^-}{M}\right)\frac{T_{\mathrm{f}}^-X_{\mathrm{f}}^2}{X^3} - \left(\frac{N^+}{M}\right)\frac{T_{\mathrm{f}}^+(L-X_{\mathrm{f}})^2}{(L-X)^3}\right] - \lambda(V=0)V \qquad [63]$$

In other words, the effect of collisions on the piston is to induce an external potential of the form $[c_1|X|^{-2} + c_2(L-X)^{-2}]$ and a friction force. It is a damped harmonic oscillator with

$$\omega_0^2 = 6\left(\frac{E_0}{M}\right)\frac{1}{X_{\mathrm{f}}(L-X_{\mathrm{f}})}$$
$$\lambda = 4\sqrt{\frac{1}{\pi}}\sqrt{\frac{E_0}{ML}}\left[\sqrt{\frac{R^-}{X_{\mathrm{f}}}} + \sqrt{\frac{R^+}{(L-X_{\mathrm{f}})}}\right] \qquad [64]$$

(recall that $R^{\pm} = mN^{\pm}/M$). For the case $N^- = N^+$ to be considered in the simulations, eqn [64] implies that the motion is weakly damped if

$$R < R_{\max} = \frac{3\pi}{2}\left[\sqrt{\frac{X_{\mathrm{f}}}{L}} + \sqrt{1 - \frac{X_{\mathrm{f}}}{L}}\right]^{-2} \qquad [65]$$

with period

$$\tau = \frac{2\pi}{\omega_0}\frac{1}{\sqrt{R - R_{\max}}} \qquad [66]$$

and strongly damped if $R > R_{\max}$, in agreement with experimental observations.

## Moments $\langle V^n \rangle_t$: Piston with Finite Mass

### Equation to First Order in $\alpha = 2m/(M+m)$

If the mass of the piston is finite with $M \gg m$, then the irreducible moments $\Delta_r$ are of the order $\alpha^{[(r+1)/2]}$ where $[(r+1)/2]$ is the integral part of $(r+1)/2$. If the factorization condition [19] is satisfied, to first order in $\alpha$ we have

$$\langle V^n \rangle_t = V^n(t) + \frac{n(n-1)}{2}V^{n-2}(t)\Delta_2(t) \qquad [67]$$

where $V(t) = \langle V \rangle_t$ and $\Delta_2(t) = \langle V^2 \rangle_t - \langle V \rangle_t^2$ are solutions of

$$\frac{1}{\gamma}\frac{\mathrm{d}}{\mathrm{d}t}V(t) = F_2 + \Delta_2 F_0$$
$$\frac{1}{\gamma}\frac{\mathrm{d}}{\mathrm{d}t}\Delta_2(t) = -4\Delta_2 F_1 + \alpha F_3 \qquad [68]$$
$$\frac{1}{\gamma}\frac{\mathrm{d}}{\mathrm{d}t}\langle E^{\pm}\rangle_t = \pm\left\{M[F_2^{\pm} + \Delta_2 F_0^{\pm}]V + (M/2)[4\Delta_2 F_1^{\pm} - \alpha F_3^{\pm}]\right\}$$

and $\Delta_2 \doteq k_{\mathrm{B}}T_{\mathrm{P}}/M$ defines the temperature of the piston.

### Infinite Cylinder: Heat Transfer

For the infinite cylinder, the factorization assumption is an exact relation and in this case the functions $F_k(V;t)$ are independent of $t$. The solution

of the autonomous system [68] with $F_k = F_k(V)$ shows that the piston evolves to a stationary state with velocity $\bar{V}$ given by

$$F_2(\bar{V}) + \frac{\alpha}{4}\frac{F_3(\bar{V})F_0(\bar{V})}{F_1(\bar{V})} = 0 \qquad [69]$$

The temperature of the piston is

$$\bar{\Delta}_2 = \frac{k_B T_P}{M} = \frac{\alpha}{4}\frac{F_3(\bar{V})}{F_1(\bar{V})} \qquad [70]$$

and the heat flux from the piston to the fluid is

$$\frac{1}{A}P_Q^{P\to -} = \frac{m^2}{2M}\left[\frac{F_3^+F_1^- - F_3^-F_1^+}{F_1^- - F_1^+}\right] \qquad [71]$$

If we choose initial conditions such that $|V(t)| \ll 1$ for all $t$, and Maxwellian distributions $\varphi^{\pm}(v)$, the solutions $V(t)$, $\Delta_2(t)$ coincide with the solutions previously obtained (eqns [36] and [37]) and

$$\frac{1}{A}P_Q^{P\to -} = (T^+ - T^-) \times \frac{m}{M}\sqrt{\frac{8k_B}{m\pi}} \times \frac{p^-p^+}{(p^+\sqrt{T^-} + p^-\sqrt{T^+})} \qquad [72]$$

In conclusion, to first order in $m/M$, there is a heat flux from the warm side to the cold one proportional to $(T^+ - T^-)$, induced by the stochastic motion of the piston.

### Finite Cylinder ($L < \infty, M < \infty$)

**Singular character of the perturbation approach** Whereas the leading order is actually the "thermodynamic behavior" $M = \infty$ in the first two stages of the evolution (fast relaxation toward mechanical equilibrium), the fluctuations of order $\mathcal{O}(\alpha)$ rule the slow relaxation toward thermal equilibrium. It is thus obvious that a naive perturbation approach cannot give access to "both" regimes. This difficulty is reminiscent of the boundary-layer problems encountered in hydrodynamics, and the perturbation method to be used here is the exact temporal analog of the matched perturbative expansion method developed for these boundary layers. The idea is to implement two different perturbation approaches:

1. one at short times, with time variable $t$ describing the fast dynamics ruling the fast relaxation toward mechanical equilibrium; and
2. one for longer times, with a rescaled time variable $\tau = \alpha t$.

The second perturbation approach above is supplemented with a "slaving principle," expressing that at each time of the slow evolution, that is, at fixed $\tau$, the still present fast dynamics has reached a local asymptotic state, slaved to the values of the slow observables. The initial conditions are set on the first-stage solution. The initial conditions of the second regime match the asymptotic behavior of the first-stage solution ("matching condition").

The slaving principle is implemented by interpreting an evolution equation of the form

$$\frac{da}{dt} \equiv \alpha\frac{da}{d\tau} = A(\tau, a), \quad A = \mathcal{O}(1) \qquad [73]$$

as follows: it indicates that $a$ is in fact a fast quantity relaxing at short times ($\ll\tau$) toward a stationary state $a_{eq}(\tau)$ slaved to the slow evolution and determined by the condition

$$A[\tau, a_{eq}(\tau)] = 0 \qquad [74]$$

(at lowest order in $\alpha$, actually $A[\tau, a_{eq}(\tau)] = \mathcal{O}(\alpha)$ which prescribes the leading order of $a_{eq}(\tau)$); the following-order terms can be arbitrarily fixed as long as only the first order of perturbation is implemented. Physically, such a condition arises to express that an instantaneous mechanical equilibrium takes place at each time $\tau$ of the slow relaxation to thermal equilibrium.

**Equations for the fluctuation-induced evolution of the system** Following this procedure, we arrive at explicit expressions for the rescaled quantities (of order $\mathcal{O}(1)$) $\widetilde{V} = V/\alpha$, $\widetilde{\Delta}_2 = \Delta_2/\alpha$, and $\widetilde{\Pi} = (p^- - p^+)/\alpha$:

$$\begin{aligned}
\widetilde{V} &= \frac{m}{3}\left(\frac{AL}{E_0}\right)\left(\frac{F_3^-F_1^+ - F_3^+F_1^-}{F_1}\right) + \mathcal{O}(\alpha) \\
\frac{\widetilde{\Pi}}{2m} &= \frac{2m}{3}\left(\frac{AL}{E_0}\right)(F_3^-F_1^+ - F_3^+F_1^-) \\
&\quad - \frac{F_3F_1}{4F_1} + \mathcal{O}(\alpha) \\
\widetilde{\Delta}_2 &= \frac{F_3}{4F_1} + \mathcal{O}(\alpha)
\end{aligned} \qquad [75]$$

We then introduce a (dimensionless) rescaled position for the piston

$$\xi = \frac{1}{2} - \frac{X}{L} \in \left[-\frac{1}{2}, \frac{1}{2}\right] \qquad [76]$$

which satisfies

$$\frac{d\xi}{d\tau} = -k_B(T^- - T^+)\left(\frac{2A}{3E_0}\right)\frac{F_1^-F_1^+}{F_1} \qquad [77]$$

To discuss eqn [77], a third assumption has to be introduced.

**Assumption 3 (Maxwellian Identities).** In the regime when $V = \mathcal{O}(\alpha)$, the relations between the functionals $F_1, F_2$, and $F_3$ are the same at lowest order in $\alpha$ as if the distributions $\rho_{surf}^{\pm}(v; V; t)$ were Maxwellian in $v$:

$$F_1^{\pm}(V) \approx \mp\rho^{\pm}\sqrt{\frac{k_B T^{\pm}}{2m\pi}}$$
$$F_3^{\pm}(V) \approx \left(\frac{2k_B T^{\pm}}{m}\right)F_1^{\pm}(V) - VF_2^{\pm}(V) \quad [78]$$

Using these identities and the (dimensionless) rescaled time

$$s = \tau\frac{2}{3L}\sqrt{\frac{k_B}{m\pi}}\sqrt{\frac{2(N^- T_0^- + N^+ T_0^+)}{N}} \quad [79]$$

where $N = N^+ + N^-$, we obtain a deterministic equation describing the piston motion (Gruber *et al.* 2003):

$$\frac{d\xi}{ds} = -\left[\sqrt{\frac{N}{2N^+}(1+2\xi)} - \sqrt{\frac{N}{2N^-}(1-2\xi)}\right]$$
$$\xi(0) = \frac{1}{2} - \frac{X_{ad}}{L} \quad [80]$$

where $X_{ad}$ is the piston position at the end of the adiabatic regime (i.e., $X_f$, eqn [62]). The meaningful observables straightforwardly follow from the solution $\xi(s)$:

$$X(s) = L\left(\frac{1}{2} - \xi(s)\right)$$
$$T^{\pm}(s) = [1 \pm 2\xi(s)]\left(\frac{N^- T_0^- + N^+ T_0^+}{2N^{\pm}}\right) \quad [81]$$

The first-order perturbation analysis using a single rescaled time $t_1 = \alpha t_0$ is valid in the regime when $V = \mathcal{O}(\alpha)$ and it gives access to the relaxation toward thermal equilibrium up to a temperature difference $T^+ - T^- = \mathcal{O}(\alpha)$. For the sake of technical completeness (rather that physical relevance, since the above first-order analysis is enough to get the observable, meaningful behavior), let us mention that the perturbation analysis can be carried over at higher orders; using further rescaled times $t_2 = \alpha^2 t_0, \ldots, t_n = \alpha^n t_0$, it would allow us to control the evolution up to a temperature difference $|T^+ - T^-| = \mathcal{O}(\alpha^n)$; however, one could expect that the factorization condition does not hold at higher orders.

## Numerical Simulations

As we have seen, the results were established under the condition that $m/M$ is a small parameter. Moreover for finite systems $(L < \infty, M < \infty)$, it was assumed that before collisions and to first order in $m/M$, the factorization and the average assumptions are satisfied. The numerical simulations are thus essential to check the validity of these assumptions, to determine the range of acceptable values $m/M$ for the perturbation expansion, to investigate the thermodynamic limit, and to guide the intuition.

In all simulation, we have taken $k_B = 1, m = 1$, $T^- = 1$ and usually $T^+ = 10$. For $L$ finite, we have taken $L = 60, X_0 = 10, A = 10^5$, and $N^+ = N^- = N/2$, that is, $p^- = R(M/A)(1/10)$ and $p^+ = 2p^-$. The number of particles $N$ was varied from a few hundreds to one or several millions; the mass $M$ of the piston from 1 to $10^5$. We give below some of the results which have been obtained for $L = \infty$ (**Figures 2 and 3**)

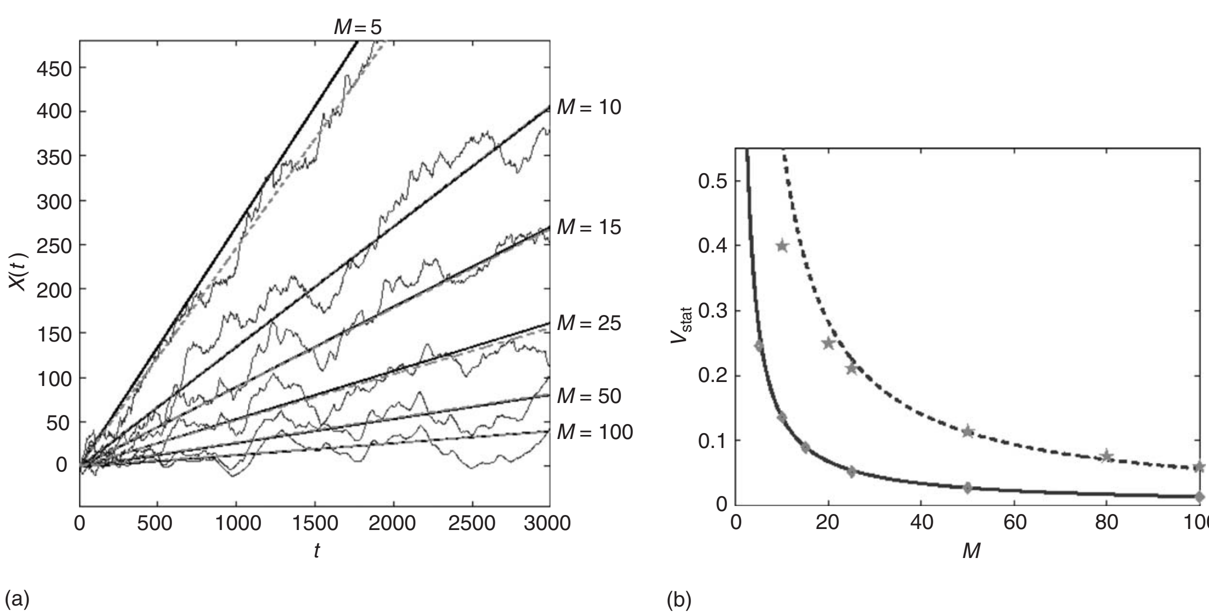

**Figure 2** Evolution of the piston for $L = \infty$, and $p^- = p^+ = 1$ as observed in simulations (stochastic line in (a), dots in (b)) compared with prediction: (a) position $X(t)$ for $T^+ = 10$; and (b) stationary velocity for $T^+ = 10$ (continuous line) and $T^+ = 100$ (dotted line), as a function of $M$.

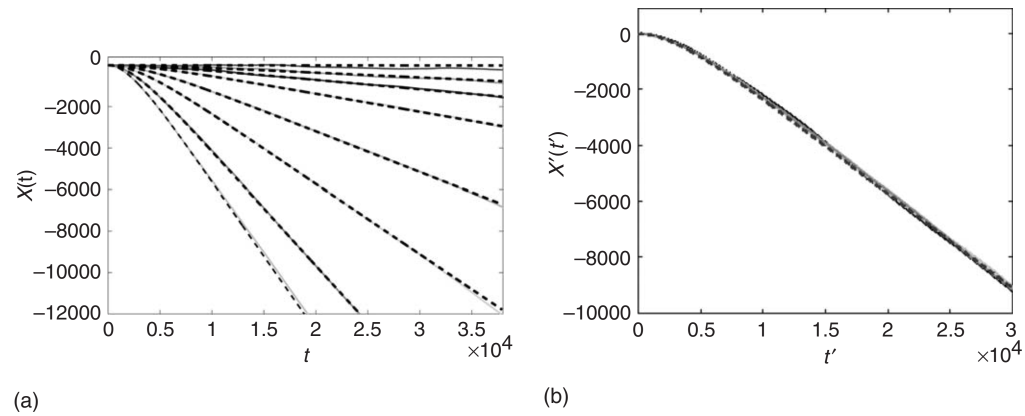

**Figure 3** Evolution of the piston for $L=\infty, M=10^4$, and $p^+ \neq p^-$ as observed in simulations (continuous line) compared with predictions (dotted line): (a) $p^-=1, p^+=p^-+\Delta p$, from top to bottom $\Delta p/p^-=0.05, 0.1, 0.2, 1, 2, 3$; and (b) $p^-=\zeta,\ p^+=2\zeta$, $\Delta p/p^-=1; X'=\zeta X, t'=\zeta t,\ \zeta=10^{-3}, 10^{-2}, 10^{-1}, 1, 10, 10^2, 10^3, 10^4$.

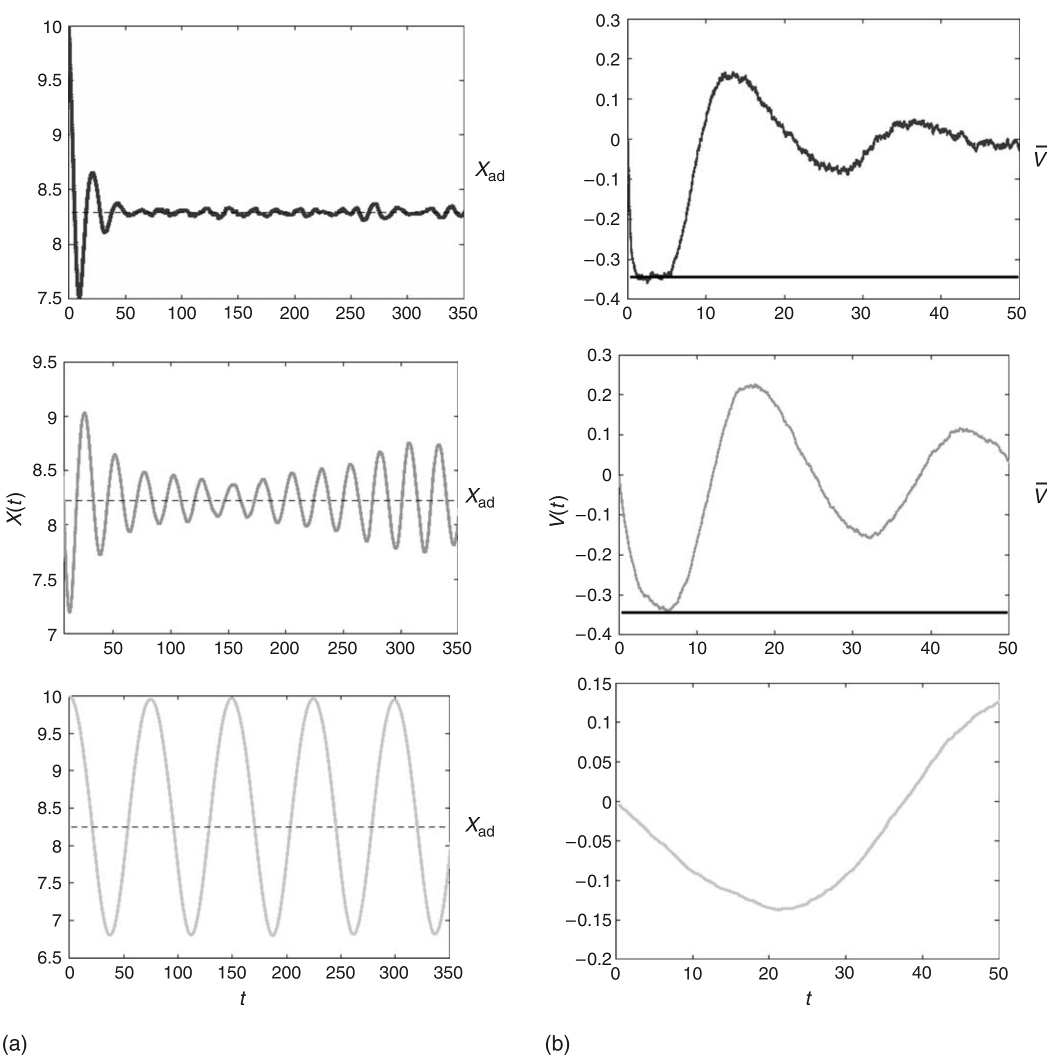

**Figure 4** "Deterministic" evolution toward mechanical equilibrium for $L<\infty, M=10^5$: (a) position $X(t)$; one finds $X_{\rm ad}^{\rm sim}=8.3$ whereas $X_{\rm ad}^{\rm th}=8.42$ and (b) velocity $V(t)$; one finds $\bar{V}^{\rm sim}=-0.343$ whereas $\bar{V}^{\rm th}=-0.3433$. From top to bottom: $R=12$: strong damping, independent of $R$ and $M$ for $R>4$ and $M>10^3$. $R=2$: critical damping. $R=0.1$: weak damping; damping coefficient increases with $R$ and $\omega_0 \sim \sqrt{R}$ for $R<1$ but is independent of $M$ for $M>10^3$.

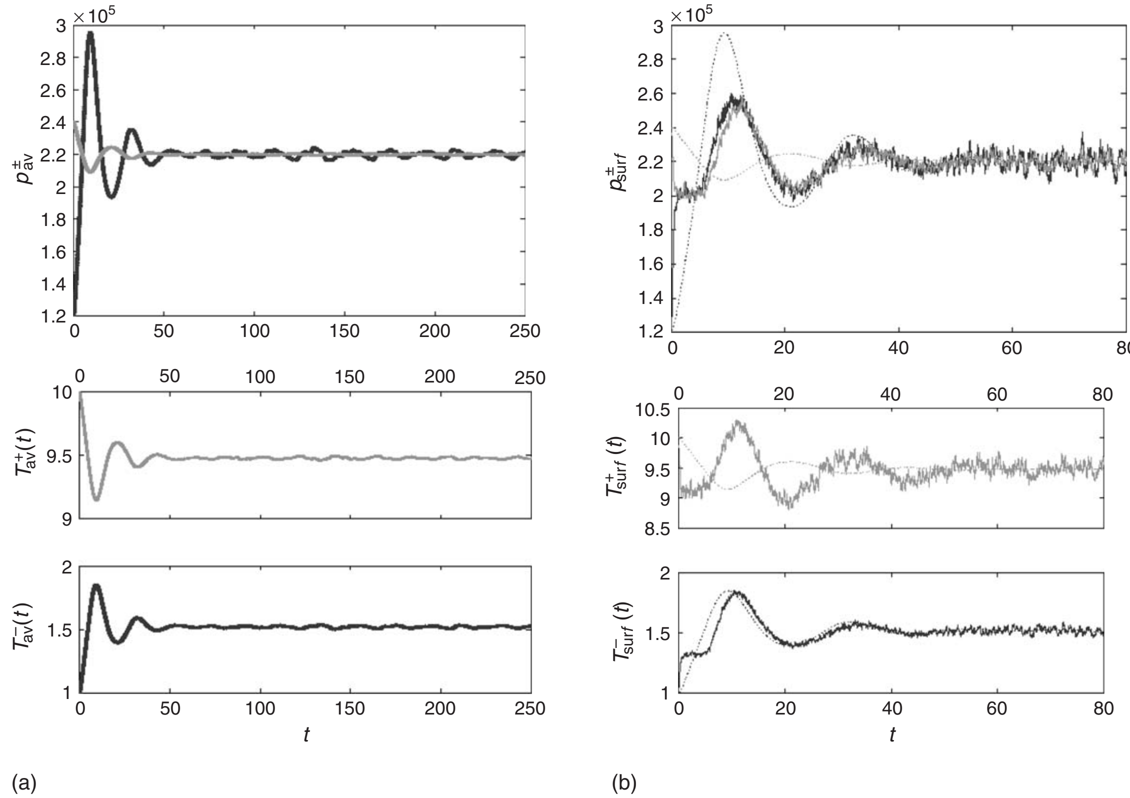

**Figure 5** Same conditions as **Figure 4**, $R = 12$: (a) average pressure and temperature in the fluid: $p^{\pm}_{\text{av}}(t) = 2E^{\pm}n^{\pm}/N^{\pm}$, $T^{\pm}_{\text{av}} = E^{\pm}/N^{\pm}k_B$ and (b) pressure and temperature at the surface of the piston. Prediction: $T^{-}_{\text{ad}} = 1.54$, $T^{+}_{\text{ad}} = 9.46$, $p^{-}_{\text{ad}} = p^{+}_{\text{ad}} = 2.2$. Simulations: $T^{-}_{\text{ad}} = 1.52$, $T^{+}_{\text{ad}} = 9.48$, $p^{-}_{\text{ad}} = p^{+}_{\text{ad}} = 2.2$.

and for $L < \infty$ approach to mechanical equilibrium (Figures 4–6) and to thermal equilibrium (Figures 7 and 8).

## Conclusions and Open Problems

In this article, the adiabatic piston has been investigated to first order in the small parameter $m/M$, but no attempt has been made to control the remainder terms. For an infinite cylinder, no other assumptions were necessary and the numerical simulations (Figures 2 and 3) are in perfect agreement with the theoretical prediction in particular for the stationary velocity $V_{\text{stat}}$, the friction coefficient $\lambda(V)$, and the relaxation time $\tau$.

For a finite cylinder ($L < \infty$) and in the thermodynamic limit ($M = \infty$), we were forced to introduce the average assumption to obtain a set of autonomous equations. As we have seen when initially $p^- \neq p^+$, this limiting case also describes the evolution to lowest order during the first two stages characterized by a time of the order $t_1 = L\sqrt{m/k_B T}$, where the evolution is adiabatic and deterministic. In the first stage, that is, before the shock wave bounces back on the piston, the simulations confirm the theoretical predictions. In particular, they show that if $R > 4$, the piston will be able to reach and maintain for some time the velocity $V_{\text{stat}}$, whereas this will not be the case for $R < 1$ (Figure 4b). In the second stage of the evolution, the simulations (Figure 4) exhibit damped oscillations toward mechanical equilibrium which are in very good agreement with the predictions for the final state $(X_{\text{ad}}, T^{\pm}_{\text{ad}})$, the frequency of oscillations and the existence of weak and strong damping depending on $R < 1$ or $R > 4$. Moreover, the general behavior of the evolution observed in the simulations as a function of the parameters was as predicted. However, the damping coefficient of these oscillations is wrong by one or several orders of magnitude. To understand this discrepancy, we note that using the average assumption we have related the damping to the friction coefficient. However, the simulations clearly show that those two dissipative effects have totally different origins. Indeed, as one can see with $L = \infty$, friction is associated with the fact that the density of the gas in front and in the back of the piston is not the same as in the bulk, and this generates a shock wave that propagates in the fluid. For finite $L$, when $R > 4$, the stationary velocity $V_{\text{stat}}$ is reached and the effect of friction is

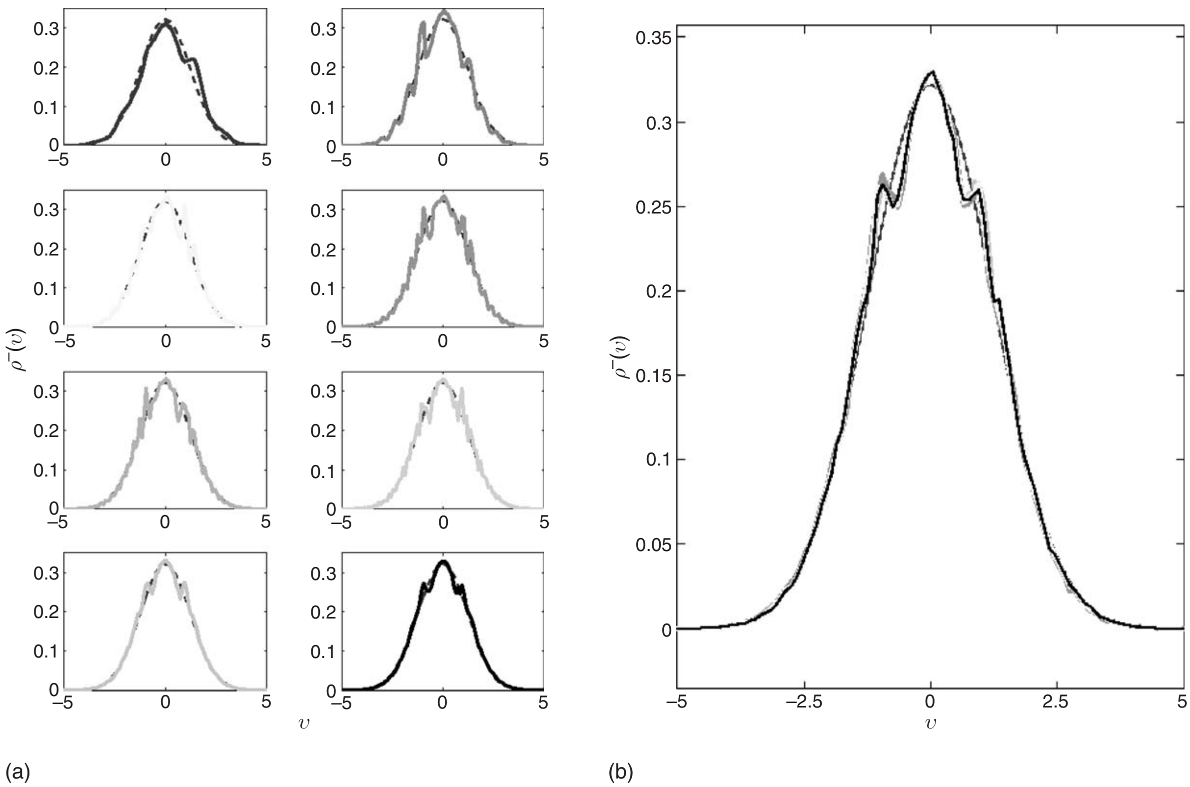

**Figure 6** Velocity distribution in the left compartment. Same conditions as **Figure 4**, $R = 12$. Dotted line corresponds to Maxwellian with $T^- = 1.52$: (a) $t = 12, 24, 36, 48, 60, 92, 144, 240$ from top to bottom and (b) $t = 276 - 460$.

to transfer in this first stage more and more energy to the fluid on one side and vice versa on the other side. However, to stop the piston and reverse its motion, only a certain amount of the transferred energy is necessary and the rest remains as dissipated energy in the fluid leading to a strong damping. On the other hand, for $R < 1$, the value $V_{\text{stat}}$ is never reached and all the energy transferred is necessary to revert the motion. In this case very little dissipation is involved and the damping will be very small. This indicates that the mechanism responsible for damping is associated with shock waves bouncing back and forth and the average assumption, which corresponds to a homogeneity condition throughout the gas, cannot describe the situation. In fact, the simulations (**Figure 5b**) indicate that the average assumption does

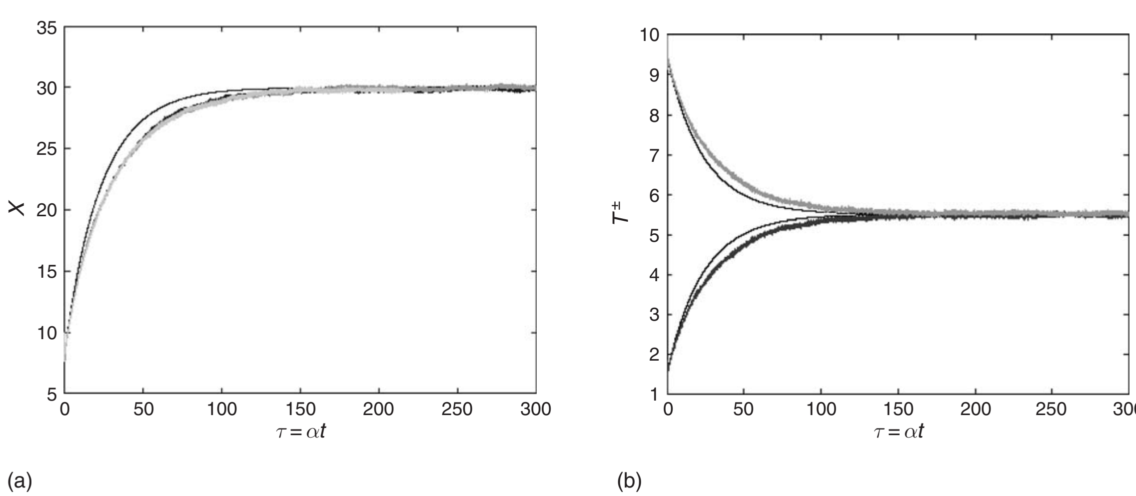

**Figure 7** Approach to thermal equilibrium, $N^{\pm} = 3 \times 10^4$. The smooth curves correspond to the predictions, the stochastic curves to simulations: (a) position $X(\tau)$, $\tau = \alpha t$, no visible difference for $M = 100, 200, 1000$ and (b) average temperatures $T^{\pm}(\tau)$, $\tau = \alpha t$, $M = 200$.

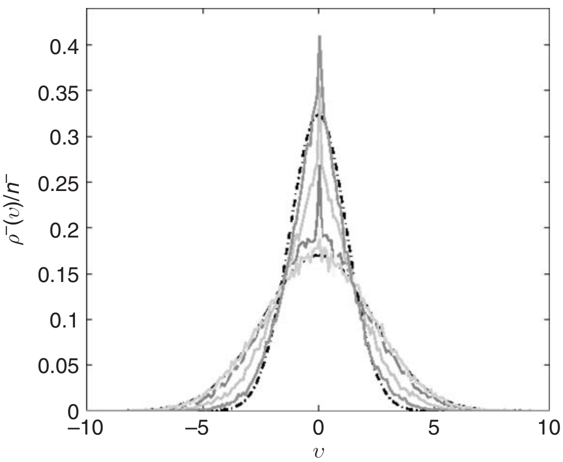
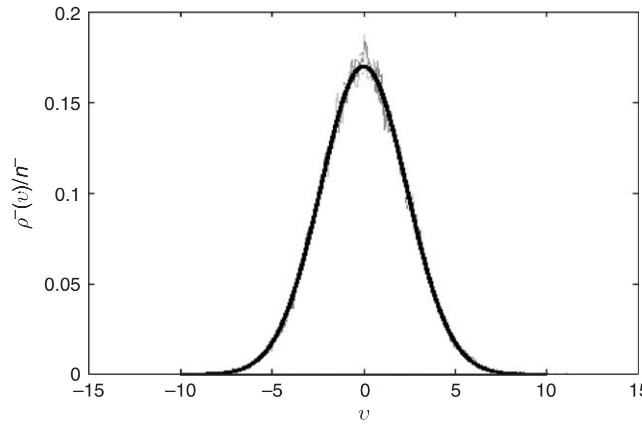


(a)



(b)

Velocity distribution function on the left for $M = 200$, $N^{\pm} = 5 \times 10^4$. (a) $\tau = \alpha\ t = 2, 4, 14, 48, 92, 144$ and (b) approach to Maxwellian distribution for $\tau > 445$.

not hold in this second stage. In conclusion, one is forced to admit that to describe correctly the adiabatic evolution, it is necessary to study the coupling between the motion of the piston and the hydrodynamic equations of the gas. Preliminary investigations have been initiated, but this is still one of the major open problems. Another problem would be to study the evolution in the case of interacting particles. However, investigations with hard disks suggest that no new effects should appear. To investigate adiabatic evolution, a simpler version of the adiabatic piston problem, without any controversy, has been introduced: this is the model of a standard piston with a constant force acting on it.

In the third stage, that is, the very slow approach to thermal equilibrium, another assumption was necessary, namely the factorization condition. The simulations (Figure 7) show a very good agreement with the prediction, and in particular the scaling property with $t' = t/M$ is perfectly verified. It appears that the small discrepancy between simulations and theoretical predictions could be due to the fact that, to compute explicitly the coefficients in the equations of motion, we have taken Maxwellian relations for the velocities of the gas particles, which is clearly not the case (Figure 8a).

The fourth stage of the evolution, that is, the approach to Maxwellian distributions (Figure 8b), is still another major open problem. Some preliminary studies have been conducted, where one investigates the stability and the evolution of the system when initially the two gases are in the same equilibrium state, but characterized by a distribution function which is not Maxwellian.

Finally, let us mention that the relation between the piston problem and the second law of thermodynamics is one more major problem. The question of entropy production out of equilibrium, and the validity of the second law, are still highly controversial. Again, preliminary results can be found in the literature. Among other things, this question has led to a model of heat conductivity gases, which reproduces the correct behavior (Gruber and Lesne 2005).

## Introduction

The anti-de Sitter/conformal field theory (AdS/CFT) correspondence is a conjectured equivalence between a quantum field theory in $d$ spacetime dimensions with conformal scaling symmetry and a quantum theory of gravity in $(d+1)$-dimensional anti-de Sitter space. The most promising approaches to quantizing gravity involve superstring theories, which are most easily defined in 10 spacetime dimensions, or $M$-theory which is defined in 11 spacetime dimensions. Hence, the AdS/CFT correspondences based on superstrings typically involve backgrounds of the form $AdS_{d+1} \times Y_{9-d}$ while those based on $M$-theory involve backgrounds of the form $AdS_{d+1} \times Y_{10-d}$, where $Y$ are compact spaces.

The examples of the AdS/CFT correspondence discussed in this article are dualities between (super)conformal nonabelian gauge theories and superstrings on $AdS_5 \times Y_5$, where $Y_5$ is a five-dimensional Einstein space (i.e., a space whose Ricci tensor is proportional to the metric, $R_{ij} = 4g_{ij}$). In particular, the most basic (and maximally supersymmetric) such duality relates $\mathcal{N} = 4$ SU($N$) super Yang–Mills (SYM) and type IIB superstring in the curved background $AdS_5 \times S^5$.

There exist special limits where this duality is more tractable than in the general case. If we take the large-$N$ limit while keeping the 't Hooft coupling $\lambda = g_{YM}^2 N$ fixed ($g_{YM}$ is the Yang–Mills coupling strength), then each Feynman graph of the gauge theory carries a topological factor $N^\chi$, where $\chi$ is the Euler characteristic of the graph. The graphs of spherical topology (often called "planar"), to be identified with string tree diagrams, are weighted by $N^2$; the graphs of toroidal topology, to be identified with string one-loop diagrams, by $N^0$, etc. This counting corresponds to the closed-string coupling constant of order $N^{-1}$. Thus, in the large-$N$ limit the gauge theory becomes "planar," and the dual string theory becomes classical. For small $g_{YM}^2 N$, the gauge theory can be studied perturbatively; in this regime the dual string theory has not been very useful because the background becomes highly curved. The real power of the AdS/CFT duality, which already has made it a very useful tool, lies in the fact that, when the gauge theory becomes strongly coupled, the curvature in the dual description becomes small; therefore, classical supergravity provides a systematic starting point for approximating the string theory.

There is a strong motivation for an improved understanding of dualities of this type. In one direction, generalizations of this duality provide the tantalizing hope of a better understanding of quantum chromodynamics (QCD); QCD is a nonabelian gauge theory that describes the strong interactions of mesons, baryons, and glueballs, and has a conformal symmetry which is broken by quantum effects. In the other direction, AdS/CFT suggests that quantum gravity may be understandable as a gauge theory. Understanding the confinement of quarks and gluons that takes place in low-energy QCD and quantizing gravity are well acknowledged to be two of the most important outstanding problems of theoretical physics.

## Some Geometrical Preliminaries

The $d$-dimensional sphere of radius $L$, $S^d$, may be defined by a constraint

$$\sum_{i=1}^{d+1} (X^i)^2 = L^2 \qquad [1]$$

on $d+1$ real coordinates $X^i$. It is a positively curved maximally symmetric space with symmetry group SO$(d+1)$. We will denote the round metric on $S^d$ of unit radius by $d\Omega_d^2$.

The $d$-dimensional anti-de Sitter space, $AdS_d$, may be defined by a constraint

$$(X^0)^2 + (X^d)^2 - \sum_{i=1}^{d-1}(X^i)^2 = L^2 \qquad [2]$$

This constraint shows that the symmetry group of $AdS_d$ is $SO(2, d-1)$. $AdS_d$ is a negatively curved maximally symmetric space, that is, its curvature tensor is related to the metric by

$$R_{abcd} = -\frac{1}{L^2}[g_{ac}g_{bd} - g_{ad}g_{bc}] \qquad [3]$$

Its metric may be written as

$$ds^2_{AdS} = L^2\left(-(y^2+1)dt^2 + \frac{dy^2}{y^2+1} + y^2\, d\Omega^2_{d-2}\right) \qquad [4]$$

where the radial coordinate $y \in [0, \infty)$, and $t$ is defined on a circle of length $2\pi$. This space has closed timelike curves; to eliminate them, we will work with the universal covering space where $t \in (-\infty, \infty)$. The boundary of $AdS_d$, which plays an important role in the AdS/CFT correspondence, is located at infinite $y$. There exists a subspace of $AdS_d$ called the Poincaré wedge, with the metric

$$ds^2 = \frac{L^2}{z^2}\left(dz^2 - (dx^0)^2 + \sum_{i=1}^{d-2}(dx^i)^2\right) \qquad [5]$$

where $z \in [0, \infty)$.

A Euclidean continuation of $AdS_d$ is the Lobachevsky space (hyperboloid), $\boldsymbol{L}_d$. It is obtained by reversing the sign of $(X^d)^2, dt^2$, and $(dx^0)^2$ in [2], [4], and [5], respectively. After this Euclidean continuation, the metrics [4] and [5] become equivalent; both of them cover the entire $\boldsymbol{L}_d$. Another equivalent way of writing the metric is

$$ds^2_L = L^2\left(d\rho^2 + \sinh^2\rho\, d\Omega^2_{d-1}\right) \qquad [6]$$

which shows that the boundary at infinite $\rho$ has the topology of $S^{d-1}$. In terms of the Euclideanized metric [5], the boundary consists of the $\boldsymbol{R}^{d-1}$ at $z = 0$, and a single point at $z = \infty$.

## The Geometry of Dirichlet Branes

Our path toward formulating the $AdS_5/CFT_4$ correspondence requires introduction of Dirichlet branes, or D-branes for short. They are soliton-like "membranes" of various internal dimensionalities contained in type II superstring theories. A Dirichlet $p$-brane (or D$p$ brane) is a $(p+1)$-dimensional hyperplane in $(9+1)$-dimensional spacetime where strings are allowed to end. A D-brane is much like a topological defect: upon touching a D-brane, a closed string can open up and turn into an open string whose ends are free to move along the D-brane. For the endpoints of such a string the $p+1$ longitudinal coordinates satisfy the conventional free (Neumann) boundary conditions, while the $9-p$ coordinates transverse to the D$p$ brane have the fixed (Dirichlet) boundary conditions, hence the origin of the term "Dirichlet brane." The D$p$ brane preserves half of the bulk supersymmetries and carries an elementary unit of charge with respect to the $(p+1)$-form gauge potential from the Ramond–Ramond (RR) sector of type II superstring.

For this article, the most important property of D-branes is that they realize gauge theories on their world volume. The massless spectrum of open strings living on a D$p$ brane is that of a maximally supersymmetric U(1) gauge theory in $p+1$ dimensions. The $9-p$ massless scalar fields present in this supermultiplet are the expected Goldstone modes associated with the transverse oscillations of the D$p$ brane, while the photons and fermions provide the unique supersymmetric completion. If we consider $N$ parallel D-branes, then there are $N^2$ different species of open strings because they can begin and end on any of the D-branes. $N^2$ is the dimension of the adjoint representation of U($N$), and indeed we find the maximally supersymmetric U($N$) gauge theory in this setting.

The relative separations of the D$p$ branes in the $9-p$ transverse dimensions are determined by the expectation values of the scalar fields. We will be interested in the case where all scalar expectation values vanish, so that the $N$ D$p$ branes are stacked on top of each other. If $N$ is large, then this stack is a heavy object embedded into a theory of closed strings which contains gravity. Naturally, this macroscopic object will curve space: it may be described by some classical metric and other background fields including the RR $(p+2)$-form field strength. Thus, we have two very different descriptions of the stack of D$p$ branes: one in terms of the U($N$) supersymmetric gauge theory on its world volume, and the other in terms of the classical RR charged $p$-brane background of the type II closed superstring theory. The relation between these two descriptions is at the heart of the connections between gauge fields and strings that are the subject of this article.

### Coincident D3 Branes

Gauge theories in $3+1$ dimensions play an important role in physics, and as explained above, parallel D3 branes realize a $(3+1)$-dimensional U($N$) SYM

theory. Let us compare a stack of D3 branes with the RR-charged black 3-brane classical solution where the metric assumes the form

$$\begin{aligned} ds^2 =& H^{-1/2}(r)\left[-f(r)(dx^0)^2 + (dx^i)^2\right] \\ &+ H^{1/2}(r)\left[f^{-1}(r)dr^2 + r^2\, d\Omega_5{}^2\right] \end{aligned} \qquad [7]$$

where $i = 1, 2, 3$ and

$$H(r) = 1 + \frac{L^4}{r^4}, \qquad f(r) = 1 - \frac{r_0{}^4}{r^4}$$

The solution also contains an RR self-dual 5-form field strength

$$\begin{aligned} F =& dx^0 \wedge dx^1 \wedge dx^2 \wedge dx^3 \wedge d(H^{-1}) \\ &+ 4L^4 \operatorname{vol}(S^5) \end{aligned} \qquad [8]$$

so that the Einstein equation of type IIB supergravity, $R_{\mu\nu} = F_{\mu\alpha\beta\gamma\delta}F_\nu{}^{\alpha\beta\gamma\delta}/96$, is satisfied.

In the extremal limit $r_0 \to 0$, the 3-brane metric becomes

$$\begin{aligned} ds^2 =& \left(1 + \frac{L^4}{r^4}\right)^{-1/2}\left(-(dx^0)^2 + (dx^i)^2\right) \\ &+ \left(1 + \frac{L^4}{r^4}\right)^{1/2}(dr^2 + r^2\, d\Omega_5^2) \end{aligned} \qquad [9]$$

Just like the stack of parallel, ground-state D3 branes, the extremal solution preserves 16 of the 32 supersymmetries present in the type IIB theory. Introducing $z = L^2/r$, one notes that the limiting form of [9] as $r \to 0$ factorizes into the direct product of two smooth spaces, the Poincaré wedge [5] of $AdS_5$, and $S^5$, with equal radii of curvature $L$. The 3-brane geometry may thus be viewed as a semi-infinite throat of radius $L$ which, for $r \gg L$, opens up into flat $(9+1)$-dimensional space. Thus, for $L$ much larger than the string length scale, $\sqrt{\alpha'}$, the entire 3-brane geometry has small curvatures everywhere and is appropriately described by the supergravity approximation to type IIB string theory.

The relation between $L$ and $\sqrt{\alpha'}$ may be found by equating the gravitational tension of the extremal 3-brane classical solution to $N$ times the tension of a single D3 brane:

$$\frac{2}{\kappa^2} L^4 \operatorname{vol}(S^5) = N\frac{\sqrt{\pi}}{\kappa} \qquad [10]$$

where $\operatorname{vol}(S^5) = \pi^3$ is the volume of a unit 5-sphere, and $\kappa = \sqrt{8\pi G}$ is the ten-dimensional gravitational constant. It follows that

$$L^4 = \frac{\kappa}{2\pi^{5/2}} N = g_{YM}^2 N\alpha'^2 \qquad [11]$$

where we used the standard relations $\kappa = 8\pi^{7/2} g_{st}\alpha'^2$ and $g_{YM}^2 = 4\pi g_{st}$ [10]. Thus, the size of the throat in string units is $\lambda^{1/4}$. This remarkable emergence of the 't Hooft coupling from gravitational considerations is at the heart of the success of the AdS/CFT correspondence. Moreover, the requirement $L \gg \sqrt{\alpha'}$ translates into $\lambda \gg 1$: the gravitational approach is valid when the 't Hooft coupling is very strong and the perturbative field-theoretic methods are not applicable.

### Example: Thermal Gauge Theory from Near-Extremal D3 Branes

An important black hole observable is the Bekenstein–Hawking (BH) entropy, which is proportional to the area of the event horizon. For the 3-brane solution [7], the horizon is located at $r = r_0$. For $r_0 > 0$ the 3-brane carries some excess energy $E$ above its extremal value, and the BH entropy is also nonvanishing. The Hawking temperature is then defined by $T^{-1} = \partial S_{BH}/\partial E$.

Setting $r_0 \ll L$ in [9], we obtain a near-extremal 3-brane geometry, whose Hawking temperature is found to be $T = r_0/(\pi L^2)$. The eight-dimensional "area" of the horizon is

$$A_h = (r_0/L)^3 V_3 L^5 \operatorname{vol}(S^5) = \pi^6 L^8 T^3 V_3 \qquad [12]$$

where $V_3$ is the spatial volume of the D3 brane (i.e., the volume of the $x^1$, $x^2$, $x^3$ coordinates). Therefore, the BH entropy is

$$S_{BH} = \frac{2\pi A_h}{\kappa^2} = \frac{\pi^2}{2} N^2 V_3 T^3 \qquad [13]$$

This gravitational entropy of a near-extremal 3-brane of Hawking temperature $T$ is to be identified with the entropy of $\mathcal{N} = 4$ supersymmetric U($N$) gauge theory (which lives on $N$ coincident D3 branes) heated up to the same temperature.

The entropy of a free U($N$) $\mathcal{N} = 4$ supermultiplet – which consists of the gauge field, $6N^2$ massless scalars, and $4N^2$ Weyl fermions – can be calculated using the standard statistical mechanics of a massless gas (the blackbody problem), and the answer is

$$S_0 = \frac{2\pi^2}{3} N^2 V_3 T^3 \qquad [14]$$

It is remarkable that the 3-brane geometry captures the $T^3$ scaling characteristic of a conformal field theory (CFT) (in a CFT this scaling is guaranteed by the extensivity of the entropy and the absence of dimensionful parameters). Also, the $N^2$ scaling indicates the presence of $O(N^2)$ unconfined degrees

of freedom, which is exactly what we expect in the $\mathcal{N}=4$ supersymmetric U($N$) gauge theory. But what is the explanation of the relative factor of 3/4 between $S_{\text{BH}}$ and $S_0$? In fact, this factor is not a contradiction but rather a prediction about the strongly coupled $\mathcal{N}=4$ SYM theory at finite temperature. As we argued above, the supergravity calculation of the BH entropy, [13], is relevant to the $\lambda \to \infty$ limit of the $\mathcal{N}=4$ SU($N$) gauge theory, while the free-field calculation, [14], applies to the $\lambda \to 0$ limit. Thus, the relative factor of 3/4 is not a discrepancy: it relates two different limits of the theory. Indeed, on general field-theoretic grounds, we expect that in the 't Hooft large-$N$ limit, the entropy is given by

$$S = \frac{2\pi^2}{3} N^2 f(\lambda) V_3 T^3 \qquad [15]$$

The function $f$ is certainly not constant: perturbative calculations valid for small $\lambda = g_{\text{YM}}^2 N$ give

$$f(\lambda) = 1 - \frac{3}{2\pi^2}\lambda + \frac{3+\sqrt{2}}{\pi^3}\lambda^{3/2} + \cdots \qquad [16]$$

Thus, the BH entropy in supergravity, [13], is translated into the prediction that

$$\lim_{\lambda\to\infty} f(\lambda) = \frac{3}{4} \qquad [17]$$

## The Essentials of the AdS/CFT Correspondence

The AdS/CFT correspondence asserts a detailed map between the physics of type IIB string theory in the throat of the classical 3-brane geometry, that is, the region $r \ll L$, and the gauge theory living on a stack of D3 branes. As already noted, in this limit $r \ll L$, the extremal D3 brane geometry factors into a direct product of $\text{AdS}_5 \times S^5$. Moreover, the gauge theory on this stack of D3 branes is the maximally supersymmetric $\mathcal{N}=4$ SYM.

Since the horizon of the near-extremal 3-brane lies in the region $r \ll L$, the entropy calculation could have been carried out directly in the throat limit, where $H(r)$ is replaced by $L^4/r^4$. Another way to motivate the identification of the gauge theory with the throat is to think about the absorption of massless particles. In the D-brane description, a particle incident from asymptotic infinity is converted into an excitation of the stack of D-branes, that is, into an excitation of the gauge theory on the world volume. In the supergravity description, a particle incident from the asymptotic (large $r$) region tunnels into the $r \ll L$ region and produces an excitation of the throat. The fact that the two different descriptions of the absorption process give identical cross sections supports the identification of excitations of $\text{AdS}_5 \times S^5$ with the excited states of the $\mathcal{N}=4$ SYM theory.

Maldacena (1998) motivated this correspondence by thinking about the low-energy ($\alpha' \to 0$) limit of the string theory. On the D3 brane side, in this low-energy limit, the interaction between the D3 branes and the closed strings propagating in the bulk vanishes, leaving a pure $\mathcal{N}=4$ SYM theory on the D3 branes decoupled from type IIB superstrings in flat space. Around the classical 3-brane solutions, there are two types of low-energy excitations. The first type propagate in the bulk region, $r \gg L$, and have a cross section for absorption by the throat which vanishes as the cube of their energy. The second type are localized in the throat, $r \leq L$, and find it harder to tunnel into the asymptotically flat region as their energy is taken smaller. Thus, both the D3 branes and the classical 3-brane solution have two decoupled components in the low-energy limit, and in both cases, one of these components is type IIB superstrings in flat space. Maldacena conjectured an equivalence between the other two components.

Immediate support for this identification comes from symmetry considerations. The isometry group of $\text{AdS}_5$ is SO(2, 4), and this is also the conformal group in $3+1$ dimensions. In addition, we have the isometries of $S^5$ which form $\text{SU}(4) \sim \text{SO}(6)$. This group is identical to the R-symmetry of the $\mathcal{N}=4$ SYM theory. After including the fermionic generators required by supersymmetry, the full isometry supergroup of the $\text{AdS}_5 \times S^5$ background is SU(2, 2|4), which is identical to the $\mathcal{N}=4$ superconformal symmetry. We will see that, in theories with reduced supersymmetry, the $S^5$ factor is replaced by other compact Einstein spaces $Y_5$, but $\text{AdS}_5$ is the "universal" factor present in the dual description of any large-$N$ CFT and makes the SO(2, 4) conformal symmetry a geometric one.

The correspondence extends beyond the supergravity limit, and we must think of $\text{AdS}_5 \times Y_5$ as a background of string theory. Indeed, type IIB strings are dual to the electric flux lines in the gauge theory, providing a string-theoretic setup for calculating correlation functions of Wilson loops. Furthermore, if $N \to \infty$ while $g_{\text{YM}}^2 N$ is held fixed and finite, then there are string scale corrections to the supergravity limit (Maldacena 1998, Gubser *et al.* 1998, Witten 1998) which proceed in powers of $\alpha'/L^2 = (g_{\text{YM}}^2 N)^{-1/2}$. For finite $N$, there are also

string loop corrections in powers of $\kappa^2/L^8 \sim N^{-2}$. As expected, with $N \to \infty$ we can take the classical limit of the string theory on $AdS_5 \times Y_5$. However, in order to understand the large-$N$ gauge theory with finite 't Hooft coupling, we should think of $AdS_5 \times Y_5$ as the target space of a two-dimensional sigma model describing the classical string physics.

### Correlation Functions and the Bulk/Boundary Correspondence

A basic premise of the AdS/CFT correspondence is the existence of a one-to-one map between gauge-invariant operators in the CFT and fields (or extended objects) in AdS. Gubser *et al.* (1998) and Witten (1998) formulated precise methods for calculating correlation functions of various operators in a CFT using its dual formulation. A physical motivation for these methods comes from earlier calculations of absorption by 3-branes. When a wave is absorbed, it tunnels from asymptotic infinity into the throat region, and then continues to propagate toward smaller $r$. Let us separate the 3-brane geometry into two regions: $r \gtrsim L$ and $r \lesssim L$. For $r \lesssim L$ the metric is approximately that of $AdS_5 \times S^5$, while for $r \gtrsim L$ it becomes very different and eventually approaches the flat metric. Signals coming in from large $r$ (small $z = L^2/r$) may be considered as disturbing the "boundary" of $AdS_5$ at $r \sim L$, and then propagating into the bulk of $AdS_5$. Discarding the $r \gtrsim L$ part of the 3-brane metric, the gauge theory correlation functions are related to the response of the string theory to boundary conditions at $r \sim L$. It is therefore natural to identify the generating functional of correlation functions in the gauge theory with the string theory path integral subject to the boundary conditions that $\phi(\boldsymbol{x}, z) = \phi_0(\boldsymbol{x})$ at $z = L$ (at $z = \infty$ all fluctuations are required to vanish). In calculating correlation functions in a CFT, we will carry out the standard Euclidean continuation; then on the string theory side, we will work with $L_5$, which is the Euclidean version of $AdS_5$.

More explicitly, we identify a gauge theory quantity $W$ with a string-theory quantity $Z_{\text{string}}$:

$$W[\phi_0(\boldsymbol{x})] = Z_{\text{string}}[\phi_0(\boldsymbol{x})] \qquad [18]$$

$W$ generates the connected Euclidean Green's functions of a gauge-theory operator $\mathcal{O}$,

$$W[\phi_0(\boldsymbol{x})] = \left\langle \exp \int d^4x \phi_0 \mathcal{O} \right\rangle \qquad [19]$$

$Z_{\text{string}}$ is the string theory path integral calculated as a functional of $\phi_0$, the boundary condition on the field $\phi$ related to $\mathcal{O}$ by the AdS/CFT duality. In the large-$N$ limit, the string theory becomes classical which implies

$$Z_{\text{string}} \sim e^{-I[\phi_0(\boldsymbol{x})]} \qquad [20]$$

where $I[\phi_0(\boldsymbol{x})]$ is the extremum of the classical string action calculated as a functional of $\phi_0$. If we are further interested in correlation functions at very large 't Hooft coupling, then the problem of extremizing the classical string action reduces to solving the equations of motion in type IIB supergravity whose form is known explicitly. A simple example of such a calculation is presented in the next subsection.

Our reasoning suggests that from the point of view of the metric [5], the boundary conditions are imposed not quite at $z = 0$, which is the true boundary of $\boldsymbol{L}_5$, but at some finite value $z = \epsilon$. It does not matter which value it is since the metric [5] is unchanged by an overall rescaling of the coordinates $(z, \boldsymbol{x})$; thus, such a rescaling can take $z = L$ into $z = \epsilon$ for any $\epsilon$. The physical meaning of this cutoff is that it acts as a UV regulator in the gauge theory. Indeed, the radial coordinate $z$ is to be considered as the effective energy scale of the gauge theory, and decreasing $z$ corresponds to increasing the energy. A safe method for performing calculations of correlation functions, therefore, is to keep the cutoff on the $z$-coordinate at intermediate stages and remove it only at the end.

### Two-Point Functions and Operator Dimensions

In the following, we present a brief discussion of two-point functions of scalar operators in $CFT_d$. The corresponding field in $\boldsymbol{L}_{d+1}$ is a scalar field of mass $m$ whose Euclidean action is proportional to

$$\frac{1}{2}\int d^d x \, dz \, z^{-d+1}\left[(\partial_z\phi)^2 + \sum_{a=1}^{d}(\partial_a\phi)^2 + \frac{m^2L^2}{z^2}\phi^2\right] \qquad [21]$$

In calculating correlation functions of vertex operators from the AdS/CFT correspondence, the first problem is to reconstruct an on-shell field in $\boldsymbol{L}_{d+1}$ from its boundary behavior. The near-boundary, that is, small $z$, behavior of the classical solution is

$$\begin{aligned}\phi(z, \boldsymbol{x}) \to {} & z^{d-\Delta}\left[\phi_0(\boldsymbol{x}) + O(z^2)\right] \\ & + z^{\Delta}\left[A(\boldsymbol{x}) + O(z^2)\right]\end{aligned} \qquad [22]$$

where $\Delta$ is one of the roots of

$$\Delta(\Delta - d) = m^2L^2 \qquad [23]$$

$\phi_0(\boldsymbol{x})$ is regarded as a "source" in [19] that couples to the dual gauge-invariant operator $\mathcal{O}$ of dimension $\Delta$, while $A(\boldsymbol{x})$ is related to the expectation value,

$$A(\boldsymbol{x}) = \frac{1}{2\Delta - d}\langle \mathcal{O}(\boldsymbol{x})\rangle \qquad [24]$$

It is possible to regularize the Euclidean action to obtain the following value as a functional of the source:

$$I[\phi_0(\boldsymbol{x})] = -(\Delta - (d/2))\pi^{-d/2}\frac{\Gamma(\Delta)}{\Gamma(\Delta - (d/2))} \times \int \mathrm{d}^d\boldsymbol{x} \int \mathrm{d}^d\boldsymbol{x}' \frac{\phi_0(\boldsymbol{x})\phi_0(\boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|^{2\Delta}} \qquad [25]$$

Varying twice with respect to $\phi_0$, we find that the two-point function of the corresponding operator is

$$\langle \mathcal{O}(\boldsymbol{x})\mathcal{O}(\boldsymbol{x}')\rangle = \frac{(2\Delta - d)\Gamma(\Delta)}{\pi^{d/2}\Gamma(\Delta - (d/2))}\frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|^{2\Delta}} \qquad [26]$$

Which of the two roots, $\Delta_+$ or $\Delta_-$, of [23]

$$\Delta_\pm = \frac{d}{2} \pm \sqrt{\frac{d^2}{4} + m^2L^2} \qquad [27]$$

should we choose for the operator dimension? For positive $m^2$, $\Delta_+$ is certainly the right choice: here the other root, $\Delta_-$, is negative. However, it turns out that for

$$-\frac{d^2}{4} < m^2L^2 < -\frac{d^2}{4} + 1 \qquad [28]$$

both roots of [23] may be chosen. Thus, there are two possible CFTs corresponding to the same classical AdS action: in one of them the corresponding operator has dimension $\Delta_+$, while in the other the dimension is $\Delta_-$. We note that $\Delta_-$ is bounded from below by $(d-2)/2$, which is precisely the unitarity bound on dimensions of scalar operators in $d$-dimensional field theory! Thus, the ability to choose dimension $\Delta_-$ is crucial for consistency of the AdS/CFT duality.

Whether string theory on $\mathrm{AdS}_5 \times Y_5$ contains fields with $m^2$ in the range [28] depends on $Y_5$. The example discussed in the next section, $Y_5 = T^{1,1}$, turns out to contain such fields, and the possibility of having dimension $\Delta_-$, [27], is crucial for consistency of the AdS/CFT duality in that case. However, for $Y_5 = \boldsymbol{S}^5$, which is dual to the $\mathcal{N}=4$ large-$N$ SYM theory, there are no such fields and all scalar dimensions are given by [27].

The operators in the $\mathcal{N}=4$ large-$N$ SYM theory naturally break up into two classes: those that correspond to the Kaluza–Klein states of supergravity and those that correspond to massive string states. Since the radius of the $S^5$ is $L$, the masses of the Kaluza–Klein states are proportional to $1/L$. Thus, the dimensions of the corresponding operators are independent of $L$ and therefore also of $\lambda$. On the gauge-theory side, this independence is explained by the fact that the supersymmetry protects the dimensions of certain operators from being renormalized: they are completely determined by the representation under the superconformal symmetry. All families of the Kaluza–Klein states, which correspond to such protected operators, were classified long ago. Correlation functions of such operators in the strong 't Hooft coupling limit may be obtained from the dependence of the supergravity action on the boundary values of corresponding Kaluza–Klein fields, as in [19]. A variety of explicit calculations have been performed for two-, three-, and even four-point functions. The four-point functions are particularly interesting because their dependence on operator positions is not determined by the conformal invariance.

On the other hand, the masses of string excitations are $m^2 = 4n/\alpha'$, where $n$ is an integer. For the corresponding operators the formula [27] predicts that the dimensions do depend on the 't Hooft coupling and, in fact, blow up for large $\lambda = g_{\mathrm{YM}}^2 N$ as $2\lambda^{1/4}\sqrt{n}$.

### Calculation of Wilson Loops

The Wilson loop operator of a nonabelian gauge theory

$$W(\mathcal{C}) = \mathrm{tr}\left[P\exp\left(\mathrm{i}\oint_{\mathcal{C}} A\right)\right] \qquad [29]$$

involves the path-ordered integral of the gauge connection $A$ along a contour $\mathcal{C}$. For $\mathcal{N}=4$ SYM, one typically uses a generalization of this loop operator which incorporates other fields in the $\mathcal{N}=4$ multiplet, the adjoint scalars and fermions. Using a rectangular contour, we can calculate the quark–antiquark potential from the expectation value $\langle W(\mathcal{C})\rangle$. One thinks of the quarks located a distance $L$ apart for a time $T$, yielding

$$\langle W\rangle \sim \mathrm{e}^{-TV(L)} \qquad [30]$$

where $V(L)$ is the potential.

According to Maldacena, and Rey and Yee, the AdS/CFT correspondence relates the Wilson loop expectation value to a sum over string world sheets ending on the boundary of $L_5(z=0)$ along the contour $\mathcal{C}$:

$$\langle W\rangle \sim \int \mathrm{e}^{-S} \qquad [31]$$

where $S$ is the action functional of the string world sheet. In the large 't Hooft coupling limit $\lambda \to \infty$, this path integral may be evaluated using a saddle-point approximation. The leading answer is $\sim e^{-S_0}$, where $S_0$ is the action for the classical solution, which is proportional to the minimal area of the string world sheet in $L_5$ subject to the boundary conditions. The area as currently defined is actually divergent, and to regularize it one must position the contour at $z = \epsilon$ (this is the same type of regulator as used in the definition of correlation functions).

Consider a circular Wilson loop of radius $a$. The action of the corresponding classical string world sheet is

$$S_0 = \sqrt{\lambda}\left(\frac{a}{\epsilon} - 1\right) \quad [32]$$

Subtracting the linearly divergent term, which is proportional to the length of the contour, one finds

$$\ln\langle W \rangle = \sqrt{\lambda} + O(\ln \lambda) \quad [33]$$

a result which has been duplicated in field theory by summing certain classes of rainbow Feynman diagrams in $\mathcal{N} = 4$ SYM. From these sums, one finds

$$\langle W \rangle_{\text{rainbow}} = \frac{2}{\sqrt{\lambda}} I_1\left(\sqrt{\lambda}\right) \quad [34]$$

where $I_1$ is a Bessel function. This formula is one of the few available proposals for extrapolation of an observable from small to large coupling. At large $\lambda$,

$$\langle W \rangle_{\text{rainbow}} \sim \sqrt{\frac{2}{\pi}} \frac{e^{\sqrt{\lambda}}}{\lambda^{3/4}} \quad [35]$$

in agreement with the geometric prediction.

The quark–antiquark potential is extracted from a rectangular Wilson loop of width $L$ and length $T$. After regularizing the divergent contribution to the energy, one finds the attractive potential

$$V(L) = -\frac{4\pi^2\sqrt{\lambda}}{\Gamma(1/4)^4 L} \quad [36]$$

The Coulombic $1/L$ dependence is required by the conformal invariance of the theory. The fact that the potential scales as the square root of the 't Hooft coupling indicates some screening of the charges at large coupling.

## Conformal Field Theories and Einstein Manifolds

Interesting generalizations of the duality between $AdS_5 \times S^5$ and $\mathcal{N} = 4$ SYM with less supersymmetry and more complicated gauge groups can be produced by placing D3 branes at the tip of a Ricci-flat six-dimensional cone $X$ (see Figure 1). The cone metric may be cast in the form

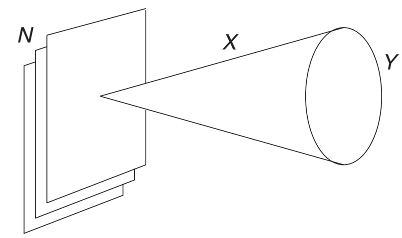

**Figure 1** D3 branes placed at the tip of a Ricci-flat cone $X$.

$$ds_X{}^2 = dr^2 + r^2\, ds_Y{}^2 \quad [37]$$

where $Y$ is the level surface of $X$. In particular, $Y$ is a positively curved Einstein manifold, that is, one for which $R_{ij} = 4g_{ij}$. In order to preserve the $\mathcal{N} = 1$ supersymmetry, $X$ must be a Calabi–Yau space; then $Y$ is defined to be Sasaki–Einstein.

The D3 branes appear as a point in $X$ and span the transverse Minkowski space $\mathbb{R}^{3,1}$. The ten-dimensional metric they produce assumes the form [9], but with the sphere metric $d\Omega_5{}^2$ replaced by the metric on $Y$, $ds_Y^2$. The equality of tensions [10] now requires that

$$L^4 = \frac{\sqrt{\pi}\kappa N}{2\,\text{vol}(Y)} = 4\pi g_s N \alpha'^2 \frac{\pi^3}{\text{vol}(Y)} \quad [38]$$

In the near-horizon limit, $r \to 0$, the geometry factors into $AdS_5 \times Y$. Because the D3 branes are located at a singularity, the gauge theory becomes much more complicated, typically involving a product of several SU($N$) factors coupled to matter in bifundamental representations, often described using a quiver diagram (see Figure 2 for an example).

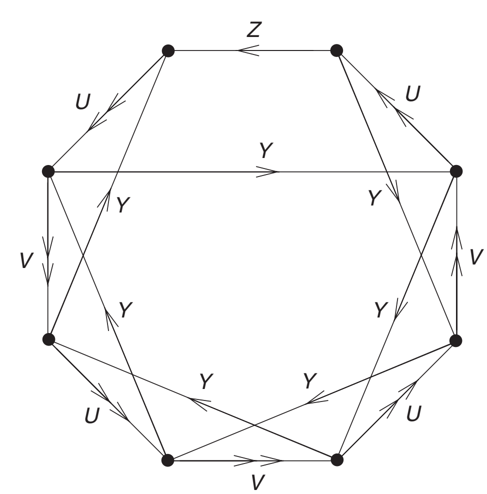

**Figure 2** The quiver for $Y^{4,3}$. Each node corresponds to an SU($N$) gauge group and each arrow to a bifundamental chiral superfield.

The simplest examples of $X$ are orbifolds $\mathbb{C}^3/\Gamma$, where $\Gamma$ is a discrete subgroup of SO(6). Indeed, if $\Gamma \subset \mathrm{SU}(3)$, then $\mathcal{N}=1$ supersymmetry is preserved. The level surface of such an $X$ is $Y = S^5/\Gamma$. In this case, the product structure of the gauge theory can be motivated by thinking about image stacks of D3 branes from the action of $\Gamma$.

The next simplest example of a Calabi–Yau cone $X$ is the conifold which may be described by the following equation in four complex variables:

$$\sum_{a=1}^{4} {z_a}^2 = 0 \qquad [39]$$

Since this equation is symmetric under an overall rescaling of the coordinates, this space is a cone. The level surface $Y$ of the conifold is a coset manifold $T^{1,1} = (\mathrm{SU}(2) \times \mathrm{SU}(2))/\mathrm{U}(1)$. This space has the $\mathrm{SO}(4) \sim \mathrm{SU}(2) \times \mathrm{SU}(2)$ symmetry which rotates the $z$'s, and also the U(1) R-symmetry under $z_a \to e^{i\theta} z_a$. The metric on $T^{1,1}$ is known explicitly; it assumes the form of an $S^1$ bundle over $S^2 \times S^2$.

The supersymmetric field theory on the D3 branes probing the conifold singularity is $\mathrm{SU}(N) \times \mathrm{SU}(N)$ gauge theory coupled to two chiral superfields, $A_i$, in the $(\boldsymbol{N}, \overline{\boldsymbol{N}})$ representation and two chiral superfields, $B_j$, in the $(\overline{\boldsymbol{N}}, \boldsymbol{N})$ representation. The $A$'s transform as a doublet under one of the global SU(2)'s, while the $B$'s transform as a doublet under the other SU(2). Cancelation of the anomaly in the U(1) R-symmetry requires that the $A$'s and the $B$'s each have R-charge 1/2. For consistency of the duality, it is necessary that we add an exactly marginal superpotential which preserves the $\mathrm{SU}(2) \times \mathrm{SU}(2) \times \mathrm{U}(1)_\mathrm{R}$ symmetry of the theory. Since a marginal superpotential has R-charge equal to 2 it must be quartic, and the symmetries fix it uniquely up to overall normalization:

$$W = \epsilon^{ij}\epsilon^{kl} \operatorname{tr} A_i B_k A_j B_l \qquad [40]$$

There are in fact infinite families of Calabi–Yau cones $X$, but there are two problems one faces in studying these generalized AdS/CFT correspondences. The first is geometric: the cones $X$ are not all well understood and only for relatively few do we have explicit metrics. However, it is often possible to calculate important quantities such as the vol($Y$) without knowing the metric. The second problem is gauge theoretic: although many techniques exist, there is no completely general procedure for constructing the gauge theory on a stack of D-branes at an arbitrary singularity.

Let us mention two important classes of Calabi–Yau cones $X$. The first class consists of cones over the so-called $Y^{p,q}$ Sasaki–Einstein spaces. Here, $p$ and $q$ are integers with $p \geq q$. Gauntlett *et al.* (2004) discovered metrics on all the $Y^{p,q}$, and the quiver gauge theories that live on the D-branes probing the singularity are now known. Making contact with the simpler examples discussed above, the $Y^{p,0}$ are orbifolds of $T^{1,1}$ while the $Y^{p,p}$ are orbifolds of $S^5$.

In the second class of cones $X$, a del Pezzo surface shrinks to zero size at the tip of the cone. A del Pezzo surface is an algebraic surface of complex dimension 2 with positive first Chern class. One simple del Pezzo surface is a complex projective space of dimension 2, $\mathbb{P}^2$, which gives rise to the $\mathcal{N}=1$ preserving $S^5/\mathbb{Z}_3$ orbifold. Another simple case is $\mathbb{P}^1 \times \mathbb{P}^1$, which leads to $T^{1,1}/\mathbb{Z}_2$. The remaining del Pezzos surfaces $B_k$ are $\mathbb{P}^2$ blown up at $k$ points, $1 \leq k \leq 8$. The cone where $B_1$ shrinks to zero size has level surface $Y^{2,1}$. Gauge theories for all the del Pezzos have been constructed. Except for the three del Pezzos just discussed, and possibly also for $B_6$, metrics on the cones over these del Pezzos are not known. Nevertheless, it is known that for $3 \leq k \leq 8$, the volume of the Sasaki–Einstein manifold $Y$ associated with $B_k$ is $\pi^3(9-k)/27$.

### The Central Charge

The central charge provides one of the most amazing ways to check the generalized AdS/CFT correspondences. The central charge $c$ and conformal anomaly $a$ can be defined as coefficients of certain curvature invariants in the trace of the stress energy tensor of the conformal gauge theory:

$$\langle T^\alpha_\alpha \rangle = -aE_4 - cI_4 \qquad [41]$$

(The curvature invariants $E_4$ and $I_4$ are quadratic in the Riemann tensor and vanish for Minkowski space.) As discussed above, correlators such as $\langle T_{\mu\nu} \rangle$ can be calculated from supergravity, and one finds

$$a = c = \frac{\pi^3 N^2}{4\,\mathrm{vol}(Y)} \qquad [42]$$

On the gauge-theory side of the correspondence, anomalies completely determine $a$ and $c$:

$$a = \tfrac{3}{32}(3 \operatorname{tr} R^3 - \operatorname{tr} R)$$
$$c = \tfrac{1}{32}(9 \operatorname{tr} R^3 - 5 \operatorname{tr} R) \qquad [43]$$

The trace notation implies a sum over the R-charges of all of the fermions in the gauge theory. (From the geometric knowledge that $a = c$, we can conclude that $\operatorname{tr} R = 0$.)

The R-charges can be determined using the principle of $a$-maximization. For a superconformal gauge theory, the R-charges of the fermions maximize $a$ subject to the constraints that the

Novikov–Shifman–Vainshtein–Zakharov (NSVZ) beta function of each gauge group vanishes and the R-charge of each superpotential term is 2.

For the $Y^{p,q}$ spaces mentioned above, one finds that

$$\mathrm{vol}(Y^{p,q}) = \frac{q^2\left(2p+\sqrt{4p^2-3q^2}\right)}{3p^2\left(3q^2-2p^2+p\sqrt{4p^2-3q^2}\right)}\pi^3 \qquad [44]$$

The gauge theory consists of $p-q$ fields $Z$, $p+q$ fields $Y$, $2p$ fields $U$, and $2q$ fields $V$. These fields all transform in the bifundamental representation of a pair of SU($N$) gauge groups (the quiver diagram for $Y^{4,3}$ is given in **Figure 2**). The NSVZ beta function and superpotential constraints determine the R-charges up to two free parameters $x$ and $y$. Let $x$ be the R-charge of $Z$ and $y$ the R-charge of $Y$. Then the $U$ have R-charge $1-(1/2)(x+y)$ and the $V$ have R-charge $1+(1/2)(x-y)$.

The technique of $a$ maximization leads to the result

$$x = \frac{1}{3q^2}\left(-4p^2+2pq+3q^2+(2p-q)\sqrt{4p^2-3q^2}\right)$$

$$y = \frac{1}{3q^2}\left(-4p^2-2pq+3q^2+(2p+q)\sqrt{4p^2-3q^2}\right)$$

Thus, as calculated by Benvenuti *et al.* (2004) and Bertolini *et al.* (2004)

$$a(Y^{p,q}) = \frac{\pi^3 N^2}{4\,\mathrm{vol}(Y^{p,q})} \qquad [45]$$

in remarkable agreement with the prediction [42] of the AdS/CFT duality.

### A Path to a Confining Theory

There exists an interesting way of breaking the conformal invariance for spaces $Y$ whose topology includes an $S^2$ factor (examples of such spaces include $T^{1,1}$ and $Y^{p,q}$, which are topologically $S^2 \times S^3$). At the tip of the cone over $Y$, one may add $M$ wrapped D5 branes to the $N$ D3 branes. The gauge theory on such a combined stack is no longer conformal; it exhibits a novel pattern of quasiperiodic renormalization group flow, called a duality cascade.

To date, the most extensive study of a theory of this type has been carried out for the conifold, where one finds an $\mathcal{N}=1$ supersymmetric SU($N$) × SU($N+M$) theory coupled to chiral superfields $A_1$, $A_2$ in the $(\mathbf{N}, \overline{\mathbf{N}+\mathbf{M}})$ representation, and $B_1$, $B_2$ in the $(\overline{\mathbf{N}}, \mathbf{N}+\mathbf{M})$ representation. D5 branes source RR 3-form flux; hence, the supergravity dual of this theory has to include $M$ units of this flux. Klebanov and Strassler (2000) found an exact nonsingular supergravity solution incorporating the 3-form and the 5-form RR field strengths, and their back-reaction on the geometry. This back-reaction creates a "geometric transition" to the deformed conifold

$$\sum_{a=1}^{4} z_a^2 = \epsilon^2 \qquad [46]$$

and introduces a "warp factor" so that the full ten-dimensional geometry has the form

$$\mathrm{d}s_{10}{}^2 = h^{-1/2}(\tau)(-(\mathrm{d}x^0)^2 + (\mathrm{d}x^i)^2) + h^{1/2}(\tau)\,\mathrm{d}\tilde{s}_6{}^2 \qquad [47]$$

where $\mathrm{d}\tilde{s}_6{}^2$ is the Calabi–Yau metric of the deformed conifold, which is known explicitly.

The field-theoretic interpretation of this solution is unconventional. After a finite amount of RG flow, the SU($N+M$) group undergoes a Seiberg duality transformation. After this transformation, and an interchange of the two gauge groups, the new gauge theory is SU($\tilde{N}$) × SU($\tilde{N}+M$) with the same matter and superpotential, and with $\tilde{N}=N-M$. The self-similar structure of the gauge theory under the Seiberg duality is the crucial fact that allows this pattern to repeat many times. If $N=(k+1)M$, where $k$ is an integer, then the duality cascade stops after $k$ steps, and we find SU($M$) × SU($2M$) gauge theory. This IR gauge theory exhibits a multitude of interesting effects visible in the dual supergravity background. One of them is confinement, which follows from the fact that the warp factor $h$ is finite and nonvanishing at the smallest radial coordinate, $\tau=0$. The methods presented in the section "Calculation of Wilson loops," then imply that the quark–antiquark potential grows linearly at large distances. Other notable IR effects are chiral symmetry breaking and the Goldstone mechanism. Particularly interesting is the appearance of an entire "baryonic branch" of the moduli space in the gauge theory, whose existence has been demonstrated also in the dual supergravity language.

## Conclusions

This article tries to present a logical path from studying gravitational properties of D-branes to the formulation of an exact duality between conformal field theories and string theory in anti-de Sitter backgrounds, and also sketches some methods for breaking the conformal symmetry. Due to space limitations, many aspects and applications of the AdS/CFT correspondence have been omitted. At the moment, practical applications of this duality are limited mainly to very strongly coupled, large-$N$ gauge theories, where the dual string description is well approximated by classical supergravity. To understand the implications of the duality for more general parameters, it is necessary to find better

methods for attacking the world sheet approach to string theories in anti-de Sitter backgrounds with RR background fields turned on. When such methods are found, it is likely that the material presented here will have turned out to be just a tiny tip of a monumental iceberg of dualities between fields and strings.

# Affine Quantum Groups

**G W Delius and N MacKay**, University of York, York, UK

Affine quantum groups are certain pseudoquasitriangular Hopf algebras that arise in mathematical physics in the context of integrable quantum field theory, integrable quantum spin chains, and solvable lattice models. They provide the algebraic framework behind the spectral parameter dependent Yang–Baxter equation

$$R_{12}(u)R_{13}(u+v)R_{23}(v) = R_{23}(v)R_{13}(u+v)R_{12}(u) \qquad [1]$$

One can distinguish three classes of affine quantum groups, each leading to a different dependence of the $R$-matrices on the spectral parameter $u$: Yangians lead to rational $R$-matrices, quantum affine algebras lead to trigonometric R-matrices, and elliptic quantum groups lead to elliptic $R$-matrices. We will mostly concentrate on the quantum affine algebras but many results hold similarly for the other classes.

After giving mathematical details about quantum affine algebras and Yangians in the first two sections, we describe how these algebras arise in different areas of mathematical physics in the three following sections. We end with a description of boundary quantum groups which extend the formalism to the boundary Yang–Baxter (reflection) equation.

## Quantum Affine Algebras

### Definition

A quantum affine algebra $U_q(\hat{\mathfrak{g}})$ is a quantization of the enveloping algebra $U(\hat{\mathfrak{g}})$ of an affine Lie algebra (Kac–Moody algebra) $\hat{\mathfrak{g}}$. So we start by introducing affine Lie algebras and their enveloping algebras before proceeding to give their quantizations.

Let $\mathfrak{g}$ be a semisimple finite-dimensional Lie algebra over $\mathbb{C}$ of rank $r$ with Cartan matrix $(a_{ij})_{i,j=1,\ldots,r}$, symmetrizable via positive integers $d_i$, so that $d_i a_{ij}$ is symmetric. In terms of the simple roots $\alpha_i$, we have

$$a_{ij} = 2\frac{\alpha_i \cdot \alpha_j}{|\alpha_i|^2} \qquad \text{and} \qquad d_i = \frac{|\alpha_i|^2}{2}.$$

We can introduce an $\alpha_0 = \sum_{i=1}^r n_i \alpha_i$ in such a way that the extended Cartan matrix $(a_{ij})_{i,j=0,\ldots,r}$ is of affine type – that is, it is positive semidefinite of rank $r$. The integers $n_i$ are referred to as Kac indices. Choosing $\alpha_0$ to be the highest root of $\mathfrak{g}$ leads to an untwisted affine Kac–Moody algebra while choosing $\alpha_0$ to be the highest short root of $\mathfrak{g}$ leads to a twisted affine Kac–Moody algebra.

One defines the affine Lie algebra $\hat{\mathfrak{g}}$ corresponding to this affine Cartan matrix as the Lie algebra (over $\mathbb{C}$) with generators $H_i, E_i^{\pm}$ for $i = 0, 1, \ldots, r$ and $D$ with relations

$$\begin{gathered}\left[H_i, E_j^{\pm}\right] = \pm a_{ij} E_i^{\pm}; \qquad [H_i, H_j] = 0 \\ \left[E_i^{+}, E_j^{-}\right] = \delta_{ij} H_i \\ [D, H_i] = 0, \qquad \left[D, E_i^{\pm}\right] = \pm \delta_{i,0} E_i^{\pm} \\ \sum_{k=0}^{1-a_{ij}} (-1)^k \binom{1-a_{ij}}{k} \left(E_i^{\pm}\right)^k E_j^{\pm} \left(E_i^{\pm}\right)^{1-a_{ij}-k} = 0, \quad i \neq j\end{gathered} \qquad [2]$$

The $E_i^{\pm}$ are referred to as Chevalley generators and the last set of relations are known as Serre relations. The generator $D$ is known as the canonical derivation. We will denote the algebra obtained by dropping the generator $D$ by $\hat{\mathfrak{g}}'$.

In applications to physics, the affine Lie algebra $\hat{\mathfrak{g}}$ often occurs in an isomorphic form as the loop Lie algebra $\mathfrak{g}[z, z^{-1}] \oplus \mathbb{C} \cdot c$ with Lie product (for untwisted $\hat{\mathfrak{g}}$)

$$\begin{aligned}&[Xz^k, Yz^l] = [X, Y]z^{k+l} + \delta_{k,-l}(X, Y)c, \\ &\quad \text{for } X, Y \in \mathfrak{g}, \; k, l \in \mathbb{Z}\end{aligned} \qquad [3]$$

and $c$ being the central element.

The universal enveloping algebra $U(\hat{\mathfrak{g}})$ of $\hat{\mathfrak{g}}$ is the unital algebra over $\mathbb{C}$ with generators $H_i, E_i^{\pm}$ for $i = 0, 1, \ldots, r$ and $D$ and with relations given by [2] where now $[\,,\,]$ stands for the commutator instead of the Lie product.

To define the quantization of $U(\hat{\mathfrak{g}})$, one can either define $U_h(\hat{\mathfrak{g}})$ (Drinfeld 1985) as an algebra over the ring $\mathbb{C}[[h]]$ of formal power series over an indeterminate $h$ or one can define $U_q(\hat{\mathfrak{g}})$ (Jimbo 1985) as an algebra over the field $\mathbb{Q}(q)$ of rational functions of $q$ with coefficients in $\mathbb{Q}$. We will present $U_h(\hat{\mathfrak{g}})$ first.

The quantum affine algebra $U_h(\hat{\mathfrak{g}})$ is the unital algebra over $\mathbb{C}[[h]]$ topologically generated by $H_i, E_i^{\pm}$ for $i = 0, 1, \ldots, r$ and $D$ with relations

$$\begin{gathered}\left[H_i, E_j^{\pm}\right] = \pm a_{ij} E_i^{\pm}; \qquad [H_i, H_j] = 0 \\ \left[E_i^{+}, E_j^{-}\right] = \delta_{ij} \frac{q_i^{H_i} - q_i^{-H_i}}{q_i - q_i^{-1}} \\ [D, H_i] = 0, \qquad \left[D, E_i^{\pm}\right] = \pm \delta_{i,0} E_i^{\pm} \\ \sum_{k=0}^{1-a_{ij}} (-1)^k \begin{bmatrix} 1-a_{ij} \\ k \end{bmatrix}_{q_i} \left(E_i^{\pm}\right)^k E_j^{\pm} \left(E_i^{\pm}\right)^{1-a_{ij}-k} = 0, \quad i \neq j\end{gathered} \qquad [4]$$

where $q_i = q^{d_i}$ and $q = e^h$. The $q$-binomial coefficients are defined by

$$[n]_q = \frac{q^n - q^{-n}}{q - q^{-1}} \qquad [5]$$

$$[n]_q! = [n]_q \cdot [n-1]_q \ldots [2]_q [1]_q \qquad [6]$$

$$\begin{bmatrix} m \\ n \end{bmatrix}_q = \frac{[m]_q!}{[n]_q! [m-n]_q!} \qquad [7]$$

The quantum affine algebra $U_h(\hat{\mathfrak{g}})$ is a Hopf algebra with coproduct

$$\begin{aligned}\Delta(D) &= D \otimes 1 + 1 \otimes D \\ \Delta(H_i) &= H_i \otimes 1 + 1 \otimes H_i \\ \Delta\left(E_i^{\pm}\right) &= E_i^{\pm} \otimes q_i^{-H_i/2} + q_i^{H_i/2} \otimes E_i^{\pm}\end{aligned} \qquad [8]$$

antipode

$$\begin{gathered}S(D) = -D, \qquad S(H_i) = -H_i \\ S\left(E_i^{\pm}\right) = -q_i^{\mp 1} E_i^{\pm}\end{gathered} \qquad [9]$$

and co-unit

$$\epsilon(D) = \epsilon(H_i) = \epsilon\left(E_i^{\pm}\right) = 0 \qquad [10]$$

It is easy to see that the classical enveloping algebra $U(\hat{\mathfrak{g}})$ can be obtained from the above by setting $h = 0$, or more formally,

$$U_h(\hat{\mathfrak{g}}) / h U_h(\hat{\mathfrak{g}}) = U(\hat{\mathfrak{g}})$$

We can also define the quantum affine algebra $U_q(\hat{\mathfrak{g}})$ as the algebra over $\mathbb{Q}(q)$ with generators $K_i, E_i^{\pm}, D$ for $i = 0, 1, \ldots, r$ and relations that are

obtained from the ones given above for $U_h(\hat{\mathfrak{g}})$ by setting

$$q_i^{H_i/2} = K_i, \quad i = 0, \ldots, r \qquad [11]$$

One can go further to an algebraic formulation over $\mathbb{C}$ in which $q$ is a complex number (with some points including $q = 0$ not allowed). This has the advantage that it becomes possible to specialize, for example, to $q$ a root of unity, where special phenomena occur.

### Representations

For applications in physics, the finite-dimensional representations of $U_h(\hat{\mathfrak{g}}')$ are the most interesting. As will be explained in later sections, these occur, for example, as particle multiplets in 2D quantum field theory or as spin Hilbert spaces in quantum spin chains. In the next subsection, we will use them to derive matrix solutions to the Yang–Baxter equation.

While for a nonaffine quantum algebra $U_h(\mathfrak{g})$ the ring of representations is isomorphic to that of the classical enveloping algebra $U(\mathfrak{g})$ (because in fact the algebras are isomorphic, as Drinfeld has pointed out), the corresponding fact is no longer true for affine quantum groups, except in the case $\hat{\mathfrak{g}} = a_n^{(1)} = \widehat{\mathfrak{sl}_{n+1}}$.

For the classical enveloping algebras $U(\hat{\mathfrak{g}}')$, any finite-dimensional representation of $U(\mathfrak{g})$ also carries a finite-dimensional representation of $U(\hat{\mathfrak{g}}')$. In the quantum case, however, in general, an irreducible representation of $U_h(\hat{\mathfrak{g}}')$ reduces to a sum of representations of $U_h(\mathfrak{g})$.

To classify the finite-dimensional representations of $U_h(\hat{\mathfrak{g}}')$, it is necessary to use a different realization of $U_h(\hat{\mathfrak{g}}')$ that looks more like a quantization of the loop algebra realization [3] than the realization in terms of Chevalley generators. In terms of the generators in this alternative realization, which we do not give here because of its complexity, the finite-dimensional representations can be viewed as pseudo-highest-weight representations. There is a set of $r$ "fundamental" representations $V^a$, $a = 1, \ldots r$, each containing the corresponding $U_h(\mathfrak{g})$ fundamental representation as a component, from the tensor products of which all the other finite-dimensional representations may be constructed. The details can be found in Chari and Pressley (1994).

Given some representation $\rho : U_h(\hat{\mathfrak{g}}') \to \mathrm{End}(V)$, we can introduce a parameter $\lambda$ with the help of the automorphism $\tau_\lambda$ of $U_h(\hat{\mathfrak{g}}')$ generated by $D$ and given by

$$\begin{aligned} \tau_\lambda(E_i^\pm) &= \lambda^{\pm s_i} E_i^\pm \\ \tau_\lambda(H_i) &= H_i \end{aligned} \qquad i = 0, \ldots, r \qquad [12]$$

Different choices for the $s_i$ correspond to different gradations. Commonly used are the "homogeneous gradation," $s_0 = 1, s_1 = \cdots = s_r = 0$, and the "principal gradation," $s_0 = s_1 = \cdots = s_r = 1$. We shall also need the "spin gradation" $s_i = d_i^{-1}$. The representations

$$\rho_\lambda = \rho \circ \tau_\lambda$$

play an important role in applications to integrable models where $\lambda$ is referred to as the (multiplicative) spectral parameter. In applications to particle scattering introduced in a later section, it is related to the rapidity of the particle. The generator $D$ can be realized as an infinitesimal scaling operator on $\lambda$ and thus plays the role of the Lorentz boost generator.

The tensor product representations $\rho_\lambda^a \otimes \rho_\mu^b$ are irreducible generically but become reducible for certain values of $\lambda/\mu$, a fact which again is important in applications (fusion procedure, particle-bound states).

### *R*-Matrices

A Hopf algebra $A$ is said to be "almost cocommutative" if there exists an invertible element $\mathcal{R} \in A \otimes A$ such that

$$\mathcal{R}\Delta(x) = (\sigma \circ \Delta(x))\mathcal{R}, \quad \text{for all } x \in A \qquad [13]$$

where $\sigma : x \otimes y \mapsto y \otimes x$ exchanges the two factors in the coproduct. In a quasitriangular Hopf algebra, this element $\mathcal{R}$ satisfies

$$\begin{aligned} (\Delta \otimes \mathrm{id})(\mathcal{R}) &= \mathcal{R}_{13}\mathcal{R}_{23} \\ (\mathrm{id} \otimes \Delta)(\mathcal{R}) &= \mathcal{R}_{13}\mathcal{R}_{12} \end{aligned} \qquad [14]$$

and is known as the "universal $R$-matrix" (*see* Hopf Algebras and $q$-Deformation Quantum Groups). As a consequence of [13] and [14], it automatically satisfies the Yang–Baxter equation

$$\mathcal{R}_{12}\mathcal{R}_{13}\mathcal{R}_{23} = \mathcal{R}_{23}\mathcal{R}_{13}\mathcal{R}_{12} \qquad [15]$$

For technical reasons, to do with the infinite number of root vectors of $\hat{\mathfrak{g}}$, the quantum affine algebra $U_h(\hat{\mathfrak{g}})$ does not possess a universal $R$-matrix that is an element of $U_h(\hat{\mathfrak{g}}) \otimes U_h(\hat{\mathfrak{g}})$. However, as pointed out by Drinfeld (1985), it possesses a pseudouniversal $R$-matrix $\mathcal{R}(\lambda) \in (U_h(\hat{\mathfrak{g}}') \otimes U_h(\hat{\mathfrak{g}}'))((\lambda))$. The $\lambda$ is related to the automorphism $\tau_\lambda$ defined in [12]. When using the homogeneous gradation, $\mathcal{R}(\lambda)$ is a formal power series in $\lambda$.

When the pseudouniversal $R$-matrix is evaluated in the tensor product of any two indecomposable finite-dimensional representations $\rho_1$ and $\rho_2$, one obtains a numerical $R$-matrix

$$R^{12}(\lambda) = (\rho^1 \otimes \rho^2)\mathcal{R}(\lambda) \qquad [16]$$

The entries of these numerical $R$-matrices are rational functions of the multiplicative spectral parameter $\lambda$ but when written in terms of the additive spectral parameter $u = \log(\lambda)$ they are trigonometric functions of $u$ and satisfy the Yang–Baxter equation in the form given in [1]. The matrix

$$\check{R}^{12}(\lambda) = \sigma \circ R^{12}(\lambda)$$

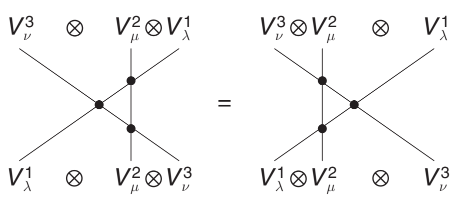
satisfies the intertwining relation

$$\begin{aligned} &\check{R}^{12}(\lambda/\mu) \cdot \left(\rho_\lambda^1 \otimes \rho_\mu^2\right)(\Delta(x)) \\ &\quad = \left(\rho_\mu^2 \otimes \rho_\lambda^1\right)(\Delta(x)) \cdot \check{R}^{12}(\lambda/\mu) \end{aligned} \qquad [17]$$

for any $x \in U_h(\hat{\mathfrak{g}}')$. It follows from the irreducibility of the tensor product representations that these $R$-matrices satisfy the Yang–Baxter equations

$$\begin{aligned} &(\mathrm{id} \otimes \check{R}^{23}(\mu/\nu))(\check{R}^{13}(\lambda/\nu) \otimes \mathrm{id})(\mathrm{id} \otimes \check{R}^{12}(\lambda/\mu)) \\ &\quad = (\check{R}^{12}(\lambda/\mu) \otimes \mathrm{id})(\mathrm{id} \otimes \check{R}^{13}(\lambda/\nu)) \\ &\qquad \times (\check{R}^{23}(\mu/\nu) \otimes \mathrm{id}) \end{aligned} \qquad [18]$$

or, graphically,



Explicit formulas for the pseudouniversal $R$-matrices were found by Khoroshkin and Tolstoy. However, these are difficult to evaluate explicitly in specific representations so that in practice it is easiest to find the numerical $R$-matrices $\check{R}^{ab}(\lambda)$ by solving the intertwining relation [17]. It should be stressed that solving the intertwining relation, which is a linear equation for the $R$-matrix, is much easier than directly solving the Yang–Baxter equation, a cubic equation.

## Yangians

As remarked by Drinfeld (1986), for untwisted $\hat{\mathfrak{g}}$ the quantum affine algebra $U_h(\hat{\mathfrak{g}}')$ degenerates as $h \to 0$ into another quasipseudotriangular Hopf algebra, the "Yangian" $Y(\mathfrak{g})$ (Drinfeld 1985). It is associated with $R$-matrices which are rational functions of the additive spectral parameter $u$. Its representation ring coincides with that of $U_h(\hat{\mathfrak{g}}')$.

Consider a general presentation of a Lie algebra $\mathfrak{g}$, with generators $I_a$ and structure constants $f_{abc}$, so that

$$[I_a, I_b] = f_{abc} I_c, \quad \Delta(I_a) = I_a \otimes 1 + 1 \otimes I_a$$

(with summation over repeated indices). The Yangian $Y(\mathfrak{g})$ is the algebra generated by these and a second set of generators $J_a$ satisfying

$$\begin{aligned} &[I_a, J_b] = f_{abc} J_c \\ &\Delta(J_a) = J_a \otimes 1 + 1 \otimes J_a + \tfrac{1}{2} f_{abc} I_c \otimes I_b \end{aligned}$$

The requirement that $\Delta$ be a homomorphism imposes further relations:

$$[J_a, [J_b, I_c]] - [I_a, [J_b, J_c]] = \alpha_{abcdeg} \{I_d, I_e, I_g\}$$

and

$$\begin{aligned} &[[J_a, J_b], [I_l, J_m]] + [[J_l, J_m], [I_a, J_b]] \\ &\quad = \left(\alpha_{abcdeg} f_{lmc} + \alpha_{lmcdeg} f_{abc}\right)\{I_d, I_e, J_g\} \end{aligned}$$

where

$$\alpha_{abcdeg} = \frac{1}{24} f_{adi} f_{bej} f_{cgk} f_{ijk}, \quad \{x_1, x_2, x_3\} = \sum_{i \neq j \neq k} x_i x_j x_k$$

When $\mathfrak{g} = \mathfrak{sl}_2$ the first of these is trivial, while for $\mathfrak{g} \neq \mathfrak{sl}_2$ the first implies the second. The co-unit is $\epsilon(I_a) = \epsilon(J_a) = 0$; the antipode is $s(I_a) = -I_a$, $s(J_a) = -J_a + (1/2) f_{abc} I_c I_b$. The Yangian may be obtained from $U_h(\hat{\mathfrak{g}}')$ by expanding in powers of $h$. For the precise relationship, see Drinfeld (1985) and MacKay (2005). In the spin gradation, the automorphism [12] generated by $D$ descends to $Y(\mathfrak{g})$ as $I_a \mapsto I_a$, $J_a \mapsto J_a + u I_a$.

There are two other realizations of $Y(\mathfrak{g})$. The first (see, for example, Molev 2003) defines $Y(\mathfrak{gl}_n)$ directly from

$$R(u - v) T_1(u) T_2(v) = T_2(v) T_1(u) R(u - v)$$

where $T_1(u) = T(u) \otimes \mathrm{id}$, $T_2(v) = \mathrm{id} \otimes T(v)$, and

$$\begin{aligned} &T(u) = \sum_{i,j=1}^{n} t_{ij}(u) \otimes e_{ij} \\ &t_{ij}(u) = \delta_{ij} + I_{ij} u^{-1} + J_{ij} u^{-2} + \cdots \end{aligned}$$

where $e_{ij}$ are the standard matrix units for $\mathfrak{gl}_n$. The rational $R$-matrix for the $n$-dimensional representation of $\mathfrak{gl}_n$ is

$$R(u - v) = 1 - \frac{P}{u - v}, \quad \text{where } P = \sum_{i,j=1}^{n} e_{ij} \otimes e_{ji}$$

is the transposition operator. $Y(\mathfrak{gl}_n)$ is then defined to be the algebra generated by $I_{ij}, J_{ij}$, and must be quotiented by the "quantum determinant" at its center to define $Y(\mathfrak{sl}_n)$. The coproduct takes a particularly simple form,

$$\Delta(t_{ij}(u)) = \sum_{k=1}^{n} t_{ik}(u) \otimes t_{kj}(u)$$

Here we do not give explicitly the third realization, namely Drinfeld's "new" realization of $Y(\mathfrak{g})$ (Drinfeld 1988), but we remark that it was in this presentation that Drinfeld found a correspondence between certain sets of polynomials and finite-dimensional irreducible representations of $Y(\mathfrak{g})$, thus classifying these (although not thereby deducing their dimension or constructing the action of $Y(\mathfrak{g})$). As remarked earlier, the structure is as in the earlier section: $Y(\mathfrak{g})$ representations are in general $\mathfrak{g}$-reducible, and there is a set of $r$ fundamental $Y(\mathfrak{g})$-representations, containing the fundamental $\mathfrak{g}$-representations as components, from which all other representations can be constructed.

## Origins in the Quantum Inverse-Scattering Method

Quantum affine algebras for general $\hat{\mathfrak{g}}$ first appear in Drinfeld (1985, 1986) and Jimbo (1985, 1986), but they have their origin in the "quantum inverse-scattering method" (QISM) of the St. Petersburg school, and the essential features of $U_h(\widehat{\mathfrak{sl}_2})$ first appear in Kulish and Reshetikhin (1983). In this section, we explain how the quantization of the Lax-pair description of affine Toda theory led to the discovery of the $U_h(\hat{\mathfrak{g}})$ coproduct, commutation relations, and $R$-matrix. We use the normalizations of Jimbo (1986), in which the $H_i$ are rescaled so that the Cartan matrix $a_{ij} = \alpha_i \cdot \alpha_j$ is symmetric.

We begin with the affine Toda field equations

$$\partial^\mu \partial_\mu \phi_i = -\frac{m^2}{\beta} \sum_{j=1}^{r} \left( e^{\beta a_{ij} \phi_j} - n_i e^{\beta \alpha_0 . \alpha_j \phi_j} \right)$$

an integrable model in $\mathbb{R}^{1+1}$ of $r$ real scalar fields $\phi_i(x,t)$ with a mass parameter $m$ and coupling constant $\beta$. Equivalently, we may write $[\partial_x + L_x, \partial_t + L_t] = 0$ for the Lax pair

$$L_x(x,t) = \frac{\beta}{2} \sum_{i=1}^{r} H_i \partial_t \phi_i + \frac{m}{2} \sum_{i,j=1}^{r} e^{(\beta/2) a_{ij} \phi_j} \left( E_i^+ + E_i^- \right) + \frac{m}{2} \sum_{j=1}^{r} e^{(\beta/2) a_{0j} \phi_j} \left( \lambda E_0^+ + \frac{1}{\lambda} E_0^- \right)$$

$$L_t(x,t) = \frac{\beta}{2} \sum_{i=1}^{r} H_i \partial_x \phi_i + \frac{m}{2} \sum_{i,j=1}^{r} e^{(\beta/2) a_{ij} \phi_j} \left( E_i^+ - E_i^- \right) + \frac{m}{2} \sum_{j=1}^{r} e^{(\beta/2) a_{0j} \phi_j} \left( \lambda E_0^+ - \frac{1}{\lambda} E_0^- \right)$$

with arbitrary $\lambda \in \mathbb{C}$. The classical integrability of the system is seen in the existence of $r(\lambda, \lambda')$ such that

$$\{T(\lambda) \otimes T(\lambda')\} = [r(\lambda, \lambda'), T(\lambda) \otimes T(\lambda')]$$

where $T(\lambda) = T(-\infty, \infty; \lambda)$ and $T(x,y;\lambda) = \boldsymbol{P} \exp(\int_x^y L(\xi;\lambda)\, d\xi)$. Taking the trace of this relation gives an infinity of charges in involution.

Quantization is problematic, owing to divergences in $T$. The QISM regularizes these by putting the model on a lattice of spacing $\Delta$, defining the lattice Lax operator to be

$$L_n(\lambda) = T((n-1/2)\Delta, (n+1/2)\Delta; \lambda) = \boldsymbol{P} \exp\left( \int_{(n-(1/2))\Delta}^{(n+(1/2))\Delta} L(\xi;\lambda)\, d\xi \right)$$

The lattice monodromy matrix is then $T(\lambda) = \lim_{l \to -\infty, m \to \infty} T_l^m$ where $T_l^m = L_m L_{m-1} \ldots L_{l+1}$, and its trace again yields an infinity of commuting charges, provided that there exists a quantum $R$-matrix $R(\lambda_1, \lambda_2)$ such that

$$R(\lambda_1,\lambda_2) L_n^1(\lambda_1) L_n^2(\lambda_2) = L_n^2(\lambda_2) L_n^1(\lambda_1) R(\lambda_1,\lambda_2) \qquad [19]$$

where $L_n^1(\lambda_1) = L_n(\lambda_1) \otimes \mathrm{id}$, $L_n^2(\lambda_2) = \mathrm{id} \otimes L_n(\lambda_2)$. That $R$ solves the Yang–Baxter equation follows from the equivalence of the two ways of intertwining $L_n(\lambda_1) \otimes L_n(\lambda_2) \otimes L_n(\lambda_3)$ with $L_n(\lambda_3) \otimes L_n(\lambda_2) \otimes L_n(\lambda_1)$.

To compute $L_n(\lambda)$, one uses the canonical, equal-time commutation relations for the $\phi_i$ and $\dot{\phi}_i$. In terms of the lattice fields

$$p_{i,n} = \int_{(n-(1/2))\Delta}^{(n+(1/2))\Delta} \dot{\phi}_i(x)\, dx$$

$$q_{i,n} = \int_{(n-(1/2))\Delta}^{(n+(1/2))\Delta} \sum_j e^{(\beta/2) a_{ij} \phi_j(x)}\, dx$$

the only nontrivial relation is $[p_{i,n}, q_{j,n}] = (i\hbar\beta/2)\delta_{ij} q_{j,n}$, and one finds

$$L_n(\lambda) = \exp\left( \frac{\beta}{2} \sum_i H_i p_{i,n} \right) + \exp\left( \frac{\beta}{4} \sum_j H_j p_{j,n} \right) \times \frac{m}{2} \left[ \sum_i q_{i,n} (E_i^+ + E_i^-) + \prod_i q_{i,n}^{-n_i} \left( \lambda E_0^+ + \frac{1}{\lambda} E_0^- \right) \right] \times \exp\left( \frac{\beta}{4} \sum_j H_j p_{j,n} \right) + O(\Delta^2)$$

the expression used by the St Petersburg school and by Jimbo. We now make the replacement $E_i^\pm \mapsto q^{-H_i/4} E_i^\pm q^{H_i/4}$, where $q = \exp(i\hbar\beta^2/2)$, and compute the $O(\Delta)$ terms in [19], which reduce to

$$
\begin{aligned}
&R(z)(H_i \otimes 1 + 1 \otimes H_i) \\
&\quad = (H_i \otimes 1 + 1 \otimes H_i)R(z) \\
&R(z)\left(E_i^{\pm} \otimes q^{-H_i/2} + q^{H_i/2} \otimes E_i^{\pm}\right) \\
&\quad = \left(q^{-H_i/2} \otimes E_i^{\pm} + E_i^{\pm} \otimes q^{H_i/2}\right)R(z) \\
&R(z)\left(z^{\pm 1}E_0^{\pm} \otimes q^{-H_0/2} + q^{H_0/2} \otimes E_0^{\pm}\right) \\
&\quad = \left(q^{-H_0/2} \otimes E_0^{\pm} + z^{\pm 1}E_0^{\pm} \otimes q^{H_0/2}\right)R(z)
\end{aligned}
$$

where $z = \lambda_1/\lambda_2$. We recognize in these the $U_h(\hat{\mathfrak{g}})$ coproduct and thus the intertwining relations, in the homogeneous gradation. These equations were solved for $R$ in defining representations of nonexceptional $\mathfrak{g}$ by Jimbo (1986).

For $\hat{\mathfrak{g}} = \widehat{\mathfrak{sl}_2}$, it was Kulish and Reshetikhin (1983) who first discovered that the requirement that the coproduct must be an algebra homomorphism forces the replacement of the commutation relations of $U(\widehat{\mathfrak{sl}_2})$ by those of $U_h(\widehat{\mathfrak{sl}_2})$; more generally it requires the replacement of $U(\hat{\mathfrak{g}})$ by $U_h(\hat{\mathfrak{g}})$.

## Affine Quantum Group Symmetry and the Exact *S*-Matrix

In the last section, we saw the origins of $U_h(\hat{\mathfrak{g}})$ in the "auxiliary" algebra introduced in the Lax pair. However, the quantum affine algebras also play a second role, as a symmetry algebra. An imaginary-coupled affine Toda field theory based on the affine algebra $\hat{\mathfrak{g}}^{\vee}$ possesses the quantum affine algebra $U_h(\hat{\mathfrak{g}})$ as a symmetry algebra, where $\hat{\mathfrak{g}}^{\vee}$ is the Langland dual to $\hat{\mathfrak{g}}$ (the algebra obtained by replacing roots by coroots).

The solitonic particle states in affine Toda theories form multiplets which transform in the fundamental representations of the quantum affine algebra. Multiparticle states transform in tensor product representations $V^a \otimes V^b$. The scattering of two solitons of type $a$ and $b$ with relative rapidity $\theta$ is described by the $S$-matrix $S^{ab}(\theta): V^a \otimes V^b \to V^b \otimes V^a$, graphically represented in Figure 1a. It then follows from the symmetry that the two-particle scattering matrix

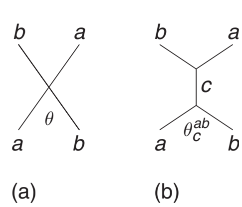


**Figure 1** (a) Graphical representation of a two-particle scattering process described by the $S$-matrix $S_{ab}(\theta)$. (b) At special values $\theta_{ab}^{c}$ of the relative spectral parameter, the two particles of types $a$ and $b$ form a bound state of type $c$.

($S$-matrix) for solitons must be proportional to the intertwiner for these tensor product representations, the $R$ matrix:

$$
S^{ab}(\theta) = f^{ab}(\theta)\check{R}^{ab}(\theta)
$$

with $\theta$ proportional to $u$, the additive spectral parameter. The scalar prefactor $f^{ab}(\theta)$ is not determined by the symmetry but is fixed by other requirements like unitarity, crossing symmetry, and the bootstrap principle.

It turns out that the axiomatic properties of the $R$-matrices are in perfect agreement with the axiomatic properties of the analytic $S$-matrix. For example, crossing symmetry of the $S$-matrix, graphically represented by

 [20]

is a consequence of the property of the universal $R$-matrix with respect to the action of the antipode $S$,

$$
(S \otimes 1)\mathcal{R} = \mathcal{R}^{-1}
$$

An $S$-matrix will have poles at certain imaginary rapidities $\theta_c^{ab}$ corresponding to the formation of virtual bound states. This is graphically represented in Figure 1b. The location of the pole is determined by the masses of the three particles involved,

$$
m_c^2 = m_a^2 + m_b^2 + 2m_a m_b \cos(\mathrm{i}\theta_c^{ab})
$$

At the bound state pole, the $S$-matrix will project onto the multiplet $V^c$. Thus, the $\check{R}$ matrix has to have this projection property as well and indeed, this turns out to be the case. The bootstrap principle, whereby the $S$-matrix for a bound state is obtained from the $S$-matrices of the constituent particles,

 [21]

is a consequence of the property [14] of the universal $R$-matrix with respect to the coproduct.

There is a famous no-go theorem due to Coleman and Mandula which states the "impossibility of combining space-time and internal symmetries in any but a trivial way." Affine quantum group symmetry circumvents this no-go theorem. In fact, the derivation $D$ is the infinitesimal two-dimensional Lorentz boost generator and the other symmetry

charges transform nontrivially under these Lorentz transformations, see [2].

The noncocommutative coproduct [8] means that a $U_h(\hat{\mathfrak{g}})$ symmetry generator, when acting on a 2-soliton state, acts differently on the left soliton than on the right soliton. This is only possible because the generator is a nonlocal symmetry charge – that is, a charge which is obtained as the space integral of the time component of a current which itself is a nonlocal expression in terms of the fields of the theory.

Similarly, many nonlinear sigma models possess nonlocal charges which form $Y(\mathfrak{g})$, and the construction proceeds similarly, now utilizing rational $R$-matrices, and with particle multiplets forming fundamental representations of $Y(\mathfrak{g})$. In each case, the three-point couplings corresponding to the formation of bound states, and thus the analogs for $U_h(\hat{\mathfrak{g}})$ and $Y(\mathfrak{g})$ of the Clebsch–Gordan couplings, obey a rather beautiful geometric rule originally deduced in simpler, purely elastic scattering models (Chari and Pressley 1996).

More details about this topic can be found in Delius (1995) and MacKay (2005).

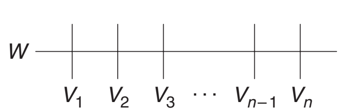
## Integrable Quantum Spin Chains

Affine quantum groups provide an unlimited supply of integrable quantum spin chains. From any $R$-matrix $R(\theta)$ for any tensor product of finite-dimensional representations $W \otimes V$, one can produce an integrable quantum system on the Hilbert space $V^{\otimes n}$. This Hilbert space can then be interpreted as the space of $n$ interacting spins. The space $W$ is an auxiliary space required in the construction but not playing a role in the physics.

Given an arbitrary $R$-matrix $R(\theta)$, one defines the monodromy matrix $T(\theta) \in \mathrm{End}(W \otimes V^{\otimes n})$ by

$$T(\theta) = R_{01}(\theta - \theta_1)R_{02}(\theta - \theta_2) \cdots R_{0n}(\theta - \theta_n)$$

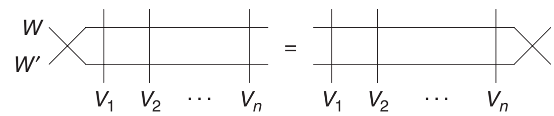
where, as usual, $R_{ij}$ is the $R$-matrix acting on the $i$th and $j$th component of the tensor product space. The $\theta_i$ can be chosen arbitrarily for convenience. Graphically the monodromy matrix can be represented as



As a consequence of the Yang–Baxter equation satisfied by the $R$-matrices the monodromy matrix satisfies

$$RTT = TTR \qquad [22]$$

or, graphically,



One defines the transfer matrix

$$\tau(\theta) = \mathrm{tr}_W T(\theta)$$

which is now an operator on $V^{\otimes n}$, the Hilbert space of the quantum spin chain. Due to [22], two transfer matrices commute,

$$[\tau(\theta), \tau(\theta')] = 0$$

and thus the $\tau(\theta)$ can be seen as a generating function of an infinite number of commuting charges, one of which will be chosen as the Hamiltonian. This Hamiltonian can then be diagonalized using the algebraic Bethe ansatz.

One is usually interested in the thermodynamic limit where the number of spins goes to infinity. In this limit, it has been conjectured, the Hilbert space of the spin chain carries a certain infinite-dimensional representation of the quantum affine algebra and this has been used to solve the model algebraically, using vertex operators (Jimbo and Miwa 1995).

## Boundary Quantum Groups

In applications to physical systems that have a boundary, the Yang–Baxter equation [1] appears in conjunction with the boundary Yang–Baxter equation, also known as the reflection equation,

$$\begin{aligned} R_{12}(u-v)K_1(u)R_{21}(u+v)K_2(v) \\ = K_2(v)R_{12}(u+v)K_1(u)R_{21}(u-v) \end{aligned} \qquad [23]$$

The matrices $K$ are known as reflection matrices. This equation was originally introduced by Cherednik to describe the reflection of particles from a boundary in an integrable scattering theory and was used by Sklyanin to construct integrable spin chains and quantum field theories with boundaries.

Boundary quantum groups are certain co-ideal subalgebras of affine quantum groups. They provide the algebraic structures underlying the solutions of the boundary Yang–Baxter equation in the same way in which affine quantum groups underlie the solutions of the ordinary Yang–Baxter equation. Both allow one to find solutions of the respective Yang–Baxter equation by solving a linear intertwining relation. In the case without spectral parameters these algebras appear in the theory of braided groups (*see* Hopf Algebras and $q$-Deformation Quantum Groups and Braided and Modular Tensor Categories).

For example, the subalgebra $B_\epsilon(\hat{\mathfrak{g}})$ of $U_h(\hat{\mathfrak{g}}')$ generated by

$$Q_i = q_i^{H_i/2}(E_i^+ + E_i^-) + \epsilon_i(q_i^{H_i} - 1), \quad i = 0, \ldots, r \qquad [24]$$

is a boundary quantum group for certain choices of the parameters $\epsilon_i \in \mathbb{C}[[h]]$. It is a left co-ideal subalgebra of $U_h(\hat{\mathfrak{g}}')$ because

$$\Delta(Q_i) = Q_i \otimes 1 + q_i^{H_i} \otimes Q_i \in U_h(\hat{\mathfrak{g}}') \otimes B_\epsilon(\hat{\mathfrak{g}}) \qquad [25]$$

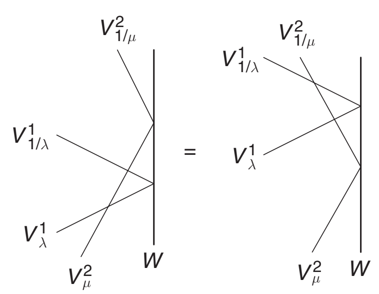
Intertwiners $K(\lambda) : V_{\eta\lambda} \to V_{\eta/\lambda}$ for some constant $\eta$ satisfying

$$K(\lambda)\rho_{\eta\lambda}(Q) = \rho_{\eta/\lambda}(Q)K(\lambda), \quad \text{for all } Q \in B_\epsilon(\hat{\mathfrak{g}}) \qquad [26]$$

provide solutions of the reflection equation in the form

$$(\mathrm{id} \otimes K^2(\mu))\check{R}^{12}(\lambda\mu)(\mathrm{id} \otimes K^1(\lambda))\check{R}^{21}(\lambda/\mu) = \check{R}^{12}(\lambda/\mu)(\mathrm{id} \otimes K^1(\lambda)) \times \check{R}^{21}(\lambda\mu)(\mathrm{id} \otimes K^2(\mu)) \qquad [27]$$

This can be extended to the case where the boundary itself carries a representation $W$ of $B_\epsilon(\hat{\mathfrak{g}})$. The boundary Yang–Baxter equation can be represented graphically as



Another example is provided by twisted Yangians where, when the $I_a$ and $J_a$ are constructed as nonlocal charges in sigma models, it is found that a boundary condition which preserves integrability leaves only the subset

$$I_i \quad \text{and} \quad \tilde{J}_p = J_p + \tfrac{1}{4} f_{piq}(I_i I_q + I_q I_i)$$

conserved, where $i$ labels the $\mathfrak{h}$-indices and $p, q$ the $\mathfrak{k}$-indices of a symmetric splitting $\mathfrak{g} = \mathfrak{h} + \mathfrak{k}$. The algebra $Y(\mathfrak{g}, \mathfrak{h})$ generated by the $I_i, \tilde{J}_p$ is, like $B_\epsilon(\hat{\mathfrak{g}})$, a co-ideal subalgebra, $\Delta(Y(\mathfrak{g}, \mathfrak{h})) \subset Y(\mathfrak{g}) \otimes Y(\mathfrak{g}, \mathfrak{h})$, and again yields an intertwining relation for $K$-matrices. For $\mathfrak{g} = \mathfrak{sl}_n$ and $\mathfrak{h} = \mathfrak{so}_n$ or $\mathfrak{sp}_{2n}$, $Y(\mathfrak{g}, \mathfrak{h})$ is the "twisted Yangian" described in Molev (2003).

All the constructions in earlier sections of this review have analogs in the boundary setting. For more details see Delius and MacKay (2003) and MacKay (2005).

# Aharonov–Bohm Effect

**M Socolovsky**, Universidad Nacional Autónoma de México, México DF, México

## Introduction

In classical electrodynamics, the interaction of charged particles with the electromagnetic field is local, through the pointlike coupling of the electric charge of the particles with the electric and magnetic fields, $\boldsymbol{E}$ and $\boldsymbol{B}$, respectively. This is mathematically expressed by the Lorentz-force law. The scalar and vector potentials, $\varphi$ and $\boldsymbol{A}$, which are the time and space components of the relativistic 4-potential $A_\mu$, are considered auxiliary quantities in terms of which the field strengths $\boldsymbol{E}$ and $\boldsymbol{B}$, the observables, are expressed in a gauge-invariant manner. The homogeneous or first pair of Maxwell equations are a direct consequence of the definition of the field strengths in terms of $A_\mu$. The inhomogeneous or second pair of Maxwell equations, which involve the charges and currents present in the problem, are also usually written in terms of $\boldsymbol{E}$ and $\boldsymbol{B}$; however when writing them in terms of $A_\mu$, the number of degrees of freedom of the electromagnetic field is explicitly reduced from six to four; and finally, with two additional gauge transformations, one ends with the two physical degrees of freedom of the electromagnetic field.

In quantum mechanics, however, both the Schrödinger equation and the path-integral approaches for scalar and unpolarized charged particles in the presence of electromagnetic fields, are written in terms of the potential and not of the field strengths. Even in the case of the Schrödinger–Pauli equation for spin 1/2 electrons with magnetic moment $\boldsymbol{\mu}$ interacting with a magnetic field $\boldsymbol{B}$, one knows that the coupling $-\boldsymbol{\mu}\cdot\boldsymbol{B}$ is the nonrelativistic limit of the Dirac equation, which depends on $A_\mu$ but not on $\boldsymbol{E}$ and $\boldsymbol{B}$. Since gauge invariance also holds in the quantum domain, it was thought that $\boldsymbol{A}$ and $\varphi$ were mere auxiliary quantities, like in the classical case.

Aharonov and Bohm, in 1959, predicted a quantum interference effect due to the motion of charged particles in regions where $\boldsymbol{B}(\boldsymbol{E})$ vanishes, but not $\boldsymbol{A}(\varphi)$, leading to a nonlocal gauge-invariant effect depending on the flux of the magnetic field in the inaccessible region, in the magnetic case, and on the difference of the integrals over time of time-varying potentials, in the electric case. (The magnetic effect was already noticed 10 years before by Ehrenberg and Siday in a paper on the refractive index of electrons.)

In the context of the Schrödinger equation, one can show that due to gauge invariance, if $\psi_0$ is a solution to the equation in the absence of an electromagnetic potential, then the product of $\psi_0(\boldsymbol{x})$ times the integral of $A_\mu$ over a path joining an arbitrary reference point $\boldsymbol{x}_0$ to $\boldsymbol{x}$ is also a solution, if the integral is path independent. However, it is the path integral of Feynman which in the formulas for propagators of charged particles in the presence of electromagnetic fields clearly shows that *the action of these fields on charged particles is nonlocal, and it is given by the celebrated nonintegrable (path-dependent) phase factor of* Wu and Yang (1975). Moreover, this fact provides an additional proof of the nonlocal character of quantum mechanics: to surround fluxes, or to develop a potential difference, the particle has to travel simultaneously at least through two paths.

Thus, the fact that the Aharonov–Bohm (A–B) effect was verified experimentally, by Chambers and others, demonstrates the necessity of introducing the (gauge-dependent) potential $A_\mu$ in describing the electromagnetic interactions of the quantum particle. This is widely regarded as the single most important piece of evidence for electromagnetism being a gauge theory. Moreover, it shows, to paraphrase Yang, that the field underdescribes the physical theory, while the potential overdescribes it, and it is the phase factor which describes it exactly.

The content of this article is essentially twofold. The first four sections are mainly physical, where we describe the magnetic A–B effect using the Schrödinger equation and the Feynman path integral. The fifth section is geometrical and is the longest of the article. We describe the effect in the context of fiber bundles and connections, namely as a result of the coupling of the wave function (section of an associated bundle) to a nontrivial flat connection (non-pure gauge vector potential with zero magnetic field) in a trivial bundle (the A–B bundle) with topologically nontrivial (non-simply-connected) base space. We discuss the moduli space of flat connections and the holonomy groups giving the phase shifts of the interference patterns. Finally, in the last section, we briefly comment on the nonabelian A–B effect.

## Electromagnetic Fields in Classical Physics

In classical physics, the motion of charged particles in the presence of electromagnetic fields is governed by the equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{p} = q\left(\boldsymbol{E} + \frac{\boldsymbol{v}}{c} \times \boldsymbol{B}\right) \qquad [1]$$

where

$$\boldsymbol{p} = \frac{m\boldsymbol{v}}{\sqrt{1-(v^2/c^2)}}$$

is the mechanical momentum of the particle with electric charge $q$, mass $m$, and velocity $\boldsymbol{v} = \dot{\boldsymbol{x}}$ ($c$ is the velocity of light in vacuum, and for $|\boldsymbol{v}| \ll c$ the left-hand side (LHS) of [1] is approximately $m\boldsymbol{v}$); the right-hand side (RHS) is the Lorentz force, where $\boldsymbol{E}$ and $\boldsymbol{B}$ are, respectively, the electric and magnetic fields at the spacetime point $(t, \boldsymbol{x})$ where the particle is located. Equation [1] is easily derived from the Euler–Lagrange equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \boldsymbol{v}}\right) - \frac{\partial L}{\partial \boldsymbol{x}} = 0 \qquad [2]$$

with the Lagrangian $L$ given by the sum of the free Lagrangian for the particle,

$$L_0 = -mc^2\sqrt{1-\frac{v^2}{c^2}} \qquad [3]$$

and the Lagrangian describing the particle–field interaction,

$$L_{\mathrm{int}} = \frac{q}{c}\boldsymbol{A}\cdot\boldsymbol{v} - q\varphi \qquad [4]$$

In [4], $\boldsymbol{A}$ and $\varphi$ are, respectively, the vector potential and the scalar potential, which together form the 4-potential $A_\mu = (A_0, -\boldsymbol{A}) = (\varphi, -A^i)$, $i = 1, 2, 3$, in terms of which the electric and magnetic field strengths are given by

$$\boldsymbol{E} = -\frac{1}{c}\frac{\partial}{\partial t}\boldsymbol{A} - \nabla\varphi \qquad [5a]$$

$$\boldsymbol{B} = \nabla \times \boldsymbol{A} \qquad [5b]$$

The classical action corresponding to a given path of the particle is

$$S = \int_{t_1}^{t_2} \mathrm{d}t\, L = \int_{t_1}^{t_2} \mathrm{d}t(L_0 + L_{\mathrm{int}}) = \int_{t_1}^{t_2} \mathrm{d}t\, L_0 + \int_{t_1}^{t_2} \mathrm{d}t\, L_{\mathrm{int}} \equiv S_0 + S_{\mathrm{int}} \qquad [6]$$

$\boldsymbol{E}$, $\boldsymbol{B}$, and $S$ are invariant under the gauge transformation

$$\boldsymbol{A} \to \boldsymbol{A}' = \boldsymbol{A} - \nabla\Lambda \qquad [7a]$$

$$\varphi \to \varphi' = \varphi + \frac{1}{c}\frac{\partial}{\partial t}\Lambda \qquad [7b]$$

where $\Lambda$ is a real-valued differentiable scalar function (at least of class $C^2$) on spacetime. That is, if $\boldsymbol{E}'$, $\boldsymbol{B}'$, and $S'_{\mathrm{int}}$ are defined in terms of $\boldsymbol{A}'$ and $\varphi'$ as $\boldsymbol{E}$, $\boldsymbol{B}$, and $S_{\mathrm{int}}$ are defined in terms of $\boldsymbol{A}$ and $\varphi$, then $\boldsymbol{E}' = \boldsymbol{E}$, $\boldsymbol{B}' = \boldsymbol{B}$, and $S'_{\mathrm{int}} = S_{\mathrm{int}}$. This fact leads to the concept that, classically, the observables $\boldsymbol{E}$ and $\boldsymbol{B}$ are the physical quantities, while $A_\mu$ is only an auxiliary quantity. Also, and most important in the present context, eqn [1] states that the motion of the particles is determined by the values or state of the field strengths in an infinitesimal neighborhood of the particles, that is, classically, $\boldsymbol{E}$ and $\boldsymbol{B}$ act locally. If one defines the differential 1-form $A \equiv A_\mu \mathrm{d}x^\mu$ (with $\mathrm{d}x^0 = c\,\mathrm{d}t$), then the components of the differential 2-form $F = \mathrm{d}A = (1/2)(\partial_\mu A_\nu - \partial_\nu A_\mu)\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \equiv (1/2)F_{\mu\nu}$ $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ are precisely the electric and magnetic fields:

$$F_{\mu\nu} = \begin{pmatrix} 0 & E^1 & E^2 & E^3 \\ -E^1 & 0 & -B^3 & B^2 \\ -E^2 & B^3 & 0 & -B^1 \\ -E^3 & -B^2 & B^1 & 0 \end{pmatrix} \qquad [8]$$

At the level of $A$,

$$\mathrm{d}F = \mathrm{d}^2 A = 0 \qquad [9]$$

is an identity, but at the level of $\boldsymbol{E}$ and $\boldsymbol{B}$, [9] amounts to the homogeneous (or first pair of) Maxwell equations obeyed by the field strengths:

$$\nabla \cdot \boldsymbol{B} = 0 \qquad [10a]$$

$$\nabla \times \boldsymbol{E} + \frac{1}{c}\frac{\partial}{\partial t}\boldsymbol{B} = 0 \qquad [10b]$$

Therefore, these equations have a geometrical origin. The second pair of Maxwell equations is dynamical, and is obtained from the field action (in the Heaviside system of units)

$$S_{\mathrm{field}} = -\frac{1}{4c}\int \mathrm{d}^4x F_{\mu\nu}F^{\mu\nu} \qquad [11]$$

which leads to $\qquad \nabla \cdot \boldsymbol{E} = 4\pi\rho \qquad [12a]$

$$\nabla \times \boldsymbol{B} - \frac{1}{c}\frac{\partial}{\partial t}\boldsymbol{E} = \frac{4\pi \boldsymbol{j}}{c} \qquad [12b]$$

where $(\rho, -\boldsymbol{j}) = (j^0, -\boldsymbol{j})$ is the 4-current satisfying, as a consequence of [12a] and [12b], the conservation law

$$\partial_\mu j^\mu = 0 \qquad [13]$$

For a pointlike particle, $\rho(t, \boldsymbol{x}) = q\delta^3(\boldsymbol{x} - \boldsymbol{x}(t))$ and $\boldsymbol{j} = \rho\boldsymbol{v}$.

## Electromagnetic Fields in Quantum Physics

In quantum physics, the motion of charged particles in external electromagnetic fields is governed by the Schrödinger equation or, equivalently, by the Feynman path integral. In both cases, however, it is the 4-potential $A_\mu$ which appears in the equations, and not the field strengths. For simplicity, we consider here scalar (spinless) charged particles or unpolarized electrons (spin-(1/2)particles), both of which, in the nonrelativistic approximation, can be described quantum mechanically by a complex wave function $\psi(t, \boldsymbol{x})$.

To derive the Schrödinger equation, one starts from the classical Hamiltonian

$$H = \boldsymbol{P}\cdot\boldsymbol{v} - L - mc^2 = \frac{1}{2}\left(\boldsymbol{P} - \frac{q}{c}\boldsymbol{A}\right)^2 + q\varphi \qquad [14]$$

where

$$\boldsymbol{P} = \frac{\partial}{\partial \boldsymbol{v}}L = \boldsymbol{p} + \frac{q}{c}\boldsymbol{A}$$

is the canonical momentum of the particle, and we have subtracted its rest energy. The replacements $\boldsymbol{P} \to -\mathrm{i}\hbar\nabla$ and $H \to \mathrm{i}\hbar\partial/\partial t$ lead to

$$\begin{aligned}\mathrm{i}\hbar\frac{\partial}{\partial t}\psi &= \left(\frac{1}{2m}\left(\mathrm{i}\hbar\nabla + \frac{q}{c}\boldsymbol{A}\right)^2 + q\varphi\right)\psi \\ &= \left(-\frac{\hbar^2}{2m}\nabla^2 + \frac{q^2}{2mc^2}A^2 \right.\\ &\quad \left. + \frac{i\hbar q}{2mc}\nabla\cdot\boldsymbol{A} + \frac{i\hbar q}{mc}\boldsymbol{A}\cdot\nabla + q\varphi\right)\psi \qquad [15]\end{aligned}$$

The gauge transformation [7a] and [7b] is a symmetry of this equation, if simultaneously to the change of the 4-potential, the wave function transforms as follows:

$$\psi(t, \boldsymbol{x}) \to \psi'(t, \boldsymbol{x}) = \mathrm{e}^{-(\mathrm{i}q/\hbar c)\Lambda}\,\psi(t, \boldsymbol{x}) \qquad [7c]$$

So, $\boldsymbol{A}'$ and $\psi'$ obey [15]. At each $(t, \boldsymbol{x})$, $\mathrm{e}^{-(\mathrm{i}q/\hbar c)\Lambda}$ belongs to U(1), the unit circle in the complex plane.

In the path-integral approach, the kernel $K(t', \boldsymbol{x}'; t, \boldsymbol{x})$, which gives the probability amplitude for the propagation of the particle from the spacetime point $(t, \boldsymbol{x})$ to the spacetime point $(t', \boldsymbol{x}')$ $(t < t')$, is given by

$$\begin{aligned}&K(t', \boldsymbol{x}'; t, \boldsymbol{x}) \\ &= \int_{\boldsymbol{x}(t)=\boldsymbol{x}}^{\boldsymbol{x}(t')=\boldsymbol{x}'} D\boldsymbol{x}(\tau)\exp\left(\frac{\mathrm{i}}{\hbar}(S_0 + S_{\text{int}})\right) \\ &= \int_{\boldsymbol{x}(t)=\boldsymbol{x}}^{\boldsymbol{x}(t')=\boldsymbol{x}'} D\boldsymbol{x}(\tau)\exp\left(\frac{\mathrm{i}}{\hbar}\int_t^{t'} \mathrm{d}\tau\left(\frac{1}{2}m\dot{x}^2 \right.\right.\\ &\quad \left.\left. + \frac{q}{c}\boldsymbol{A}\cdot\boldsymbol{v} - q\varphi\right)\right) \\ &= \int_{\boldsymbol{x}(t)=\boldsymbol{x}}^{\boldsymbol{x}(t')=\boldsymbol{x}'} D\boldsymbol{x}(\tau)\exp\left(\frac{\mathrm{i}}{\hbar}\int_t^{t'} \mathrm{d}\tau\frac{1}{2}m\dot{x}^2\right) \\ &\quad \times \exp\left(\frac{\mathrm{i}q}{\hbar c}\int_t^{t'}(\boldsymbol{A}\cdot\mathrm{d}\boldsymbol{x} - \varphi\,\mathrm{d}x^0)\right) \\ &= \int_{\boldsymbol{x}(t)=\boldsymbol{x}}^{\boldsymbol{x}(t')=\boldsymbol{x}'} D\boldsymbol{x}(\tau)\exp\left(\frac{\mathrm{i}}{\hbar}\int_t^{t'} \mathrm{d}\tau\frac{1}{2}m\dot{x}^2\right) \\ &\quad \times \exp\left(\frac{\mathrm{i}q}{\hbar c}\int_t^{t'}\mathrm{d}x^\mu A_\mu\right) \qquad [16]\end{aligned}$$

where the integral $\int D\boldsymbol{x}(\tau)\ldots$ is over all continuous spacetime paths $(\tau, \boldsymbol{x}(\tau))$ which join $(t, \boldsymbol{x})$ with $(t', \boldsymbol{x}')$. If one knows the wave function at $(t, \boldsymbol{x})$, then the wave function at $(t', \boldsymbol{x}')$ is given by

$$\psi(t', \boldsymbol{x}') = \int \mathrm{d}^3\boldsymbol{x}\; K(t', \boldsymbol{x}'; t, \boldsymbol{x})\psi(t, \boldsymbol{x}) \qquad [17]$$

An important point is the natural appearance in the integrand of the functional integral of the factor

$$\mathrm{e}^{(\mathrm{i}q/\hbar c)\int_\gamma A}$$

for each path $\gamma$ joining $(t, \boldsymbol{x})$ with $(t', \boldsymbol{x}')$.

## A Solution to the Schrödinger Equation

In what follows, we shall restrict ourselves to static magnetic fields; then in the previous formulas, we set $\varphi = 0$ and $\boldsymbol{A}(t, \boldsymbol{x}) = \boldsymbol{A}(\boldsymbol{x})$. It is then easy to show that if $\boldsymbol{x}_0$ is an arbitrary reference point and the integral $\int_{\boldsymbol{x}_0}^{\boldsymbol{x}} \boldsymbol{A}(\boldsymbol{x}')\cdot\mathrm{d}\boldsymbol{x}'$ is independent of the integration path from $\boldsymbol{x}_0$ to $\boldsymbol{x}$, that is, it is a well-defined function $f$ of $\boldsymbol{x}$, and if $\psi_0$ is a solution of the free Schrödinger equation, that is,

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\psi_0 = -\frac{\hbar^2}{2m}\nabla^2\psi_0 \qquad [18]$$

then

$$\psi(t, \boldsymbol{x}) = \exp\left(\frac{\mathrm{i}q}{\hbar c}\int_{\boldsymbol{x}_0}^{\boldsymbol{x}}\boldsymbol{A}(\boldsymbol{x}')\cdot\mathrm{d}\boldsymbol{x}'\right)\psi_0(t, \boldsymbol{x}) \qquad [19]$$

is a solution of [15]. In fact, replacing [19] in [15], the LHS gives

$$\exp\left(\frac{\mathrm{i}q}{\hbar c}f(\boldsymbol{x})\right)\mathrm{i}\hbar\frac{\partial}{\partial t}\psi_0$$

while for the RHS one has

$$\exp\left(\frac{\mathrm{i}q}{\hbar c}f(\boldsymbol{x})\right)\left(-\frac{\hbar^2}{2m}\right)\nabla^2\psi_0$$

The cancelation of the exponential factors shows that, under the condition of path independence, there is no effect of the potential on the charged particles. Another way to see this is by making a gauge transformation [7a]–[7c] with $\Lambda(\boldsymbol{x}) = f(\boldsymbol{x})$, which changes $\psi \to \psi_0$ and $\boldsymbol{A} \to \boldsymbol{A}' = \boldsymbol{A} - \nabla \int_{x_0}^{x} \boldsymbol{A}(\boldsymbol{x}') \cdot \mathrm{d}\boldsymbol{x}' = \boldsymbol{A} - \boldsymbol{A} = 0$.

The condition of path independence amounts, however, to the condition that no magnetic field is present since, if $\int_\gamma A$ depends on $\gamma$, then for some pair of paths $\gamma$ and $\gamma'$ from $(t, \boldsymbol{x})$ to $(t', \boldsymbol{x}')$, $0 \neq \int_\gamma A - \int_{\gamma'} A = \int_\gamma A + \int_{-\gamma'} A = \oint_{\gamma\cup(-\gamma')} A = \int_\Sigma \mathrm{d}\boldsymbol{\sigma} \cdot (\nabla \times \boldsymbol{A})$, where in the last equality we applied Stokes theorem ($\Sigma$ is any surface with boundary $\gamma \cup (-\gamma')$), which shows that $\boldsymbol{B} = \nabla \times \boldsymbol{A}$ must not vanish everywhere and has a nonzero flux $\Phi$ through $\Sigma$ given by

$$\Phi = \int_\Sigma \mathrm{d}\boldsymbol{\sigma} \cdot \boldsymbol{B} \qquad [20]$$

The conclusion of this section is that the ansatz [19] for solving [15] can only be applied in simply connected regions with no magnetic field strength present.

## Aharonov–Bohm Proposal

In 1959, Aharonov and Bohm proposed an experiment to test, in quantum mechanics, the coupling of electric charges to electromagnetic field strengths through a local interaction with the electromagnetic potential $A_\mu$, but not with the field strengths themselves. However, as we saw before, no physical effect exists, that is, $A_\mu$ can be gauged away, unless magnetic and/or electric fields exist somewhere, although not necessarily overlapping the wave function of the particles.

Consider the usual two-slit experiment as depicted in **Figure 1**, with the additional presence, behind the slits, of a long and narrow solenoid enclosing a nonvanishing magnetic flux $\Phi$ due to a constant and homogeneous magnetic field $\boldsymbol{B}$ normal to the plane of the figure (in direction $z$); outside of the solenoid, the magnetic field is zero. If the radius of the solenoid is $R$, a vector potential $\boldsymbol{A}$ that produces such field strength is given by

$$\boldsymbol{A}(\boldsymbol{x}) = \begin{cases} (|\boldsymbol{B}|r/2)\hat{\varphi}, & r \leq R \\ (\Phi/2\pi r)\hat{\varphi}, & r > R \end{cases} \qquad [21]$$

where $\Phi = \pi R^2 |\boldsymbol{B}|$ and $\hat{\varphi}$ is a unit vector in the azimuthal direction. In fact,

$$\boldsymbol{B} = \nabla \times \boldsymbol{A}(\boldsymbol{x}) = \begin{cases} |\boldsymbol{B}|\hat{z}, & r \leq R \\ 0, & r > R \end{cases} \qquad [22]$$

Notice that at $r = R$, $\boldsymbol{A}$ is continuous but not continuously differentiable. Also, the ideal limit of an infinitely long solenoid makes the problem two-dimensional, that is, in the $x$–$y$ plane.

The probability amplitude for an electron emitted at the source S to arrive at the point P on the screen $\Pi$, is given by the sum of two probability amplitudes, namely those corresponding to passing through the slits 1 and 2. The solenoid is assumed to be impenetrable to the electrons; mathematically, this corresponds to a motion in a non-simply-connected region. In the approximation for the path integral [16], in which one considers the contribution of only two classes of paths, that is, the class $\{\gamma\}$ represented by path I, and the class $\{\gamma'\}$ represented by path II, if the wave function at the source is $\psi_\mathrm{S}$, then the wave function at P is given by

$$\begin{aligned} \psi_\mathrm{P} &= \left( \int_{\{\gamma\}} \mathrm{e}^{(\mathrm{i}/\hbar)S_0(\gamma)} \mathrm{e}^{-(\mathrm{i}|e|/\hbar c)\int_\gamma A} \right. \\ &\quad \left. + \int_{\{\gamma'\}} \mathrm{e}^{(\mathrm{i}/\hbar)S_0(\gamma')} \mathrm{e}^{-(\mathrm{i}|e|/\hbar c)\int_{\gamma'} A} \right) \psi_\mathrm{S} \\ &= \mathrm{e}^{-(\mathrm{i}|e|/\hbar c)\int_\mathrm{I} A} \int_{\{\gamma\}} \mathrm{e}^{(\mathrm{i}/\hbar)S_0(\gamma)} \psi_\mathrm{S} \\ &\quad + \mathrm{e}^{-(\mathrm{i}|e|/\hbar c)\int_\mathrm{II} A} \int_{\{\gamma'\}} \mathrm{e}^{(\mathrm{i}/\hbar)S_0(\gamma')} \psi_\mathrm{S} \\ &= \mathrm{e}^{-(\mathrm{i}|e|/\hbar c)\int_\mathrm{I} A} \left( \psi_\mathrm{P}^0(\mathrm{I}) \right. \\ &\quad \left. + \mathrm{e}^{-(\mathrm{i}|e|/\hbar c)\left(\int_{\mathrm{II}\cup(-\mathrm{I})} A\right)} \psi_\mathrm{P}^0(\mathrm{II}) \right) \\ &= \mathrm{e}^{-(\mathrm{i}|e|/\hbar c)\int_\mathrm{I} A} \left( \psi_\mathrm{P}^0(\mathrm{I}) + \mathrm{e}^{-2\pi\mathrm{i}(\Phi/\Phi_0)} \psi_\mathrm{P}^0(\mathrm{II}) \right) \end{aligned} \qquad [23]$$

where, in the second line, we used the path independence of the integral of $A$ within each class of paths;

$$\psi_\mathrm{P}^0(\mathrm{I}) = \int_{\{\gamma\}} \mathrm{e}^{(\mathrm{i}/\hbar)\int_{\{\gamma\}} S_0(\gamma)} \psi_\mathrm{S}$$

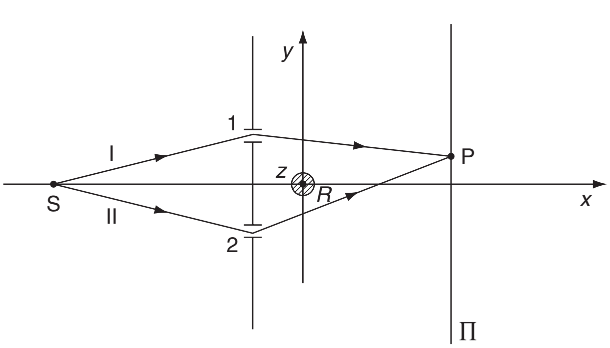

**Figure 1** Magnetic Aharonov–Bohm effect.

and

$$\psi_P^0(\mathrm{II}) = \int_{\{\gamma'\}} e^{(i/\hbar)S_0(\gamma')}\psi_S$$

and, in the last equality, we applied the extended version of Stokes theorem (by Craven), to allow for noncontinuously differentiable vector potentials; and the quantum of magnetic flux associated with the charge $|e|$ is defined by

$$\Phi_0 = 2\pi\frac{\hbar c}{|e|} \cong 4.135 \times 10^{-7}\,\mathrm{G\,cm^2} \qquad [24]$$

($=2\pi/|e| = \sqrt{\pi/\alpha} \cong \sqrt{137\pi}$ in the natural system of units (n.s.u.) $\hbar = c = 1$; $\alpha$ is the fine structure constant). Then the probability of finding the electron at P is proportional to

$$|\psi_P|^2 = |\psi_P^0(\mathrm{I})|^2 + |\psi_P^0(\mathrm{II})|^2 + 2\mathrm{Re}\left(e^{2\pi i(\Phi/\Phi_0)}\psi_P^0(\mathrm{I})\psi_P^0(\mathrm{II})^*\right) \qquad [25]$$

which exhibits an interference pattern shifted with respect to that without the magnetic field: as $\boldsymbol{B}$ and therefore $\Phi$ change, dark and bright interference fringes alternate periodically at the screen $\Pi$, with period $\Phi_0$. This is the magnetic A–B effect, which has been quantitatively verified in many experiments, the first one in 1960 by Chambers. The effect is:

1. *gauge invariant*, since $\boldsymbol{B}$ and therefore $\Phi$ are gauge invariant;
2. *nonlocal*, since it depends on the magnetic field inside the solenoid, where the electrons never enter;
3. *quantum mechanical*, since classically the charges do not feel any force and therefore no effect would be expected in this limit; and
4. *topological*, since the electrons necessarily move in a non-simply-connected space.

But perhaps the most important implication of the A–B effect is a dramatic additional confirmation of the nonlocal character of quantum mechanics: the electron has to "travel" along the two paths (I and II) simultaneously; on the contrary, no flux would be surrounded and then no shift of the (then nonexistent) interference fringes would be observed at the screen $\Pi$.

Calculations in the path-integral approach including the whole set of homotopy classes of paths around the solenoid, indexed by an integer $m$, have been performed by several authors, leading to a formula of the type

$$\psi_P = \sum_{m=-\infty}^{\infty} e^{-im\delta}\psi_P^0(m) \qquad [26]$$

with

$$\delta = 2\pi\frac{\Phi}{\Phi_0} \qquad [27]$$

(Schulman 1971, Kobe 1979). As in [23],

$$\psi_P(\Phi + k\Phi_0) = \psi_P(\Phi), \quad k \in \mathbb{Z} \qquad [28]$$

There is a close relation between the A–B effect and the Dirac quantization condition (DQC) in the presence of electric and magnetic charges: according to [25] (or [26]) the A–B effect disappears when the flux $\Phi$ equals $n\Phi_0 = 2\pi n(\hbar c/|e|)$, $n \in \mathbb{Z}$, that is, when the condition

$$|e|\Phi = nhc \qquad [29]$$

holds. But this is the DQC (Dirac 1931) when $\Phi$ is the flux associated with a magnetic charge $g$: $\Phi(g) = (g/4\pi r^2) \times 4\pi r^2 = g$, leading to $|e|g = nhc$ ($2\pi n$ in the n.s.u.). This is precisely the condition for the Dirac string to be unobservable in quantum mechanics: to give no A–B effect.

## Geometry of the A–B Effect

In this section we study the space of gauge classes of flat potentials outside the solenoid, which determine the A–B effect; the topological structure of the A–B bundle; and the holonomy groups of the connections, which precisely give the phase shifts of the wave functions. We use the n.s.u. system; in particular, if [L] is the unit of length, then $[A_\mu] = [\mathrm{L}]^{-1}$, $[|e|] = [\mathrm{L}]^0$, and $\Phi_0 = 2\pi/|e| = \sqrt{\pi/\alpha} \cong \sqrt{137\pi}$, where $\alpha$ is the fine structure constant.

To synthesize, one can say that *the abelian A–B effect is a nonlocal gauge-invariant quantum effect due to the coupling of the wave function (section of an associated bundle) to a nontrivial (non-exact) flat (closed) connection in a trivial principal bundle with a non-simply-connected base space*. In the following subsections, we will give a detailed explanation of these statements.

### The A–B Bundle

The gauge group of electromagnetism is the abelian Lie group U(1) with Lie algebra (the tangent space at the identity) $u(1) = i\mathbb{R}$. In the limit of an infinitely long and infinitesimally thin solenoid carrying the magnetic flux $\Phi$, the space available to the electrons is the plane minus a point, that is, $\mathbb{R}^{2*}$, which is of the same homotopy type as the circle $S^1$. Then the set of isomorphism classes of U(1) bundles over $\mathbb{R}^{2*}$ is in one-to-one correspondence with the set of homotopy classes of maps from $S^0$ to $S^1$ (Steenrod 1951), which consists of only one point: if $f, g$:

$S^0 \to S^1$ are given by $f(1) = e^{i\varphi_1}$, $f(-1) = e^{i\varphi_2}$, $g(1) = e^{i\theta_1}$, and $g(-1) = e^{i\theta_2}$, then $H : S^0 \times [0,1] \to S^1$ given by $H(1,t) = e^{i((1-t)\varphi_1 + t\theta_1)}$ and $H(-1,t) = e^{i((1-t)\varphi_2 + t\theta_2)}$ is a homotopy between $f$ and $g$. Then, up to equivalence, the relevant bundle for the A–B effect is the product bundle

$$\xi_{A-B} : U(1) \to \mathbb{R}^{2*} \times U(1) \to \mathbb{R}^{2*} \qquad [30a]$$

Since $\mathbb{R}^{2*}$ is homeomorphic to an open disk minus a point $(D_0^2)^*$, then the total space of the bundle is homeomorphic to an open solid 2-torus minus a circle, since $(T_0^2)^* = (D_0^2)^* \times S^1$. Then the A–B bundle has the topological structure

$$\xi_{A-B} : S^1 \to (T_0^2)^* \to (D_0^2)^* \qquad [30b]$$

### The Gauge Group and the Moduli Space of Flat Connections

The gauge group of the bundle $\xi_{A-B}$ is the set of smooth functions from the base space to the structure group, that is, $\mathcal{G} = C^\infty(\mathbb{R}^{2*}, U(1))$. Since $\mathcal{G} \subset C^0(\mathbb{R}^{2*}, U(1)) = \{\text{continuous functions } \mathbb{R}^{2*} \to U(1)\}$ and $[\mathbb{R}^{2*}, U(1)] = \{\text{homotopy classes of continuous functions } \mathbb{R}^{2*} \to U(1)\} \cong [S^1, S^1] \cong \pi_1(S^1) \cong \mathbb{Z}$, given $f \in \mathcal{G}$ there exists a unique $n \in \mathbb{Z}$ such that $f$ is homotopic to $f_n (f \sim f_n)$, where $f_n : \mathbb{R}^{2*} \to U(1)$ is given by $f_n(re^{i\varphi}) = e^{in\varphi}$, $\varphi \in [0, 2\pi)$.

$\mathcal{G}$ acts on the space of flat connections on $\xi_{A-B}$ given by the closed $u(1)$-valued differential 1-forms on $\mathbb{R}^{2*}$:

$$\mathcal{C}_0 = \{\mathcal{A} \in \Omega^1(\mathbb{R}^{2*}; u(1)), d\mathcal{A} = 0\} \qquad [31]$$

through

$$\mathcal{C}_0 \times \mathcal{G} \to \mathcal{C}_0, \quad (\mathcal{A}, f) \to \mathcal{A} + f^{-1}df \qquad [32]$$

where $f^{-1}(x,y) = (f(x,y))^{-1}$. The moduli space

$$\mathcal{M}_0 = \frac{\mathcal{C}_0}{\mathcal{G}} = \{\text{gauge equivalence classes of flat connections on } \xi_{A-B}\} = \{[\mathcal{A}] = \{\mathcal{A} + f^{-1}df,\ f \in \mathcal{G}\}, \mathcal{A} \in \mathcal{C}_0\} \qquad [33]$$

is isomorphic to the circle $S^1$ with length 1. This can be seen as follows: the de Rham cohomology of $\mathbb{R}^{2*}$ with coefficients in $i\mathbb{R}$ in dimension 1 is

$$H^1_{DR}(\mathbb{R}^{2*}; i\mathbb{R}) = \{\lambda[\mathcal{A}_0]_{DR}, \lambda \in \mathbb{R}\} \cong H^1_{DR}(S^1; i\mathbb{R}) \cong \mathbb{R} \qquad [34]$$

where

$$\mathcal{A}_0 = i\frac{x\,dy - y\,dx}{x^2 + y^2} \in \mathcal{C}_0 \qquad [35]$$

is the connection that, once multiplied by $-|e|^{-1}$ (see below) generates the flux $-\Phi_0$ and therefore no A–B effect: $\mathcal{A}_0$ is closed ($d\mathcal{A}_0 = 0$) but not exact ($(x\,dy - y\,dx)/(x^2+y^2) = d\varphi$ only for $\varphi \in (0, 2\pi)$, $\varphi = 0$ is excluded); $[\mathcal{A}_0]_{DR} = \mathcal{A}_0 + d\beta$ with $\beta \in \Omega^0(R^{2*}; i\mathbb{R})$. $\beta$ gives an element of $\mathcal{G}$ through the composite $\exp \circ \beta : \mathbb{R}^{2*} \to U(1), (x,y) \mapsto e^{i\beta(x,y)}$. The A–B effect with flux $\Phi = -\lambda\Phi_0$ is produced by the connection $\mathcal{A} = \lambda\mathcal{A}_0$. To determine $\mathcal{M}_0$, one finds the smallest $\sigma \in \mathbb{R}$ such that $(\lambda + \sigma)\mathcal{A}_0 \sim \lambda\mathcal{A}_0$, that is, $(\lambda+\sigma)\mathcal{A}_0 \in [\lambda\mathcal{A}_0]$, which means, from [33], that $(\lambda+\sigma)\mathcal{A}_0 = \lambda\mathcal{A}_0 + f^{-1}df$ or $\sigma\mathcal{A}_0 = f^{-1}df$. For $\varphi \neq 0$, $\mathcal{A}_0 = i d\varphi$ and $f_1^{-1}df_1 = i d\varphi$, then $\sigma = 1$, and therefore $(\lambda+1)\mathcal{A}_0 \sim \lambda\mathcal{A}_0$, in particular $\mathcal{A}_0 \sim 0$.

A remark concerning the gauge group $\mathcal{G}$ is the following. In classical electrodynamics, according to [7a] and [7b], the symmetry group could be taken to be the additive group $(\mathbb{R}, +)$ instead of the multiplicative group U(1). Since $\mathbb{R}$ is contractible, then the gauge group would be $\mathcal{G}_{cl} = C^\infty(\mathbb{R}^{2*}, \mathbb{R})$ with $[\mathbb{R}^{2*}, \mathbb{R}] \cong 0$, so that the homomorphism $\Psi : \mathcal{G}_{cl} \to \mathcal{G}$, $\Psi(f)(x) = e^{if(x)}$ would not exhaust $\mathcal{G}$ since $\Psi(f) \in [1]$ for any $f \in \mathcal{G}_{cl}$: in fact, $H : \mathbb{R}^{2*} \times [0,1] \to U(1)$ given by $H(x,t) = e^{i(1-t)f(x)}$ is a homotopy between $\Psi(f)$ and 1. However, the quantization of electric charges implies that in fact the gauge group is U(1) and not $\mathbb{R}$. This is equivalent mathematically to the possible existence of magnetic monopoles which require nontrivial bundles for their description.

### Covariant Derivative, Parallel Transport, and Holonomy

Let $G$ be a matrix Lie group with Lie algebra $\boldsymbol{g}$, $B$ a differentiable manifold, $\xi : G \to P \xrightarrow{\pi} B$ a principal bundle, $V$ a vector space, $G \times V \to V$ an action, and $\xi_V : V \to P \times_G V \xrightarrow{\pi_V} B$ the corresponding associated vector bundle ($\xi_V$ is trivial if $\xi$ is trivial). Call $\Gamma(\xi_V)$ the sections of $\xi_V$, $\Gamma(TB)(\Gamma(TP))$ the sections of the tangent bundle of $B(P)$, and $\Gamma_{eq}(P, V)$ the set of functions $\gamma : P \to V$ satisfying $\gamma(pg) = g^{-1}\gamma(p)$ (equivariant functions from $P$ to $V$). $s \in \Gamma(\xi_V)$ induces $\gamma_s \in \Gamma_{eq}(P,V)$ with $\gamma_s(p) = v$, where $s(\pi(p)) = [p, v]$ and $\gamma \in \Gamma_{eq}(P,V)$ induces $s_\gamma \in \Gamma(\xi_V)$ with $s_\gamma(b) = [p, \gamma(p)]$, where $p \in \pi^{-1}(\{b\})$. If $H$ is a connection on $\xi$, that is, a smooth assignment of a (horizontal) vector subspace $H_p$ of $T_pP$ at each $p$ of $P$, algebraically determined by a smooth $\boldsymbol{g}$-valued 1-form $\omega$ on $P$ through $H_p = \ker(\omega_p)$, $s \in \Gamma(\xi_V)$, $X \in \Gamma(TB)$, and $X^\uparrow \in \Gamma(TP)$ the horizontal lifting of $X$ by $\omega$, then $X^\uparrow(\gamma_s) \in \Gamma_{eq}(P,V)$, and covariant

derivative of $s$ with respect to $\omega$ in the direction of $X$ is defined by

$$\nabla_X^\omega s := s_{X\uparrow(\gamma_s)} \quad [36a]$$

If $\phi:\pi^{-1}(U) \to U \times G$ is a local trivialization of $\xi$, $x^\mu$, $\mu = 1, \ldots, \dim B$ are local coordinates on $U$, and $e_i$, $i = 1, \ldots, \dim V$ is a basis of the local sections in $\pi_V^{-1}(U)$, then the local expression of [36a] is

$$\nabla^{\omega_U}_{X^\mu\partial/\partial x^\mu}(s^i e_i) = X^\mu\left(\delta_i^j \frac{\partial}{\partial x^\mu} + \mathcal{A}^j_{\mu i}\right)s^i e_j \quad [36b]$$

where

$$\mathcal{A}_{U_i}^{\ j} = \mathcal{A}^j_{\mu i}\mathrm{d}x^\mu = (\sigma^*\omega_U)^j_i \quad [36c]$$

is the geometrical gauge potential in $U$, given by the pullback of $\omega_U$, the restriction of $\omega$ to $\pi^{-1}(U)$, by the local section $\sigma: U \to \pi^{-1}(U)$, $\sigma(b) = \phi^{-1}(b,1)$. ($\mathcal{A}^j_{\mu i}$ is defined through $\nabla^{\omega_U}_{\partial/\partial x^\mu} e_i = \mathcal{A}^j_{\mu i} e_j$.) The operator

$$D^j_{\mu i} = \delta^j_i \frac{\partial}{\partial x^\mu} + \mathcal{A}^j_{\mu i} \quad [36d]$$

is the usual local covariant derivative. In an overlapping trivialization, [36b] is replaced by

$$\nabla^{\omega_{U'}}_{X^\mu\partial/\partial x^\mu}(s'^i e'_i) = X^\mu\left(\delta_i^j \frac{\partial}{\partial x^\mu} + \mathcal{A}'^j_{\mu i}\right)s'^i e'_j$$

with $e'_j = g^k_j e_k$ and $s'^i = g^{-1}{}^i_l s^l$ on $U \cap U'$, then the local potential transforms as

$$\mathcal{A}^j_{\mu l} = g^j_k \mathcal{A}'^k_{\mu i} g^{-1}{}^i_l + (\partial_\mu g^j_k) g^{-1}{}^k_l \quad [36e]$$

which for $G$ abelian has the form [32].

For each smooth path $c:[0,1] \to B$ joining the points $b$ and $b'$, and each $p \in P_b = \pi^{-1}(\{b\})$, there exists a unique path $c^\uparrow$ in $P$ through $p$ with $\dot{c}^\uparrow(t) \in H_{c(t)}$ for all $t \in [0,1]$. $c^\uparrow$ is the horizontal lifting of $c$ by $\omega$ through $p$. Thus, for each connection and path there exists a diffeomorphism $P^\omega_c: P_b \to P_{b'}$ called parallel transport. If $c$ is a loop at $b$, then $P^\omega_c \in \mathrm{Diff}(P_b)$ is called the holonomy of $\omega$ at $b$ along $c$. To the loop space of $B$ at $b$, $\Omega(B;b)$, corresponds a subgroup $\mathrm{Hol}^\omega_b$ of $\mathrm{Diff}(P_b)$ called the holonomy of $\omega$ at $b$. If $c \in \Omega(B;b)$ and $\beta$ is a lifting of $c$ through $q \in P_b$, then there exists a unique path $g:[0,1] \to G$ such that $c^\uparrow(t) = \beta(t)g(t)$ with $c^\uparrow(0) = qg(0) = p$; $g$ satisfies the differential equation

$$\frac{\mathrm{d}}{\mathrm{d}t} g(t) + \omega_{\beta(t)}(\dot{\beta}(t)) = 0 \quad [37]$$

whose solution is the time-ordered exponential

$$\begin{aligned} g(t)g(0)^{-1} &= T\exp\left(\int_0^t \mathrm{d}\tau\, \omega_{\beta(\tau)}(\dot{\beta}(\tau))\right) \\ &= 1 + \sum_{m=1}^\infty (-1)^m \int_0^t \mathrm{d}\tau_1 \omega_{\beta(\tau_1)}(\dot{\beta}(\tau_1)) \\ &\quad \times \int_0^{\tau_1} \mathrm{d}\tau_2 \omega_{\beta(\tau_2)}(\dot{\beta}(\tau_2)) \cdots \\ &\quad \times \int_0^{\tau_{m-1}} \mathrm{d}\tau_m \omega_{\beta(\tau_m)}(\dot{\beta}(\tau_m)) \end{aligned} \quad [38]$$

If $q = p$ then $g(0) = 1$. For each $p \in P$, the set of elements $g' \in G$ such that $c^\uparrow(1) = pg'$ for $c \in \Omega(B;\pi(p))$ is a subgroup of $G$, $\mathrm{Hol}^\omega_p$, called the holonomy *of* $\omega$ at $p$. (For each $p$, there exists a group isomorphism $\mathrm{Hol}^\omega_p \to \mathrm{Hol}^\omega_{\pi(p)}$, and if $p$ and $p'$ are connected by a horizontal curve, then $\mathrm{Hol}^\omega_p = \mathrm{Hol}^\omega_{p'}$; if all $p'$s in $P$ are horizontally connected, then $\mathrm{Hol}^\omega_p = G$ for all $p \in P$.) If $(U,\phi)$ is a local trivialization of $\xi$, $c \subset U$, and $\beta(t) = \sigma(c(t))$, then one has the local formula

$$c^\uparrow(t) = \phi^{-1}(c(t),1)\left(T\exp\left(-\int_{c(0)}^{c(t)} \mathcal{A}_U\right)\right)g(0) \quad [39]$$

In particular, if $\xi$ is a product bundle, then $\phi$ is the identity, and choosing $g(0)=1$ gives

$$c^\uparrow(t) = \left(c(t), T\exp\left(-\int_{c(0)}^{c(t)} \mathcal{A}_U\right)\right) \quad [40]$$

In our case, $V = \mathbb{C}$, $\xi$ is a product bundle, $s = \psi$, the wave function, is a global section of the associated bundle

$$\xi_\mathbb{C}: \mathbb{C} \to \mathbb{R}^{2*} \times \mathbb{C} \xrightarrow{\pi_\mathbb{C}} \mathrm{R}^{2*} \quad [41]$$

$G = \mathrm{U}(1)$ with $\boldsymbol{g} = \mathrm{i}\mathbb{R}$ and an action $\mathrm{U}(1) \times \mathbb{C} \to \mathbb{C}$, $(\mathrm{e}^{\mathrm{i}\varphi}, z) \mapsto \mathrm{e}^{\mathrm{i}\varphi} z$; therefore, $\mathcal{A}_\mu = \mathcal{A}_{0\mu} = \mathrm{i}a_\mu$ with $a_\mu$ real valued, and the covariant derivative is

$$D_\mu\psi = \left(\frac{\partial}{\partial x_\mu} + \mathrm{i}a_\mu\right)\psi \quad [36f]$$

If $\psi$ carries the electric charge $q$, we define the physical gauge potential $A_\mu$ through

$$a_\mu = qA_\mu \quad [42]$$

and, for the covariant derivative, after multiplying by i, we obtain the operator appearing in eqn [15], $\mathrm{i}D_\mu\psi = (\mathrm{i}(\partial/\partial x^\mu) - qA_\mu)\psi$: in fact, for the spatial part the coupling is $(\mathrm{i}\nabla + q\boldsymbol{A})\psi$, and for the temporal part one has $(\mathrm{i}\partial/\partial t - q\varphi)\psi$. For the electron, $q = -|e|$ and $a_\mu = -|e|A_\mu = -(2\pi/\Phi_0)A_\mu$.

For $c \in \Omega(\mathbb{R}^{2*};(x_0, y_0))$, which turns $n$ times around the solenoid at $(0, 0)$, eqn [40] gives

$$c^{\uparrow} = ((x_0, y_0), e^{-n \oint_c A}) = ((x_0, y_0), e^{-in \oint_c a}) \\ = ((x_0, y_0), e^{-i|e|n \oint_c A \cdot dx}) = ((x_0, y_0), e^{-2\pi i n \Phi/\Phi_0})$$

and therefore, for $\Phi/\Phi_0 = \lambda \in [0, 1)$ we have the holonomy groups

$$\mathrm{Hol}^{\omega(\Phi)}_{((x_0,y_0),1)} = \{e^{-2\pi i n(\Phi/\Phi_0)}\}_{n\in\mathbb{Z}} = \begin{cases} \mathbb{Z}_q, & \lambda = p/q,\ p, q \in \mathbb{Z},\ (p, q) = 1 \\ \mathbb{Z}, & \lambda \notin \mathbb{Q} \end{cases} \quad [43]$$

In the second case, $\mathrm{Hol}^{\omega(\Phi)}_{((x_0,y_0),1)}$ is dense in U(1): in fact, suppose that for $n_1, n_2 \in \mathbb{Z}$, $n_1 \neq n_2$, $e^{2\pi i n_1 \lambda} = e^{2\pi i n_2 \lambda}$, then $e^{2\pi i (n_1 - n_2)\lambda} = 1$ and so $(n_1 - n_2)\lambda = m$ for some $m \in \mathbb{Z}$; therefore, $\lambda \in \mathbb{Q}$, which is a contradiction.

Finally, we should mention that the A–B effect can be understood as a geometric phase *à la* Berry, though not necessarily through an adiabatic change of the parameters on which the Hamiltonian depends. The Berry potential $a_B$ turns out to be proportional to the real magnetic vector potential $\boldsymbol{A}$: in the n.s.u., and for electrons,

$$a_B = -|e|\boldsymbol{A} \quad [44]$$

### Nonabelian and Gravitational A–B Effects

Since the fundamental group $\Pi_1(\mathbb{R}^{2*}, (x_0, y_0)) \cong \mathbb{Z}$, eqn [43] shows that there is a homomorphism $\varphi(\omega)$: $\Pi_1(\mathbb{R}^{2*}, (x_0, y_0)) \to U(1)$, $\varphi(\omega)(n) = e^{-2\pi i n \lambda}$, with $\varphi(\omega)\ (\Pi_1(\mathbb{R}^{2*})) = \mathrm{Hol}^{\omega(\Phi)}_{((x_0,y_0),1)}$, which characterizes the A–B effect in that case. In general, an A–B effect in a $G$-bundle with a connection $\omega$ is characterized by a group homomorphism from the fundamental group of the base space $B$ onto the holonomy group of the connection, which is a subgroup of the structure group. The A–B effect is nonabelian if the holonomy group is nonabelian, which requires both $G$ and $\Pi_1(B, \boldsymbol{x})$ to be nonabelian. Examples with Yang–Mills and gravitational fields are considered in the literature.

# Algebraic Approach to Quantum Field Theory

**R Brunetti and K Fredenhagen**, Universität Hamburg, Hamburg, Germany

### Introduction

Quantum field theory may be understood as the incorporation of the principle of locality, which is at the basis of classical field theory, into quantum physics. There are, however, severe obstacles against a straightforward translation of concepts of classical field theory into quantum theory, among them the notorious divergences of quantum field theory and the intrinsic nonlocality of quantum physics. Therefore, the concept of locality is somewhat obscured in the formalism of quantum field theory as it is typically exposed in textbooks. Nonlocal concepts such as the vacuum, the notion of particles or the $S$-matrix play a fundamental role, and neither the

relation to classical field theory nor the influence of background fields can be properly treated.

Algebraic quantum field theory (AQFT; synonymously, local quantum physics), on the contrary, aims at emphasizing the concept of locality at every instance. As the nonlocal features of quantum physics occur at the level of states ("entanglement"), not at the level of observables, it is better not to base the theory on the Hilbert space of states but on the algebra of observables. Subsystems of a given system then simply correspond to subalgebras of a given algebra. The locality concept is abstractly encoded in a notion of independence of subsystems; two subsystems are independent if the algebra of observables which they generate is isomorphic to the tensor product of the algebras of the subsystems.

Spacetime can then – in the spirit of Leibniz – be considered as an ordering device for systems. So, one associates with regions of spacetime the algebras of observables which can be measured in the pertinent region, with the condition that the algebras of subregions of a given region can be identified with subalgebras of the algebra of the region.

Problems arise if one aims at a generally covariant approach in the spirit of general relativity. Then, in order to avoid pitfalls like in the "hole problem," systems corresponding to isometric regions must be isomorphic. Since isomorphic regions may be embedded into different spacetimes, this amounts to a simultaneous treatment of all spacetimes of a suitable class. We will see that category theory furnishes such a description, where the objects are the systems and the morphisms the embeddings of a system as a subsystem of other systems.

States arise as secondary objects via Hilbert space representations, or directly as linear functionals on the algebras of observables which can be interpreted as expectation values and are, therefore, positive and normalized. It is crucial that inequivalent representations ("sectors") can occur, and the analysis of the structure of the sectors is one of the big successes of AQFT. One can also study the particle interpretation of certain states as well as (equilibrium and nonequilibrium) thermodynamical properties.

The mathematical methods in AQFT are mainly taken from the theory of operator algebras, a field of mathematics which developed in close contact to mathematical physics, in particular to AQFT. Unfortunately, the most important field theories, from the point of view of elementary particle physics, as quantum electrodynamics or the standard model could not yet be constructed beyond formal perturbation theory with the annoying consequence that it seemed that the concepts of AQFT could not be applied to them. However, it has recently been shown that formal perturbation theory can be reshaped in the spirit of AQFT such that the algebras of observables of these models can be constructed as algebras of formal power series of Hilbert space operators. The price to pay is that the deep mathematics of operator algebras cannot be applied, but the crucial features of the algebraic approach can be used.

AQFT was originally proposed by Haag as a concept by which scattering of particles can be understood as a consequence of the principle of locality. It was then put into a mathematically precise form by Araki, Haag, and Kastler. After the analysis of particle scattering by Haag and Ruelle and the clarification of the relation to the Lehmann–Symanzik–Zimmermann (LSZ) formalism by Hepp, the structure of superselection sectors was studied first by Borchers and then in a fundamental series of papers by Doplicher, Haag, and Roberts (DHR) (see, e.g., Doplicher *et al.* (1971, 1974)) (soon after Buchholz and Fredenhagen established the relation to particles), and finally Doplicher and Roberts uncovered the structure of superselection sectors as the dual of a compact group thereby generalizing the Tannaka–Krein theorem of characterization of group duals.

With the advent of two-dimensional conformal field theory, new models were constructed and it was shown that the DHR analysis can be generalized to these models. Directly related to conformal theories is the algebraic approach to holography in anti-de Sitter (AdS) spacetime by Rehren.

The general framework of AQFT may be described as a covariant functor between two categories. The first one contains the information on local relations and is crucial for the interpretation. Its objects are topological spaces with additional structures (typically globally hyperbolic Lorentzian spaces, possibly spin bundles with connections, etc.), its morphisms being the structure-preserving embeddings. In the case of globally hyperbolic Lorentzian spacetimes, one requires that the embeddings are isometric and preserve the causal structure. The second category describes the algebraic structure of observables. In quantum physics the standard assumption is that one deals with the category of $C^*$-algebras where the morphisms are unital embeddings. In classical physics, one looks instead at Poisson algebras, and in perturbative quantum field theory one admits algebras which possess nontrivial representations as formal power series of Hilbert space operators. It is the leading principle of AQFT that the functor $\mathscr{A}$ contains all physical information. In particular, two theories are equivalent if the corresponding functors are naturally equivalent.

In the analysis of the functor $\mathscr{A}$, a crucial role is played by natural transformations from other functors on the locality category. For instance, a field $A$ may be defined as a natural transformation from the category of test function spaces to the category of observable algebras via their functors related to the locality category.

## Quantum Field Theories as Covariant Functors

The rigorous implementation of the generally covariant locality principle uses the language of category theory.

The following two categories are used:

**Loc**: The class of objects obj(**Loc**) is formed by all (smooth) $d$-dimensional ($d \geq 2$ is held fixed), globally hyperbolic Lorentzian spacetimes $M$ which are oriented and time oriented. Given any two such objects $M_1$ and $M_2$, the morphisms $\psi \in \hom_{\mathbf{Loc}}(M_1, M_2)$ are taken to be the isometric embeddings $\psi: M_1 \to M_2$ of $M_1$ into $M_2$ but with the following constraints:

(i) if $\gamma: [a, b] \to M_2$ is any causal curve and $\gamma(a), \gamma(b) \in \psi(M_1)$ then the whole curve must be in the image $\psi(M_1)$, that is, $\gamma(t) \in \psi(M_1)$ for all $t \in [a, b]$;

(ii) any morphism preserves orientation and time orientation of the embedded spacetime. The composition is defined as the composition of maps, the unit element in $\hom_{\mathbf{Loc}}(M, M)$ is given by the identical embedding $\mathrm{id}_M : M \mapsto M$ for any $M \in \mathrm{obj}(\mathbf{Loc})$.

**Obs**: The class of objects obj(**Obs**) is formed by all $C^*$-algebras possessing unit elements, and the morphisms are faithful (injective) unit-preserving $*$-homomorphisms. The composition is again defined as the composition of maps, the unit element in $\hom_{\mathbf{Obs}}(\mathcal{A}, \mathcal{A})$ is for any $\mathcal{A} \in \mathrm{obj}(\mathbf{Obs})$ given by the identical map $\mathrm{id}_{\mathcal{A}} : A \mapsto A, A \in \mathcal{A}$.

The categories are chosen for definitiveness. One may envisage changes according to particular needs, as, for instance, in perturbation theory where instead of $C^*$-algebras general topological $*$-algebras are better suited. Or one may use von Neumann algebras, in case particular states are selected. On the other hand, one might consider for **Loc** bundles over spacetimes, or (in conformally invariant theories) admit conformal embeddings as morphisms. In case one is interested in spacetimes which are not globally hyperbolic, one could look at the globally hyperbolic subregions (where one needs to be careful about the causal convexity condition (i) above).

The concept of locally covariant quantum field theory is defined as follows.

**Definition 1**

(i) A locally covariant quantum field theory is a covariant functor $\mathscr{A}$ from **Loc** to **Obs** and (writing $\alpha_\psi$ for $\mathscr{A}(\psi)$) with the covariance properties

$$\alpha_{\psi'} \circ \alpha_\psi = \alpha_{\psi' \circ \psi}, \qquad \alpha_{\mathrm{id}_M} = \mathrm{id}_{\mathscr{A}(M)}$$

for all morphisms $\psi \in \hom_{\mathbf{Loc}}(M_1, M_2)$, all morphisms $\psi' \in \hom_{\mathbf{Loc}}(M_2, M_3)$, and all $M \in \mathrm{obj}(\mathbf{Loc})$.

(ii) A locally covariant quantum field theory described by a covariant functor $\mathscr{A}$ is called "causal" if the following holds: whenever there are morphisms $\psi_j \in \hom_{\mathbf{Loc}}(M_j, M), j = 1, 2$, so that the sets $\psi_1(M_1)$ and $\psi_2(M_2)$ are causally separated in $M$, then one has

$$\left[\alpha_{\psi_1}(\mathscr{A}(M_1)), \alpha_{\psi_2}(\mathscr{A}(M_2))\right] = \{0\}$$

where the element-wise commutation makes sense in $\mathscr{A}(M)$.

(iii) One says that a locally covariant quantum field theory given by the functor $\mathscr{A}$ obeys the "time-slice axiom" if

$$\alpha_\psi(\mathscr{A}(M)) = \mathscr{A}(M')$$

holds for all $\psi \in \hom_{\mathbf{Loc}}(M, M')$ such that $\psi(M)$ contains a Cauchy surface for $M'$.

Thus, a quantum field theory is an assignment of $C^*$-algebras to (all) globally hyperbolic spacetimes so that the algebras are identifiable when the spacetimes are isometric, in the indicated way. This is a precise description of the generally covariant locality principle.

## The Traditional Approach

The traditional framework of AQFT, in the Araki–Haag–Kastler sense, on a fixed globally hyperbolic spacetime can be recovered from a locally covariant quantum field theory, that is, from a covariant functor $\mathscr{A}$ with the properties listed above.

Indeed, let $M$ be an object in obj(**Loc**). $\mathcal{K}(M)$ denotes the set of all open subsets in $M$ which are relatively compact and also contain, with each pair of points $x$ and $y$, all $\boldsymbol{g}$-causal curves in $M$ connecting $x$ and $y$ (cf. condition (i) in the definition of **Loc**). $O \in \mathcal{K}(M)$, endowed with the metric of $M$ restricted to $O$ and with the induced orientation and time orientation, is a member of obj(**Loc**), and the injection map $\iota_{M,O} : O \to M$, that is, the identical map restricted to $O$, is an element in $\hom_{\mathbf{Loc}}(O, M)$.

With this notation, it is easy to prove the following assertion:

**Theorem 1** *Let $\mathscr{A}$ be a covariant functor with the above-stated properties, and define a map $\mathcal{K}(M) \ni O \mapsto \mathcal{A}(O) \subset \mathscr{A}(M)$ by setting*

$$\mathcal{A}(O) := \alpha_{\iota_{M,O}}(\mathscr{A}(O))$$

*Then the following statements hold*:

(i) *The map fulfills isotony, that is,*

$$O_1 \subset O_2 \Rightarrow \mathcal{A}(O_1) \subset \mathcal{A}(O_2) \\ \text{for all } O_1, O_2 \in \mathcal{K}(M)$$

(ii) *If there exists a group G of isometric diffeomorphisms $\kappa : M \to M$ (so that $\kappa * \mathbf{g} = \mathbf{g}$) preserving orientation and time orientation, then there is a representation $G \ni \kappa \mapsto \tilde{\alpha}_\kappa$ of G by $C^*$-algebra automorphisms $\tilde{\alpha}_\kappa : \mathscr{A}(M) \to \mathscr{A}(M)$ such that*

$$\tilde{\alpha}_\kappa(\mathcal{A}(O)) = \mathcal{A}(\kappa(O)), \quad O \in \mathcal{K}(M)$$

(iii) *If the theory given by $\mathscr{A}$ is additionally causal, then it holds that*

$$[\mathcal{A}(O_1), \mathcal{A}(O_2)] = \{0\}$$

*for all $O_1, O_2 \in \mathcal{K}(M)$ with $O_1$ causally separated from $O_2$.*

These properties are just the basic assumptions of the Araki–Haag–Kastler framework.

## The Achievements of the Traditional Approach

In the Araki–Haag–Kastler approach in Minkowski spacetime $\mathbb{M}$, many results have been obtained in the last 40 years, some of them also becoming a source of inspiration to mathematics. A description of the achievements can be organized in terms of a length-scale basis, from the small to the large. We assume in this section that the algebra $\mathscr{A}(\mathbb{M})$ is faithfully and irreducibly represented on a Hilbert space $\mathcal{H}$, that the Poincaré transformations are unitarily implemented with positive energy, and that the subspace of Poincaré invariant vectors is one dimensional (uniqueness of the vacuum). Moreover, algebras correponding to regions which are spacelike to a nonempty open region are assumed to be weakly closed (i.e., von Neumann algebras on $\mathcal{H}$), and the condition of weak additivity is fulfilled, that is, for all $O \in \mathcal{K}(\mathbb{M})$ the algebra generated from the algebras $\mathcal{A}(O + x), x \in \mathbb{M}$ is weakly dense in $\mathscr{A}(\mathbb{M})$.

### Ultraviolet Structure and Idealized Localizations

This section deals with the problem of inspecting the theory at very small scales. In the limiting case, one is interested in idealized localizations, eventually the points of spacetimes. But the observable algebras are trivial at any point $x \in \mathbb{M}$, namely

$$\bigcap_{O \ni x} \mathcal{A}(O) = \mathbb{C}\mathbf{1}, \quad O \in \mathcal{K}(\mathbb{M})$$

Hence, pointlike localized observables are necessarily singular. Actually, the Wightman formulation of quantum field theory is based on the use of distributions on spacetime with values in the algebra of observables (as a topological $*$-algebra). In spite of technical complications whose physical significance is unclear, this formalism is well suited for a discussion of the connection with the Euclidean theory, which allows, in fortunate cases, a treatment by path integrals; it is more directly related to models and admits, via the operator-product expansion, a study of the short-distance behavior. It is, therefore, an important question how the algebraic approach is related to the Wightman formalism. The reader is referred to the literature for exploring the results on this relation.

Whereas these results point to an essential equivalence of both formalisms, one needs in addition a criterion for the existence of sufficiently many Wightman fields associated with a given local net. Such a criterion can be given in terms of a compactness condition to be discussed in the next subsection. As a benefit, one derives an operator-product expansion which has to be assumed in the Wightman approach.

In the purely algebraic approach, the ultraviolet structure has been investigated by Buchholz and Verch. Small-scale properties of theories are studied with the help of the so-called scaling algebras whose elements can be described as orbits of observables under all possible renormalization group motions. There results a classification of theories in the scaling limit which can be grouped into three broad classes: theories for which the scaling limit is purely classical (commutative algebras), those for which the limit is essentially unique (stable ultraviolet fixed point) and not classical, and those for which this is not the case (unstable ultraviolet fixed point). This classification does not rely on perturbation expansions. It allows an intrinsic definition of confinement in terms of the so-called ultraparticles, that is, particles which are visible only in the scaling limit.

### Phase-Space Analysis

As far as finite distances are concerned, there are two apparently competing principles, those of

nuclearity and modularity. The first one suggests that locally, after a cutoff in energy, one has a situation similar to that of old quantum mechanics, namely a finite number of states in a finite volume of phase space. Aiming at a precise formulation, Haag and Swieca introduced their notion of compactness, which Buchholz and Wichmann sharpened into that of nuclearity. The latter authors proposed that the set generated from the vacuum vector $\Omega$,

$$\{e^{-\beta H} A\Omega \mid A \in \mathcal{A}(O), \|A\| < 1\}$$

$H$ denoting the generator of time translations (Hamiltonian), is nuclear for any $\beta > 0$, roughly stating that it is contained in the image of the unit ball under a trace class operator. The nuclear size $Z(\beta, O)$ of the set plays the role of the partition function of the model and has to satisfy certain bounds in the parameter $\beta$. The consequence of this constraint is the existence of product states, namely those normal states for which observables localized in two given spacelike separated regions are uncorrelated. A further consequence is the existence of thermal equilibrium states (KMS states) for all $\beta > 0$.

The second principle concerns the fact that, even locally, quantum field theory has infinitely many degrees of freedom. This becomes visible in the Reeh–Schlieder theorem, which states that every vector $\Phi$ which is in the range of $e^{-\beta H}$ for some $\beta > 0$ (in particular, the vacuum $\Omega$) is cyclic and separating for the algebras $\mathcal{A}(O), O \in \mathcal{K}(\mathbb{M})$, that is, $\mathcal{A}(O)\Phi$ is dense in $\mathcal{H}$ ($\Phi$ is cyclic) and $A\Phi = 0, A \in \mathcal{A}(O)$ implies $A = 0$ ($\Phi$ is separating). The pair $(\mathcal{A}(O), \Omega)$ is then a von Neumann algebra in the so-called standard form. On such a pair, the Tomita–Takesaki theory can be applied, namely the densely defined operator

$$SA\Omega = A^*\Omega, \quad A \in \mathcal{A}(O)$$

is closable, and the polar decomposition of its closure $\bar{S} = J\Delta^{1/2}$ delivers an antiunitary involution $J$ (the modular conjugation) and a positive self-adjoint operator $\Delta$ (the modular operator) associated with the standard pair $(\mathcal{A}(O), \Omega)$. These operators have the properties

$$J\mathcal{A}(O)J = \mathcal{A}(O)'$$

where the prime denotes the commutant, and

$$\Delta^{it}\mathcal{A}(O)\Delta^{-it} = \mathcal{A}(O), \quad t \in \mathbb{R}$$

The importance of this structure is based on the fact disclosed by Bisognano and Wichmann using Poincaré-covariant Wightman fields and local algebras generated by them, that for specific regions in Minkowski spacetime the modular operators have a geometrical meaning. Indeed, these authors showed for the pair $(\mathcal{A}(W), \Omega)$, where $W$ denotes the wedge region $W = \{x \in \mathbb{M} \mid |x^0| < x^1\}$, that the associated modular unitary $\Delta^{it}$ is the Lorentz boost with velocity $\tanh(2\pi t)$ in the direction 1 and that the modular conjugation $J$ is the $CP_1T$ symmetry operator with parity $P_1$ the reflection with respect to the $x^1 = 0$ plane. Later, Borchers discovered that already on the purely algebraic level a corresponding structure exists. He proved that, given any standard pair $(\mathcal{A}, \Phi)$ and a one-parameter group of unitaries $\tau \to U(\tau)$ acting on the Hilbert space $\mathcal{H}$ with a positive generator and such that $\Phi$ is invariant and $U(\tau)\mathcal{A}U(\tau)^* \subset \mathcal{A}, \tau > 0$, then the associated modular operators $\Delta$ and $J$ fulfill the commutation relations

$$\Delta^{it}U(\tau)\Delta^{-it} = U(e^{-2\pi t}\tau)$$
$$JU(\tau)J = U(-\tau)$$

which are just the commutation relations between boosts and lightlike translations.

Surprisingly, there is a direct connection between the two concepts of nuclearity and modularity. Indeed, in the nuclearity condition, it is possible to replace the Hamiltonian operator by a specific function of the modular operator associated with a slightly larger region. Furthermore, under mild conditions, nuclearity and modularity together determine the structure of local algebras completely; they are isomorphic to the unique hyperfinite type $III_1$ von Neumann algebra.

### Sectors, Symmetries, Statistics, and Particles

Large scales are appropriate for discussing global issues like superselection sectors, statistics and symmetries as far as large spacelike distances are concerned, and scattering theory, with the resulting notions of particles and infraparticles, as far as large timelike distances are concerned.

In purely massive theories, where the vacuum sector has a mass gap and the mass shell of the particles are isolated, a very satisfactory description of the multiparticle structure at large times can be given. Using the concept of almost local particle generators,

$$\Psi = A(t)\Omega$$

where $\Psi$ is a single-particle state (i.e., an eigenstate of the mass operator), $A(t)$ is a family of almost local operators essentially localized in the kinematical region accessible from a given point by a motion with the velocities contained in the spectrum of $\Psi$, one obtains the multiparticle states as limits of products $A_1(t)\cdots A_n(t)\Omega$ for disjoint velocity supports. The corresponding closed subspaces are

invariant under Poincaré transformations and are unitarily equivalent to the Fock spaces of noninteracting particles.

For massless particles, no almost-local particle generators can be expected to exist. In even dimensions, however, one can exploit Huygens principle to construct asymptotic particle generators which are in the commutant of the algebra of the forward or backward lightcone, respectively. Again, their products can be determined and multiparticle states obtained.

Much less well understood is the case of massive particles in a theory which also possesses massless particles. Here, in general, the corresponding states are not eigenstates of the mass operator. Since quantum electrodynamics (QED) as well as the standard model of elementary particles have this problem, the correct treatment of scattering in these models is still under discussion. One attempt to a correct treatment is based on the concept of the so-called particle weights, that is, unbounded positive functionals on a suitable algebra. This algebra is generated by positive almost-local operators annihilating the vacuum and interpreted as counters.

The structure at large spacelike scales may be analyzed by the theory of superselection sectors. The best-understood case is that of locally generated sectors which are the objects of the DHR theory. Starting from a distinguished representation $\pi_0$ (vacuum representation) which is assumed to fulfill the Haag duality,

$$\pi_0\big(\mathcal{A}(O)\big) = \pi_0\big(\mathcal{A}(O')\big)'$$

for all double cones $O$, one may look at all representations which are equivalent to the vacuum representation if restricted to the observables localized in double cones in the spacelike complement of a given double cone. Such representations give rise to endomorphisms of the algebra of observables, and the product of endomorphisms can be interpreted as a product of sectors ("fusion"). In general, these representations violate the Haag duality, but there is a subclass of the so-called finite statistics sectors where the violation of Haag duality is small, in the sense that the nontrivial inclusion

$$\pi\big(\mathcal{A}(O)\big) \subset \pi\big(\mathcal{A}(O')\big)'$$

has a finite Jones index. These sectors form (in at least three spacetime dimensions) a symmetric tensor category with some further properties which can be identified, in a generalization of the Tannaka–Krein theorem, as the dual of a unique compact group. This group plays the role of a global gauge group. The symmetry of the category is expressed in terms of a representation of the symmetric group. One may then enlarge the algebra of observables and obtain an algebra of operators which transform covariantly under the global gauge group and satisfy Bose or Fermi commutation relations for spacelike separation.

In two spacetime dimensions, one obtains instead braided tensor categories. They have been classified under additional conditions (conformal symmetry, central charge $c < 1$) in a remarkable work by Kawahigashi and Longo. Moreover, in their paper, one finds that by using completely new methods ($Q$-systems) a new model is unveiled, apparently inaccessible by methods used by others. To some extent, these categories can be interpreted as duals of generalized quantum groups.

The question arises whether all representations describing elementary particles are, in the massive case, DHR representations. One can show that in the case of a representation with an isolated mass shell there is an associated vacuum representation which becomes equivalent to the particle representation after restriction to observables localized spacelike to a given infinitely extended spacelike cone. This property is weaker than the DHR condition but allows, in four spacetime dimensions, the same construction of a global gauge group and of covariant fields with Bose and Fermi commutation relations, respectively, as the DHR condition. In three space dimensions, however, one finds a braided tensor category, which has similar properties as those known from topological field theories in three dimensions.

The sector structure in massless theories is not well understood, due to the infrared problem. This is in particular true for QED.

## Fields as Natural Transformations

In order to be able to interpret the theory in terms of measurements, one has to be able to compare observables associated with different regions of spacetime, or, even different spacetimes. In the absence of nontrivial isometries, such a comparison can be made in terms of locally covariant fields. By definition, these are natural transformations from the functor of quantum field theory to another functor on the category of spacetimes **Loc**.

The standard case is the functor which associates with every spacetime $M$ its space $\mathcal{D}(M)$ of smooth compactly supported test functions. There, the morphisms are the pushforwards $\mathcal{D}\psi \equiv \psi_*$.

**Definition 2** A locally covariant quantum field $\Phi$ is a natural transformation between the functors $\mathscr{D}$ and $\mathscr{A}$, that is, for any object $M$ in obj(**Loc**) there exists a morphism $\Phi_M : \mathcal{D}(M) \to \mathscr{A}(M)$ such that for

any pair of objects $M_1$ and $M_2$ and any morphism $\psi$ between them, the following diagram commutes:

$$\begin{array}{ccc} \mathcal{D}(M_1) & \xrightarrow{\Phi_{M_1}} & \mathcal{A}(M_1) \\ \psi_* \downarrow & & \downarrow \alpha_\psi \\ \mathcal{D}(M_2) & \underset{\Phi_{M_2}}{\longrightarrow} & \mathcal{A}(M_2) \end{array}$$

The commutativity of the diagram means, explicitly, that

$$\alpha_\psi \circ \Phi_{M_1} = \Phi_{M_2} \circ \psi_*$$

which is the requirement sought for the covariance of fields. It contains, in particular, the standard covariance condition for spacetime isometries.

Fields in the above sense are not necessarily linear. Examples for fields which are also linear are the scalar massive free Klein–Gordon fields on all globally hyperbolic spacetimes and its locally covariant Wick polynomials. In particular, the energy–momentum tensors can be constructed as locally covariant fields, and they provide a crucial tool for discussing the back-reaction problem for matter fields.

An example for the more general notion of a field are the local $S$-matrices in the Stückelberg–Bogolubov–Epstein–Glaser sense. These are unitaries $S_M(\lambda)$ with $M \in \mathrm{obj}(\mathbf{Loc})$ and $\lambda \in \mathcal{D}(M)$ which satisfy the conditions

$$S_M(0) = 1$$
$$S_M(\lambda + \mu + \nu) = S_M(\lambda + \mu) S_M(\mu)^{-1} S_M(\mu + \nu)$$

for $\lambda, \mu, \nu \in \mathcal{D}(M)$ such that the supports of $\lambda$ and $\nu$ can be separated by a Cauchy surface of $M$ with $\mathrm{supp}\,\lambda$ in the future of the surface.

The importance of these $S$-matrices relies on the fact that they can be used to define a new quantum field theory. The new theory is locally covariant if the original theory is and if the local $S$-matrices satisfy the condition of the locally covariant field above. A perturbative construction of interacting quantum field theory on globally hyperbolic spacetimes was completed in this way by Hollands and Wald, based on previous work by Brunetti and Fredenhagen.

## Synopsis

*Anomalies* are the breaking of classical symmetries by quantum mechanical radiative corrections, which arise when the regularizations needed to evaluate small fermion loop Feynman diagrams conflict with a classical symmetry of the theory. They have important implications for a wide range of issues in quantum field theory, mathematical physics, and string theory.

## Chiral Anomalies, Abelian and Nonabelian

Consider quantum electrodynamics, with the fermionic Lagrangian density

$$\mathcal{L} = \bar{\psi}(\mathrm{i}\gamma^{\mu}\partial_{\mu} - e_0\gamma^{\mu}B_{\mu} - m_0)\psi \qquad [1a]$$

where $\bar{\psi} = \psi^{\dagger}\gamma^0$, $e_0$ and $m_0$ are the bare charge and mass, and $B_{\mu}$ is the electromagnetic gauge potential. (We reserve the notation $A$ for axial-vector quantities.) Under a chiral transformation

$$\psi \to \mathrm{e}^{\mathrm{i}\lambda\gamma_5}\psi \qquad [1b]$$

with constant $\lambda$, the kinetic term in eqn [1a] is invariant (because $\gamma_5$ commutes with $\gamma^0\gamma^{\mu}$), whereas the mass term is not invariant. Therefore, naive application of Noether's theorem would lead one to expect that the axial-vector current

$$j^5_{\mu} = \bar{\psi}\gamma_{\mu}\gamma_5\psi \qquad [1c]$$

obtained from the Lagrangian density by applying a chiral transformation with spatially varying $\lambda$, should have a divergence given by the change under chiral transformation of the mass term in eqn [1a]. Up to tree approximation, this is indeed true, but when one computes the $AVV$ Feynman diagram with one axial-vector and two vector vertices (see Figure 1), and insists on conservation of the vector current $j_{\mu} = \bar{\psi}\gamma_{\mu}\psi$, one finds that to order $e_0^2$, the classical Noether theorem is modified to read

$$\partial^{\mu}j^5_{\mu}(x) = 2\mathrm{i}m_0 j^5(x) + \frac{e_0^2}{16\pi^2}F^{\xi\sigma}(x)F^{\tau\rho}(x)\epsilon_{\xi\sigma\tau\rho} \qquad [2]$$

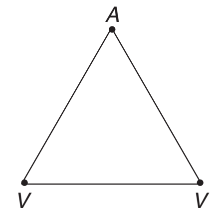

**Figure 1** The *AVV* triangle diagram responsible for the abelian chiral anomaly.

with $F^{\xi\sigma}(x) = \partial^{\sigma}B^{\xi}(x) - \partial^{\xi}B^{\sigma}(x)$ the electromagnetic field strength tensor. The second term in eqn [2], which would be unexpected from the application of the classical Noether theorem, is the abelian axial-vector anomaly (often called the Adler–Bell–Jackiw (or ABJ) anomaly after the seminal papers on the subject). Since vector current conservation, together with the axial-vector current anomaly, implies that the left- and right-handed chiral currents $j_{\mu} \pm j^5_{\mu}$ are also anomalous, the axial-vector anomaly is frequently called the "chiral anomaly," and we shall use the terms interchangeably in this article.

There are a number of different ways to understand why the extra term in eqn [2] appears. (1) Working through the formal Feynman diagrammatic Ward identity proof of the Noether theorem, one finds that there is a step where the closed fermion loop contributions are eliminated by a shift of the loop-integration variable. For Feynman diagrams that are convergent, this is not a problem, but the $AVV$ diagram is linearly divergent. The linear divergence vanishes under symmetric integration, but the shift then produces a finite residue, which gives the anomaly. (2) If one defines the $AVV$ diagram by Pauli–Villars regularization with regulator mass $M_0$ that is allowed to approach infinity at the end of the calculation, one finds a classical Noether theorem in the regulated theory,

$$\partial^{\mu}j^5_{\mu}|_{m_0} - \partial^{\mu}j^5_{\mu}|_{M_0} = 2\mathrm{i}m_0 j^5|_{m_0} - 2\mathrm{i}M_0 j^5|_{M_0} \qquad [3a]$$

with the subscripts $m_0$ and $M_0$ indicating that fermion loops are to be calculated with fermion mass $m_0$ and $M_0$, respectively. Taking the vacuum to two-photon matrix element of eqn [3a], one finds that the matrix element $\langle 0|j^5|_{M_0}|\gamma\gamma\rangle$, which is unambiguously computable after imposing vector-current conservation, falls off only as $M_0^{-1}$ as the regulator mass approaches infinity. Thus, the product of $2\mathrm{i}M_0$ with this matrix element has a finite limit, which gives the anomaly. (3) If the

gauge-invariant axial-vector current is defined by point-splitting

$$j^5_\mu(x) = \bar{\psi}(x+\epsilon/2)\gamma_\mu\gamma_5\psi(x-\epsilon/2)\mathrm{e}^{-\mathrm{i}e_0\epsilon^\sigma B_\sigma(x)} \quad [3b]$$

with $\epsilon \to 0$ at the end of the calculation, one observes that the divergence of eqn [3b] contains an extra term with a factor of $\epsilon$. On careful evaluation, one finds that the coefficient of this factor is an expression that behaves as $\epsilon^{-1}$, which gives the anomaly in the limit of vanishing $\epsilon$. (4) Finally, if the field theory is defined by a functional integral over the classical action, the standard Noether analysis shows that the classical action is invariant under the chiral transformation of eqn [1b], apart from the contribution of the mass term, which gives the naive axial-vector divergence. However, as pointed out by Fujikawa, the chiral transformation must also be applied to the functional integration measure, and since the measure is an infinite product, it must be regularized to be well defined. Careful calculation shows that the regularized measure is not chiral invariant, but contributes an extra term to the axial-vector Ward identity that is precisely the chiral anomaly.

A key feature of the anomaly is that it is irreducible: a local polynomial counter term cannot be added to the $AVV$ diagram that preserves vector-current conservation and eliminates the anomaly. More generally, one can show that there is no way of modifying quantum electrodynamics so as to eliminate the chiral anomaly, without spoiling either vector-current conservation (i.e., electromagnetic gauge invariance), renormalizability, or unitarity. Thus, the chiral anomaly is a new physical effect in renormalizable quantum field theory, which is not present in the prequantization classical theory.

The abelian chiral anomaly is the simplest case of the anomaly phenomenon. It was extended to nonabelian gauge theories by Bardeen using a point-splitting method to compute the divergence, followed by adding polynomial counter terms to remove as many of the residual terms as possible. The resulting irreducible divergence is the nonabelian chiral anomaly, which in terms of Yang–Mills field strengths for vector and axial-vector gauge potentials $V^\mu$ and $A^\mu$,

$$\begin{aligned} F_V^{\mu\nu}(x) &= \partial^\mu V^\nu(x) - \partial^\nu V^\mu(x) - \mathrm{i}[V^\mu(x), V^\nu(x)] \\ &\quad - \mathrm{i}[A^\mu(x), A^\nu(x)] \\ F_A^{\mu\nu}(x) &= \partial^\mu A^\nu(x) - \partial^\nu A^\mu(x) - \mathrm{i}[V^\mu(x), A^\nu(x)] \\ &\quad - \mathrm{i}[A^\mu(x), V^\nu(x)] \end{aligned} \quad [4a]$$

is given by

$$\begin{aligned} \partial^\mu j^a_{5\mu}(x) &= \text{normal divergence term} \\ &\quad + (1/4\pi^2)\epsilon_{\mu\nu\sigma\tau}\mathrm{tr}\lambda^a_A[(1/4)F_V^{\mu\nu}(x)F_V^{\sigma\tau}(x) \\ &\quad + (1/12)F_A^{\mu\nu}(x)F_A^{\sigma\tau}(x) \\ &\quad + (2/3)\mathrm{i}A^\mu(x)A^\nu(x)F_V^{\sigma\tau}(x) \\ &\quad + (2/3)\mathrm{i}F_V^{\mu\nu}(x)A^\sigma(x)A^\tau(x) \\ &\quad + (2/3)\mathrm{i}A^\mu(x)F_V^{\nu\sigma}(x)A^\tau(x) \\ &\quad - (8/3)A^\mu(x)A^\nu(x)A^\sigma(x)A^\tau(x)] \end{aligned} \quad [4b]$$

In eqn [4b], "tr" denotes a trace over internal degrees of freedom, and $\lambda^a_A$ is the internal symmetry matrix associated with the axial-vector external field. In the abelian case, where there is no internal symmetry structure, the terms involving two or four factors of $A^\mu, A^\nu, \ldots$ vanish by antisymmetry of $\epsilon_{\mu\nu\sigma\tau}$, and one recovers the $AVV$ triangle anomaly, as well as a kinematically related anomaly in the $AAA$ triangle diagram. In the nonabelian case, with nontrivial internal symmetry structure, there are also box- and pentagon-diagram anomalies.

In addition to coupling to spin-1 gauge fields, fermions can also couple to spin-2 gauge fields, associated with the graviton. When the coupling of fermions to gravitation is taken into account, the axial-vector current $\bar{\psi}T\gamma_\mu\gamma_5\psi$, with $T$ an internal symmetry matrix, has an additional anomalous contribution to its divergence proportional to

$$\mathrm{tr}\, T\epsilon_{\xi\sigma\tau\rho}R^{\xi\sigma\alpha\beta}R^{\tau\rho}{}_{\alpha\beta} \quad [4c]$$

where $R_{\xi\sigma\tau\rho}$ is the Riemann curvature tensor of the gravitational field.

## Chiral Anomaly Nonrenormalization

A salient feature of the chiral anomaly is the fact that it is not renormalized by higher-order radiative corrections. In other words, the one-loop expressions of eqns [2] and [4b] give the exact anomaly coefficient without modification in higher orders of perturbation theory. In gauge theories such as quantum electrodynamics and quantum chromodynamics, this result (the Adler–Bardeen theorem) can be understood heuristically as follows. Write down a modified Lagrangian, in which regulators are included for all gauge-boson fields. Since the gauge-boson regulators do not influence the chiral-symmetry properties of the theory, the divergences of the chiral currents are not affected by their inclusion, and so the only sources of anomalies in the regularized theory are small single-fermion loops, giving the anomaly expressions of eqns [2] and [4b]. Since the renormalized theory is obtained as the limit of

the regularized theory as the regulator masses approach infinity, this result applies to the renormalized theory as well.

The above argument can be made precise, and extends to nongauge theories such as the $\sigma$-model as well. For both gauge theories and the $\sigma$-model, cancellation of radiative corrections to the anomaly coefficient has been explicitly demonstrated in fourth-order calculations. Nonperturbative demonstrations of anomaly renormalization have also been given using the Callan–Symanzik equations. For example, in quantum electrodynamics, Zee, and Lowenstein and Schroer, showed that a factor $f$ that gives the ratio of the true anomaly to its one-loop value obeys the differential equation

$$\left(m\frac{\partial}{\partial m}+\alpha\beta(\alpha)\frac{\partial}{\partial\alpha}\right)f=0 \qquad [5]$$

Since $f$ is dimensionless, it can have no dependence on the mass $m$, and since $\beta(\alpha)$ is nonzero this implies $\partial f/\partial\alpha=0$. Thus, $f$ has no dependence on $\alpha$, and so $f=1$.

## Applications of Chiral Anomalies

Chiral anomalies have numerous applications in the standard model of particle physics and its extensions, and we describe here a few of the most important ones.

### Neutral Pion Decay $\pi^0\to\gamma\gamma$

As a result of the abelian chiral anomaly, the partially conserved axial-vector current (PCAC) equation relevant to neutral pion decay is modified to read

$$\partial^\mu\mathcal{F}^5_{3\mu}(x) = \left(f_\pi\mu_\pi^2/\sqrt{2}\right)\phi_\pi(x)+S\frac{\alpha_0}{4\pi}F^{\xi\sigma}(x)F^{\tau\rho}(x)\epsilon_{\xi\sigma\tau\rho} \qquad [6a]$$

with $\mu_\pi$ the pion mass, $f_\pi\simeq 131\,\text{MeV}$ the charged-pion decay constant, and $S$ a constant determined by the constituent fermion charges and axial-vector couplings. Taking the matrix element of eqn [6a] between the vacuum state and a two-photon state, and using the fact that the left-hand side has a kinematic zero (the Sutherland–Veltman theorem), one sees that the $\pi^0\to\gamma\gamma$ amplitude $F$ is completely determined by the anomaly term, giving the formula

$$F=-(\alpha/\pi)2S\sqrt{2}/f_\pi \qquad [6b]$$

For a single set of fractionally charged quarks, the amplitude $F$ is a factor of three too small to agree with experiment; for three fractionally charged quarks (or an equivalent Han–Nambu triplet), eqn [6b] gives the correct neutral pion decay rate. This calculation was one of the first pieces of evidence for the color degree of freedom of quarks.

### Anomaly Cancellation in Gauge Theories

In quantum electrodynamics, the gauge particle (the photon) couples to the vector current, and so the anomalous conservation properties of the axial-vector current have no effect. The same statement holds for the gauge gluons in quantum chromodynamics, when treated in isolation from the other interactions. However, in the electroweak theory that embeds quantum electrodynamics in a theory of the weak force, the gauge particles (the $W^\pm$ and $Z$ intermediate bosons) couple to chiral currents, which are left- or right-handed linear combinations of the vector and axial-vector currents. In this case, the chiral anomaly leads to problems with the renormalizability of the theory, unless the anomalies cancel between different fermion species. Writing all fermions as left-handed, the condition for anomaly cancellation is

$$\begin{aligned}&\mathrm{tr}\{T_\alpha,T_\beta\}T_\gamma=\mathrm{tr}(T_\alpha T_\beta+T_\beta T_\alpha)T_\gamma=0\\&\quad\text{for all }\alpha,\beta,\gamma\end{aligned} \qquad [7]$$

with $T_\alpha$ the coupling matrices of gauge bosons to left-handed fermions. These conditions are obeyed in the standard model, by virtue of three nontrivial sum rules on the fermion gauge couplings being satisfied (four sum rules, if one includes the gravitational contribution to the chiral anomaly given in eqn [4c], which also cancels in the standard model). Note that anomaly cancellation in the locally gauged currents of the standard model does not imply anomaly cancellation in global-flavor currents. Thus, the flavor axial-vector current anomaly that gives the $\pi^0\to\gamma\gamma$ matrix element remains anomalous in the full electroweak theory. Anomaly cancellation imposes important constraints on the construction of grand unified models that combine the electroweak theory with quantum chromodynamics. For instance, in SU(5) the fermions are put into a $\bar{5}$ and 10 representation, which together, but not individually, are anomaly free. The larger unification groups SO(10) and $E_6$ satisfy eqn [7] for all representations, and so are automatically anomaly free.

### Instanton Physics and the Theta Vacuum

The theory of anomalies is intimately tied to the physics associated with instanton classical Yang–Mills theory solutions. Since the instanton field

strength is self-dual, the nonvanishing instanton Euclidean action

$$S_E = \int d^4x \frac{1}{4} F_{\mu\nu}F^{\mu\nu} = 8\pi^2 \qquad [8a]$$

implies that the integral of the pseudoscalar density $F_{\mu\nu}F_{\lambda\sigma}\epsilon^{\mu\nu\lambda\sigma}$ over the instanton is also nonzero,

$$\int d^4x F_{\mu\nu}F_{\lambda\sigma}\epsilon^{\mu\nu\lambda\sigma} = 64\pi^2 \qquad [8b]$$

Referring back to eqn [4b], this means that the integral of the nonabelian chiral anomaly for fermions in the background field of an instanton is an integer, which in the Minkowski space continuation has the interpretation of a topological winding number change produced by the instanton tunneling solution. This fact has a number of profound consequences. Since a vacuum with a definite winding number $|\nu\rangle$ is unstable under instanton tunneling, careful analysis shows that the nonabelian vacuum that has correct clustering properties is a Fourier superposition

$$|\theta\rangle = \sum_\nu e^{i\theta\nu}|\nu\rangle \qquad [8c]$$

giving rise to the $\theta$-vacuum of quantum chromodynamics, and a host of issues associated with (the lack of) strong *CP* violation, the Peccei–Quinn mechanism, and axion physics. Also, the fact that the integral of eqn [8b] is nonzero means that the U(1) chiral symmetry of quantum chromodynamics is broken by instantons, which as shown by 't Hooft resolves the longstanding "U(1) problem" of strong interactions, that of explaining why the flavor singlet pseudoscalar meson $\eta'$ is not light, unlike its flavor octet partners.

### Anomaly Matching Conditions

The anomaly structure of a theory, as shown by 't Hooft, leads to important constraints on the formation of massless composite bound states. Consider a theory with a set of left-handed fermions $\psi^{if}$, with *i* a "color" index acted on by a nonabelian gauge force, and *f* an ungauged family or "flavor" index. Suppose that the family multiplet structure is such that the global chiral symmetries associated with the flavor index have nonvanishing anomalies $\mathrm{tr}\{T_\alpha, T_\beta\}T_\gamma$. Then the 't Hooft condition asserts that if the color forces result in the formation of composite massless bound states of the original completely confined fermions, and if there is no spontaneous breaking of the original global flavor symmetries, then these bound states must contain left-handed spin-1/2 composites with a representation structure *S* that has the same anomaly coefficient as that in the underlying theory. In other words, we must have

$$\mathrm{tr}\{S_\alpha, S_\beta\}S_\gamma = \mathrm{tr}\{T_\alpha, T_\beta\}T_\gamma \qquad [9]$$

To prove this, one adjoins to the theory a set of right-handed spectator fermions $\psi^f$ with the same flavor structure as the original set, but which are not acted on by the color force. These right-handed fermions cancel the original anomaly, making the underlying theory anomaly free at zero color coupling; since dynamics cannot spontaneously generate anomalies, the theory, when the color dynamics is turned on, must also have no global chiral anomalies. This implies that the bound-state spectrum must conspire to cancel the anomalies associated with the right-handed spectators; in other words, the bound-state anomaly structure must match that of the original fermions. This anomaly matching condition has found applications in the study of the possible compositeness of quarks and leptons. It has also been applied to the derivation of nonperturbative dynamical results in whole classes of supersymmetric theories, where the combined tools of holomorphicity, instanton physics, and anomaly matching have given incisive results.

## Global Structure of Anomalies

We noted earlier that chiral anomalies are irreducible, in that they cannot be eliminated by adding a local polynomial counter-term to the action. However, anomalies can be described by a nonlocal effective action, obtained by integrating out the fermion field dynamics, and this point of view proves very useful in the nonabelian case. Starting with the abelian case for orientation, we note that if $A^\mu$ is an external axial-vector field, and we write an effective action $\Gamma[A]$, then the axial-vector current $j^5_\mu$ associated with $A^\mu$ is given (up to an overall constant) by the variational derivative expression

$$j^5_\mu(x) = \frac{\delta\Gamma[A]}{\delta A^\mu(x)} \qquad [10a]$$

and the abelian anomaly appears as the fact that the expression

$$\partial^\mu j^5_\mu = X\Gamma[A] = G \neq 0, \quad X = \partial^\mu \frac{\delta}{\delta A^\mu(x)} \qquad [10b]$$

is nonvanishing even when the theory is classically chiral invariant. Turning now to the nonabelian case, the variational derivative appearing in eqns [10a] and [10b] must be replaced by an appropriate

covariant derivative. In terms of the internal-symmetry component fields $A_\mu^a$ and $V_\mu^a$ of the Yang–Mills potentials of eqn [4a], one introduces operators

$$-X^a(x) = \partial^\mu \frac{\delta}{\delta A_\mu^a(x)} + f_{abc} V_\mu^b \frac{\delta}{\delta A_\mu^c(x)} + f_{abc} A_\mu^b \frac{\delta}{\delta V_\mu^c(x)}$$
$$-Y^a(x) = \partial^\mu \frac{\delta}{\delta V_\mu^a(x)} + f_{abc} V_\mu^b \frac{\delta}{\delta V_\mu^c(x)} + f_{abc} A_\mu^b \frac{\delta}{\delta A_\mu^c(x)} \qquad [11a]$$

with $f_{abc}$ the antisymmetric nonabelian group structure constants. The operators $X^a$ and $Y^a$ are easily seen to obey the commutation relations

$$[X^a(x), X^b(y)] = f_{abc}\delta(x-y)Y_c(x)$$
$$[X^a(x), Y^b(y)] = f_{abc}\delta(x-y)X_c(x) \qquad [11b]$$
$$[Y^a(x), Y^b(y)] = f_{abc}\delta(x-y)Y_c(x)$$

Let $\Gamma[V, A]$ be the effective action as a functional of the fields $V^\mu, A^\mu$, constructed so that the vector currents are covariantly conserved, as expressed formally by

$$Y^a \Gamma[V, A] = 0 \qquad [12a]$$

Then the nonabelian axial-vector current anomaly is given by

$$X^a \Gamma[V, A] = G^a \qquad [12b]$$

From eqns [12a] and [12b] and the first line of eqn [11b], we have

$$X^b G^a - X^a G^b = (X^b X^a - X^a X^b)\Gamma[V, A] \propto f_{abc} Y^c \Gamma[V, A] = 0 \qquad [12c]$$

which is the Wess–Zumino consistency condition on the structure of the anomaly $G^a$. It can be shown that this condition uniquely fixes the form of the nonabelian anomaly to be that of eqn [4b], up to an overall constant, which can be determined by comparison with the simplest anomalous $AVV$ triangle graph. A physical consequence of the consistency condition is that the $\pi^0 \to \gamma\gamma$ decay amplitude determines uniquely certain other anomalous amplitudes, such as $2\gamma \to 3\pi, \gamma \to 3\pi$, and a five pseudoscalar vertex.

Although the action $\Gamma[V, A]$ is necessarily nonlocal, Wess and Zumino were able to write down a local action, involving an auxiliary pseudoscalar field, that obeys the anomalous Ward identities and the consistency conditions. Subsequently, Witten gave a new construction of this local action, in terms of the integral of a fifth-rank antisymmetric tensor over a five-dimensional disk which has a four-dimensional space as its boundary. He also showed that requiring $e^{i\Gamma}$ to be independent of the choice of the spanning disk requires, in analogy with Dirac's quantization condition for monopole charge, the condition that the overall coefficient in the nonabelian anomaly be quantized in integer multiples. Comparison with the lowest-order triangle diagram shows that in the case of $SU(N_c)$ gauge theory, this integer is just the number of colors $N_c$. Thus, global considerations tightly constrain the nonabelian chiral anomaly structure, and dictate that up to an integer-proportionality constant, it must have the form given in eqns [4a] and [4b].

## Trace Anomalies

The discovery of chiral anomalies inspired the search for other examples of anomalous behavior. First indications of a perturbative trace anomaly obtained in a study of broken scale invariance by Coleman and Jackiw were shown by Crewther, and by Chanowitz and Ellis, to correspond to an anomaly in the three-point function $\theta_\sigma^\sigma V_\mu V_\nu$, where $\theta_\mu^\mu$ is the energy–momentum tensor. Letting $\Delta_{\mu\nu}(p)$ be the momentum space expression for this three-point function, and $\Pi_{\mu\nu}$ the corresponding $V_\mu V_\nu$ two-point function, the trace anomaly equation in quantum electrodynamics reads

$$\Delta_{\mu\nu}(p) = \left(2 - p_\sigma \frac{\partial}{\partial p_\sigma}\right)\Pi_{\mu\nu}(p) - \frac{R}{6\pi^2}(p_\mu p_\nu - \eta_{\mu\nu}p^2) \qquad [13a]$$

with the first term on the right-hand side the naive divergence, and the second term the trace anomaly, with anomaly coefficient $R$ given by

$$R = \sum_{i,\mathrm{spin}\,\frac{1}{2}} Q_i^2 + \frac{1}{4}\sum_{i,\mathrm{spin}\,0} Q_i^2 \qquad [13b]$$

The fact that there should be a trace anomaly can readily be inferred from a trace analog of the Pauli–Villars regulator argument for the chiral anomaly given in eqn [3a]. Letting $j = \bar{\psi}\psi$ be the scalar current in abelian electrodynamics, one has

$$\theta_\mu^\mu|_{m_0} - \theta_\mu^\mu|_{M_0} = m_0 j|_{m_0} - M_0 j|_{M_0} \qquad [13c]$$

Taking the vacuum to two-photon matrix element of this equation, and imposing vector-current conservation, one finds that the matrix element $\langle 0|j|_{M_0}|\gamma\gamma\rangle$ is proportional to $M_0^{-1}\langle 0|F_{\lambda\sigma}F^{\lambda\sigma}|\gamma\gamma\rangle_{M_0}$ for a large regulator mass, and so makes a

nonvanishing contribution to the right-hand side of eqn [13c], giving the lowest-order trace anomaly.

Unlike the chiral anomaly, the trace anomaly is renormalized in higher orders of perturbation theory; heuristically, the reason is that whereas boson field regulators do not affect the chiral symmetry properties of a gauge theory (which are determined just by the fermionic terms in the Lagrangian), they do alter the energy–momentum tensor, since gravitation couples to all fields, including regulator fields. An analysis using the Callan–Symanzik equations shows, however, that the trace anomaly is computable to all orders in terms of various renormalization group functions of the coupling. For example, in abelian electrodynamics, defining $\beta(\alpha)$ and $\delta(\alpha)$ by $\beta(\alpha) = (m/\alpha)\partial\alpha/\partial m$ and $1 + \delta(\alpha) = (m/m_0)\partial m_0/\partial m$, the trace of the energy–momentum tensor is given to all orders by

$$\theta^{\mu}_{\mu} = [1 + \delta(\alpha)]m_0\bar{\psi}\psi + \tfrac{1}{4}\beta(\alpha)N[F_{\lambda\sigma}F^{\lambda\sigma}] + \cdots \quad [14]$$

with $N[\ ]$ specifying conditions that make the division into two terms in eqn [14] unique, and with the ellipsis $\cdots$ indicating terms that vanish by the equations of motion. A similar relation holds in the nonabelian case, again with the $\beta$ function appearing as the coefficient of the anomalous $\mathrm{tr}\,N[F_{\lambda\sigma}F^{\lambda\sigma}]$ term.

Just as in the chiral anomaly case, when spin-0, spin-1/2, or spin-1 fields propagate on a background spacetime, there are curvature-dependent contributions to the trace anomaly, in other words, gravitational anomalies. These typically take the form of complicated linear combinations of terms of the form $R^2, R_{\mu\nu}R^{\mu\nu}, R_{\mu\nu\lambda\sigma}R^{\mu\nu\lambda\sigma}, R_{,\mu}{}^{;\mu}$, with coefficients depending on the matter fields involved.

In supersymmetric theories, the axial-vector current and the energy–momentum tensor are both components of the supercurrent, and so their anomalies imply the existence of corresponding supercurrent anomalies. The issue of how the nonrenormalization of chiral anomalies (which have a supercurrent generalization given by the Konishi anomaly), and the renormalization of trace anomalies, can coexist in supersymmetric theories originally engendered considerable confusion. This apparent puzzle is now understood in the context of a perturbatively exact expression for the $\beta$ function in supersymmetric field theories (the so-called NSVZ, for Novikov, Shifman, Vainshtein, and Zakharov, $\beta$ function). Supersymmetry anomalies can be used to infer the structure of effective actions in supersymmetric theories, and these in turn have important implications for possibilities for dynamical supersymmetry breaking. Anomalies may also play a role, through anomaly mediation, in communicating supersymmetry breaking in "hidden sectors" of a theory, which do not contain the physical fields that we directly observe, to the "physical sector" containing the observed fields.

## Further Anomaly Topics

The above discussion has focused on some of the principal features and applications of anomalies. There are further topics of interest in the physics and mathematics of anomalies that are discussed in detail in the references cited in the "Further reading" section. We briefly describe a few of them here.

### Anomalies in Other Spacetime Dimensions and in String Theory

The focus above has been on anomalies in four-dimensional spacetime, but anomalies of various types occur both in lower-dimensional quantum field theories (such as theories in two- and three-dimensional spacetimes) and in quantum field theories in higher-dimensional spacetimes (such as $N = 1$ supergravity in ten-dimensional spacetime). Anomalies also play an important role in the formulation and consistency of string theory. The bosonic string is consistent only in 26-dimensional spacetime, and the analogous supersymmetric string only in ten-dimensional spacetime, because in other dimensions both these theories violate Lorentz invariance after quantization. In the Polyakov path-integral formulation of these string theories, these special dimensions are associated with the cancellation of the Weyl anomaly, which is the relevant form of the trace anomaly discussed above. Yang–Mills, gravitational, and mixed Yang–Mills gravitational anomalies make an appearance both in $N = 1$ ten-dimensional supergravity and in superstring theory, and again special dimensions play a role. In these theories, only when the associated internal symmetry groups are either SO(32) or $E_8 \times E_8$ is elimination of all anomalies possible, by cancellation of hexagon-diagram anomalies with anomalous tree diagrams involving exchange of a massless antisymmetric two-form field. This mechanism, due to Green and Schwarz, requires the factorization of a sixth-order trace invariant that appears in the hexagon anomaly in terms of lower-order invariants, as well as two numerical conditions on the adjoint representation generator structure, restricting the allowed gauge groups to the two noted above.

### Covariant versus Consistent Anomalies; Descent Equations

The nonabelian anomaly of eqns [4a] and [4b] is called the "consistent anomaly," because it obeys the

Wess–Zumino consistency conditions of eqn [12c]. This anomaly, however, is not gauge covariant, as can be seen from the fact that it involves not only the Yang–Mills field strengths $F^{\mu\nu}_{V,A}$, but the potentials $V^{\mu}, A^{\mu}$ as well. It turns out to be possible, by adding appropriate polynomials to the currents, to transform the consistent anomaly to a form, called the "covariant anomaly," which is gauge covariant under gauge transformations of the potentials $V^{\mu}, A^{\mu}$. This anomaly, however, does not obey the Wess–Zumino consistency conditions, and cannot be obtained from variation of an effective action functional.

The consistent anomalies (but not the covariant anomalies) obey a remarkable set of relations, called the Stora–Zumino descent equations, which relate the abelian anomaly in $2n+2$ spacetime dimensions to the nonabelian anomaly in $2n$ spacetime dimensions. This set of equations has been interpreted physically by Callan and Harvey as reflecting the fact that the Dirac equation has chiral zero modes in the presence of strings in $2n+2$ dimensions and of domain walls in $2n+1$ dimensions.

### Anomalies and Fermion Doubling in Lattice Gauge Theories

A longstanding problem in lattice formulations of gauge field theories is that when fermions are introduced on the lattice, the process of discretization introduces an undesirable doubling of the fermion particle modes. In particular, when an attempt is made to put chiral gauge theories, such as the electroweak theory, on the lattice, one finds that the doublers eliminate the chiral anomalies, by cancellation between modes with positive and negative axial-vector charge. Thus, for a long time, it appeared doubtful whether chiral gauge theories could be simulated on the lattice. However, recent work has led to formulations of lattice fermions that use a mathematical analog of a domain wall to successfully incorporate chiral fermions and the chiral anomaly into lattice gauge theory calculations.

### Relation of Anomalies to the Atiyah–Singer Index Theorem

The singlet ($\lambda_A^a = 1$) anomaly of eqn [4b] is closely related to the Atiyah–Singer index theorem. Specifically, the Euclidean spacetime integral of the singlet anomaly constructed from a gauge field can be shown to give the index of the related Dirac operator for a fermion moving in that background gauge field, where the index is defined as the difference between the numbers of right- and left-handed zero-eigenvalue normalizable solutions of the Dirac equation. Since the index is a topological invariant, this again implies that the Euclidean spacetime integral of the anomaly is a topological invariant, as noted above in our discussion of instanton-related applications of anomalies.

## Retrospect

The wide range of implications of anomalies has surprised – even astonished – the founders of the subject. New anomaly applications have appeared within the last few years, and very likely the future will see continued growth of the area of quantum field theory concerned with the physics and mathematics of anomalies.

# Arithmetic Quantum Chaos

**J Marklof**, University of Bristol, Bristol, UK

## Introduction

The central objective in the study of quantum chaos is to characterize universal properties of quantum systems that reflect the regular or chaotic features of the underlying classical dynamics. Most developments of the past 25 years have been influenced by the pioneering models on statistical properties of eigenstates (Berry 1977) and energy levels (Berry and Tabor 1977, Bohigas *et al.* 1984). Arithmetic quantum chaos (AQC) refers to the investigation of quantum systems with additional arithmetic structures that allow a significantly more extensive analysis than is generally possible. On the other hand, the special number-theoretic features also render these systems nongeneric, and thus some of the expected universal phenomena fail to emerge. Important examples of such systems include the modular surface and linear automorphisms of tori ("cat maps") which will be described below.

The geodesic motion of a point particle on a compact Riemannian surface $\mathcal{M}$ of constant negative curvature is the prime example of an Anosov flow, one of the strongest characterizations of dynamical chaos. The corresponding quantum eigenstates $\varphi_j$ and energy levels $\lambda_j$ are given by the solution of the eigenvalue problem for the Laplace–Beltrami operator $\Delta$ (or Laplacian for short)

$$(\Delta + \lambda)\varphi = 0, \qquad \|\varphi\|_{L^2(\mathcal{M})} = 1 \qquad [1]$$

where the eigenvalues

$$\lambda_0 = 0 < \lambda_1 \le \lambda_2 \le \cdots \to \infty \qquad [2]$$

form a discrete spectrum with an asymptotic density governed by Weyl's law

$$\#\{j : \lambda_j \le \lambda\} \sim \frac{\text{Area}(\Gamma\backslash\mathbb{H})}{4\pi}\lambda, \quad \lambda \to \infty \qquad [3]$$

We rescale the sequence by setting

$$X_j = \frac{\text{Area}(\Gamma\backslash\mathbb{H})}{4\pi}\lambda_j \qquad [4]$$

which yields a sequence of asymptotic density 1. One of the central conjectures in AQC says that, if $\mathcal{M}$ is an arithmetic hyperbolic surface (see the next section for examples of this very special class of surfaces of constant negative curvature), the eigenvalues of the Laplacian have the same local statistical properties as independent random variables from a Poisson process (see, e.g., the surveys by Sarnak (1995) and Bogomolny *et al.* (1997)). This means that the probability of finding $k$ eigenvalues $X_j$ in randomly shifted interval $[X, X+L]$ of fixed length $L$ is distributed according to the Poisson law $L^k e^{-L}/k!$. The gaps between eigenvalues have an exponential distribution,

$$\frac{1}{N}\#\{j \le N : X_{j+1} - X_j \in [a,b]\} \to \int_a^b e^{-s}\,ds \qquad [5]$$

as $N \to \infty$, and thus eigenvalues are likely to appear in clusters. This is in contrast to the general expectation that the energy level statistics of generic chaotic systems follow the distributions of random matrix ensembles; Poisson statistics are usually associated with quantized integrable systems. Although we are at present far from a proof of [5], the deviation from random matrix theory is well understood (see the section "Eigenvalue statistics and Selberg trace formula").

Highly excited quantum eigenstates $\varphi_j (j \to \infty)$ (cf. Figure 1) of chaotic systems are conjectured to behave locally like random wave solutions of [1],

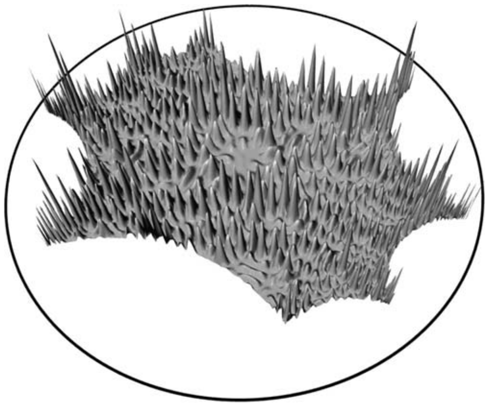

**Figure 1** Image of the absolute-value-squared of an eigenfunction $\varphi_j(z)$ for a nonarithmetic surface of genus 2. The surface is obtained by identifying opposite sides of the fundamental region. Reproduced from Aurich and Steiner (1993) Statistical properties of highly excited quantum eigenstates of a strongly chaotic system. *Physica D* 64(1–3): 185–214, with permission from R Aurich.

where boundary conditions are ignored. This hypothesis was put forward by Berry in 1977 and tested numerically, for example, in the case of certain arithmetic and nonarithmetic surfaces of constant negative curvature (Hejhal and Rackner 1992, Aurich and Steiner 1993). One of the implications is that eigenstates should have uniform mass on the surface $\mathcal{M}$, that is, for any bounded continuous function $g:\mathcal{M}\to\mathbb{R}$

$$\int_{\mathcal{M}} |\varphi_j|^2 g\, \mathrm{d}A \to \int_{\mathcal{M}} g\, \mathrm{d}A, \quad j\to\infty \qquad [6]$$

where $\mathrm{d}A$ is the Riemannian area element on $\mathcal{M}$. This phenomenon, referred to as quantum unique ergodicity (QUE), is expected to hold for general surfaces of negative curvature, according to a conjecture by Rudnick and Sarnak (1994). In the case of arithmetic hyperbolic surfaces, there has been substantial progress on this conjecture in the works of Lindenstrauss, Watson, and Luo–Sarnak (discussed later in this article; see also the review by Sarnak (2003)). For general manifolds with ergodic geodesic flow, the convergence in [6] is so far established only for subsequences of eigenfunctions of density 1 (Schnirelman–Zelditch–Colin de Verdière theorem, *see* Quantum Ergodicity and Mixing of Eigenfunctions), and it cannot be ruled out that exceptional subsequences of eigenfunctions have singular limit, for example, localized on closed geodesics. Such "scarring" of eigenfunctions, at least in some weak form, has been suggested by numerical experiments in Euclidean domains, and the existence of singular quantum limits is a matter of controversy in the current physics and mathematics literature. A first rigorous proof of the existence of scarred eigenstates has recently been established in the case of quantized toral automorphisms. Remarkably, these quantum cat maps may also exhibit QUE. A more detailed account of results for these maps is given in the section "Quantum eigenstates of cat maps"; see also Rudnick (2001) and De Bièvre (to appear).

There have been a number of other fruitful interactions between quantum chaos and number theory, in particular the connections of spectral statistics of integrable quantum systems with the value distribution properties of quadratic forms, and analogies in the statistical behavior of energy levels of chaotic systems and the zeros of the Riemann zeta function. We refer the reader to Marklof (2006) and Berry and Keating (1999), respectively, for information on these topics.

## Hyperbolic Surfaces

Let us begin with some basic notions of hyperbolic geometry. The hyperbolic plane $\mathbb{H}$ may be abstractly defined as the simply connected two-dimensional Riemannian manifold with Gaussian curvature –1. A convenient parametrization of $\mathbb{H}$ is provided by the complex upper-half plane, $\mathfrak{H}=\{x+\mathrm{i}y: x\in\mathbb{R}, y>0\}$, with Riemannian line and volume elements

$$\mathrm{d}s^2=\frac{\mathrm{d}x^2+\mathrm{d}y^2}{y^2}, \qquad \mathrm{d}A=\frac{\mathrm{d}x\,\mathrm{d}y}{y^2} \qquad [7]$$

respectively. The group of orientation-preserving isometries of $\mathbb{H}$ is given by fractional linear transformations

$$\mathfrak{H}\to\mathfrak{H}, \qquad z\mapsto\frac{az+b}{cz+d}$$
$$\begin{pmatrix} a & b\\ c & d\end{pmatrix}\in \mathrm{SL}(2,\mathbb{R}) \qquad [8]$$

where $\mathrm{SL}(2,\mathbb{R})$ is the group of $2\times 2$ matrices with unit determinant. Since the matrices 1 and –1 represent the same transformation, the group of orientation-preserving isometries can be identified with $\mathrm{PSL}(2,\mathbb{R}):=\mathrm{SL}(2,\mathbb{R})/\{\pm 1\}$. A finite-volume hyperbolic surface may now be represented as the quotient $\Gamma\backslash\mathbb{H}$, where $\Gamma\subset\mathrm{PSL}(2,\mathbb{R})$ is a Fuchsian group of the first kind. An arithmetic hyperbolic surface (such as the modular surface) is obtained, if $\Gamma$ has, loosely speaking, some representation in $n\times n$ matrices with integer coefficients, for some suitable $n$.

This is evident in the case of the modular surface, where the fundamental group is the modular group

$$\Gamma = \mathrm{PSL}(2,\mathbb{Z}) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{PSL}(2,\mathbb{R}) \colon a,b,c,d \in \mathbb{Z} \right\} / \{\pm 1\}$$

A fundamental domain for the action of the modular group $\mathrm{PSL}(2,\mathbb{Z})$ on $\mathfrak{H}$ is the set

$$\mathcal{F}_{\mathrm{PSL}(2,\mathbb{Z})} = \left\{ z \in \mathfrak{H} : |z| > 1, -\tfrac{1}{2} < \mathrm{Re}\, z < \tfrac{1}{2} \right\} \qquad [9]$$

(see **Figure 2**). The modular group is generated by the translation

$$\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} : z \mapsto z+1$$

and the inversion

$$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} : z \mapsto -1/z$$

These generators identify sections of the boundary of $\mathcal{F}_{\mathrm{PSL}(2,\mathbb{Z})}$. By gluing the fundamental domain along identified edges, we obtain a realization of the modular surface, a noncompact surface with one cusp at $z \to \infty$, and two conic singularities at $z = \mathrm{i}$ and $z = 1/2 + \mathrm{i}\sqrt{3}/2$.

An interesting example of a compact arithmetic surface is the "regular octagon," a hyperbolic surface of genus 2. Its fundamental domain is shown in **Figure 3** as a subset of the Poincaré disc $\mathfrak{D} = \{z \in \mathbb{C} \colon |z| < 1\}$, which yields an alternative parametrization of the hyperbolic plane $\mathbb{H}$. In these coordinates, the Riemannian line and volume element read

$$\mathrm{d}s^2 = \frac{4(\mathrm{d}x^2 + \mathrm{d}y^2)}{(1 - x^2 - y^2)^2}, \quad \mathrm{d}A = \frac{4\mathrm{d}x\,\mathrm{d}y}{(1 - x^2 - y^2)^2} \qquad [10]$$

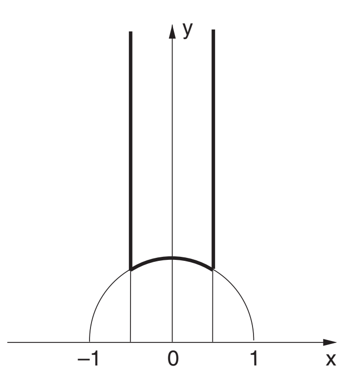

**Figure 2** Fundamental domain of the modular group PSL(2, *Z*) in the complex upper-half plane.

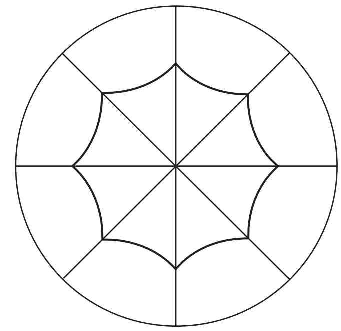

**Figure 3** Fundamental domain of the regular octagon in the Poincaré disk.

The group of orientation-preserving isometries is now represented by $\mathrm{PSU}(1,1) = \mathrm{SU}(1,1)/\{\pm 1\}$, where

$$\mathrm{SU}(1,1) = \left\{ \begin{pmatrix} \alpha & \beta \\ \bar{\beta} & \bar{\alpha} \end{pmatrix} \colon \alpha, \beta \in \mathbb{C}, |\alpha|^2 - |\beta|^2 = 1 \right\} \qquad [11]$$

acting on $\mathfrak{D}$ as above via fractional linear transformations. The fundamental group of the regular octagon surface is the subgroup of all elements in $\mathrm{PSU}(1,1)$ with coefficients of the form

$$\alpha = k + l\sqrt{2}, \quad \beta = (m + n\sqrt{2})\sqrt{1 + \sqrt{2}} \qquad [12]$$

where $k, l, m, n \in \mathbb{Z}[\mathrm{i}]$, that is, Gaussian integers of the form $k_1 + \mathrm{i}k_2, k_1, k_2 \in \mathbb{Z}$. Note that not all choices of $k, l, m, n \in \mathbb{Z}[\mathrm{i}]$ satisfy the condition $|\alpha|^2 - |\beta|^2 = 1$. Since all elements $\gamma \neq 1$ of $\Gamma$ act fix-point free on $\mathbb{H}$, the surface $\Gamma \backslash \mathbb{H}$ is smooth without conic singularities.

In the following, we will restrict our attention to a representative case, the modular surface with $\Gamma = \mathrm{PSL}(2,\mathbb{Z})$.

## Eigenvalue Statistics and Selberg Trace Formula

The statistical properties of the rescaled eigenvalues $X_j$ (cf. [4]) of the Laplacian can be characterized by their distribution in small intervals

$$\mathcal{N}(x, L) := \#\{j : x \le X_j \le x + L\} \qquad [13]$$

where $x$ is uniformly distributed, say, in the interval $[X, 2X]$, $X$ large. Numerical experiments by Bogomolny, Georgeot, Giannoni, and Schmit, as well as Bolte, Steil, and Steiner (see references in

Bogomolny (1997)) suggest that the $X_j$ are asymptotically Poisson distributed:

**Conjecture 1** For any bounded function $g:\mathbb{Z}_{\geq 0}\to\mathbb{C}$ we have

$$\frac{1}{X}\int_X^{2X} g(\mathcal{N}(x,L))\,\mathrm{d}x \to \sum_{k=0}^{\infty} g(k)\frac{L^k\mathrm{e}^{-L}}{k!} \qquad [14]$$

as $T\to\infty$.

One may also consider larger intervals, where $L\to\infty$ as $X\to\infty$. In this case, the assumption on the independence of the $X_j$ predicts a central-limit theorem. Weyl's law [3] implies that the expectation value is asymptotically, for $T\to\infty$,

$$\frac{1}{X}\int_X^{2X} \mathcal{N}(x,L)\,\mathrm{d}x \sim L \qquad [15]$$

This asymptotics holds for any sequence of $L$ bounded away from zero (e.g., $L$ constant, or $L\to\infty$).

Define the variance by

$$\Sigma^2(X,L) = \frac{1}{X}\int_X^{2X}(\mathcal{N}(x,L)-L)^2\,\mathrm{d}x \qquad [16]$$

In view of the above conjecture, one expects $\Sigma^2(X,L)\sim L$ in the limit $X\to\infty, L/\sqrt{X}\to 0$ (the variance exhibits a less universal behavior in the range $L\gg\sqrt{X}$ (the notation $A\ll B$ means there is a constant $c>0$ such that $A\leq cB$), cf. Sarnak (1995), and a central-limit theorem for the fluctuations around the mean:

**Conjecture 2** For any bounded function $g:\mathbb{R}\to\mathbb{C}$ we have

$$\frac{1}{X}\int_X^{2X} g\left(\frac{\mathcal{N}(x,L)-L}{\sqrt{\Sigma^2(x,L)}}\right)\mathrm{d}x \to \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} g(t)\,\mathrm{e}^{-(1/2)t^2}\,\mathrm{d}t \qquad [17]$$

as $X,L\to\infty, L\ll X$.

The main tool in the attempts to prove the above conjectures has been the Selberg trace formula. It relates sums over eigenvalues of the Laplacians to sums over lengths of closed geodesics on the hyperbolic surface. The trace formula is in its simplest form in the case of compact hyperbolic surfaces; we have

$$\sum_{j=0}^{\infty} h(\rho_j) = \frac{\mathrm{Area}(\mathcal{M})}{4\pi}\int_{-\infty}^{\infty} h(\rho)\tanh(\pi\rho)\rho\,\mathrm{d}\rho + \sum_{\gamma\in H_*}\sum_{n=1}^{\infty}\frac{\ell_\gamma\, g(n\ell_\gamma)}{2\sinh(n\ell_\gamma/2)} \qquad [18]$$

where $H_*$ is the set of all primitive oriented closed geodesics $\gamma$, and $\ell_\gamma$ their lengths. The quantity $\rho_j$ is related to the eigenvalue $\lambda_j$ by the equation $\lambda_j=\rho_j^2+1/4$. The trace formula [18] holds for a large class of even test functions $h$. For example, it is sufficient to assume that $h$ is infinitely differentiable, and that the Fourier transform of $h$,

$$g(t) = \frac{1}{2\pi}\int_{\mathbb{R}} h(\rho)\,\mathrm{e}^{-\mathrm{i}\rho t}\,\mathrm{d}\rho \qquad [19]$$

has compact support. The trace formula for noncompact surfaces has additional terms from the parabolic elements in the corresponding group, and includes also sums over the resonances of the continuous part of the spectrum. The noncompact modular surface behaves in many ways like a compact surface. In particular, Selberg showed that the number of eigenvalues embedded in the continuous spectrum satisfies the same Weyl law as in the compact case (Sarnak 2003).

Setting

$$h(\rho) = \chi_{[X,X+L]}\left(\frac{\mathrm{Area}(\mathcal{M})}{4\pi}\left(\rho^2+\frac{1}{4}\right)\right) \qquad [20]$$

where $\chi_{[X,X+L]}$ is the characteristic function of the interval $[X,X+L]$, we may thus view $\mathcal{N}(X,L)$ as the left-hand side of the trace formula. The above test function $h$ is, however, not admissible, and requires appropriate smoothing. Luo and Sarnak (cf. Sarnak (2003)) developed an argument of this type to obtain a lower bound on the average number variance,

$$\frac{1}{L}\int_0^L \Sigma^2(X,L')\,\mathrm{d}L' \gg \frac{\sqrt{X}}{(\log X)^2} \qquad [21]$$

in the regime $\sqrt{X}/\log X\ll L\ll\sqrt{X}$, which is consistent with the Poisson conjecture $\Sigma^2(X,L)\sim L$. Bogomolny, Levyraz, and Schmit suggested a remarkable limiting formula for the two-point correlation function for the modular surface (cf. Bogomolny *et al.* (1997) and Bogomolny (2006)), based on an analysis of the correlations between multiplicities of lengths of closed geodesics. A rigorous analysis of the fluctuations of multiplicities is given by Peter (cf. Bogomolny (2006)). Rudnick (2005) has recently established a smoothed version of Conjecture 2 in the regime

$$\frac{\sqrt{X}}{L}\to\infty, \qquad \frac{\sqrt{X}}{L\log X}\to 0 \qquad [22]$$

where the characteristic function in [20] is replaced by a certain class of smooth test functions.

All of the above approaches use the Selberg trace formula, exploiting the particular properties of the

distribution of lengths of closed geodesics in arithmetic hyperbolic surfaces. These will be discussed in more detail in the next section, following the work of Bogomolny, Georgeot, Giannoni and Schmit, Bolte, and Luo and Sarnak (see Bogomolny *et al.* (1997) and Sarnak (1995) for references).

## Distribution of Lengths of Closed Geodesics

The classical prime geodesic theorem asserts that the number $N(\ell)$ of primitive closed geodesics of length less than $\ell$ is asymptotically

$$N(\ell) \sim \frac{e^{\ell}}{\ell} \qquad [23]$$

One of the significant geometrical characteristics of arithmetic hyperbolic surfaces is that the number of closed geodesics with the same length $\ell$ grows exponentially with $\ell$. This phenomenon is most easily explained in the case of the modular surface, where the set of lengths $\ell$ appearing in the lengths spectrum is characterized by the condition

$$2\cosh(\ell/2) = |\mathrm{tr}\ \gamma| \qquad [24]$$

where $\gamma$ runs over all elements in $\mathrm{SL}(2, \mathbb{Z})$ with $|\mathrm{tr}\gamma| > 2$. It is not hard to see that any integer $n > 2$ appears in the set $\{|\mathrm{tr}\ \gamma| : \gamma \in \mathrm{SL}(2, \mathbb{Z})\}$, and hence the set of distinct lengths of closed geodesics is

$$\mathcal{L} = \{2\ \mathrm{arcosh}(n/2) : n = 3, 4, 5, \ldots\} \qquad [25]$$

Therefore, the number of distinct lengths less than $\ell$ is asymptotically (for large $\ell$)

$$N'(\ell) = \#(\mathcal{L} \cap [0, \ell]) \sim e^{\ell/2} \qquad [26]$$

Equations [26] and [23] say that on average the number of geodesics with the same lengths is at least $\asymp e^{\ell/2}/\ell$.

The prime geodesic theorem [23] holds equally for all hyperbolic surfaces with finite area, while [26] is specific to the modular surface. For general arithmetic surfaces, we have the upper bound

$$N'(\ell) \leq c e^{\ell/2} \qquad [27]$$

for some constant $c > 0$ that may depend on the surface. Although one expects $N'(\ell)$ to be asymptotic to $(1/2)N(\ell)$ for generic surfaces (since most geodesics have a time-reversal partner which thus has the same length, and otherwise all lengths are distinct), there are examples of nonarithmetic Hecke triangles where numerical and heuristic arguments suggest $N'(\ell) \sim c_1 e^{c_2 \ell}/\ell$ for suitable constants $c_1 > 0$ and $0 < c_2 < 1/2$ (cf. Bogomolny (2006)). Hence exponential degeneracy in the length spectrum seems to occur in a weaker form also for nonarithmetic surfaces.

A further useful property of the length spectrum of arithmetic surfaces is the bounded clustering property: there is a constant $C$ (again surface dependent) such that

$$\#(\mathcal{L} \cap [\ell, \ell + 1]) \leq C \qquad [28]$$

for all $\ell$. This fact is evident in the case of the modular surface; the general case is proved by Luo and Sarnak (cf. Sarnak (1995)).

## Quantum Unique Ergodicity

The unit tangent bundle of a hyperbolic surface $\Gamma\backslash\mathbb{H}$ describes the physical phase space on which the classical dynamics takes place. A convenient parametrization of the unit tangent bundle is given by the quotient $\Gamma\backslash\mathrm{PSL}(2, \mathbb{R}$ – this may be seen be means of the Iwasawa decomposition for an element $g \in \mathrm{PSL}(2, \mathbb{R})$,

$$g = \begin{pmatrix} 1 & x \\ 0 & 1 \end{pmatrix} \begin{pmatrix} y^{1/2} & 0 \\ 0 & y^{-1/2} \end{pmatrix} \times \begin{pmatrix} \cos\theta/2 & \sin\theta/2 \\ -\sin\theta/2 & \cos\theta/2 \end{pmatrix} \qquad [29]$$

where $x + iy \in \mathfrak{H}$ represents the position of the particle in $\Gamma\backslash\mathbb{H}$ in half-plane coordinates, and $\theta \in [0, 2\pi)$ the direction of its velocity. Multiplying the matrix [29] from the left by $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ and writing the result again in the Iwasawa form [29], one obtains the action

$$(z, \phi) \mapsto \left( \frac{az + b}{cz + d}, \theta - 2\arg(cz + d) \right) \qquad [30]$$

which represents precisely the geometric action of isometries on the unit tangent bundle.

The geodesic flow $\Phi^t$ on $\Gamma\backslash\mathrm{PSL}(2, \mathbb{R})$ is represented by the right translation

$$\Phi^t : \Gamma g \mapsto \Gamma g \begin{pmatrix} e^{t/2} & 0 \\ 0 & e^{-t/2} \end{pmatrix} \qquad [31]$$

The Haar measure $\mu$ on $\mathrm{PSL}(2, \mathbb{R})$ is thus trivially invariant under the geodesic flow. It is well known that $\mu$ is not the only invariant measure, that is, $\Phi^t$ is not uniquely ergodic, and that there is in fact an abundance of invariant measures. The simplest examples are those with uniform mass on one, or a countable collection of, closed geodesics.

To test the distribution of an eigenfunction $\varphi_j$ in phase space, one associates with a function

$a \in C^\infty(\Gamma\backslash PSL(2, \mathbb{R}))$ the quantum observable $Op(a)$, a zeroth order pseudodifferential operator with principal symbol $a$. Using semiclassical techniques based on Friedrich's symmetrization, one can show that the matrix element

$$\nu_j(a) = \langle Op(a)\varphi_j, \varphi_j \rangle \qquad [32]$$

is asymptotic (as $j \to \infty$) to a positive functional that defines a probability measure on $\Gamma\backslash PSL(2, \mathbb{R})$. Therefore, if $\mathcal{M}$ is compact, any weak limit of $\nu_j$ represents a probability measure on $\Gamma\backslash PSL(2, \mathbb{R})$. Egorov's theorem (*see* Quantum Ergodicity and Mixing of Eigenfunctions) in turn implies that any such limit must be invariant under the geodesic flow, and the main challenge in proving QUE is to rule out all invariant measures apart from Haar.

**Conjecture 3** (Rudnick and Sarnak (1994); see Sarnak (1995, 2003)). For every compact hyperbolic surface $\Gamma\backslash\mathbb{H}$, the sequence $\nu_j$ converges weakly to $\mu$.

Lindenstrauss has proved this conjecture for compact arithmetic hyperbolic surfaces of congruence type (such as the second example in the section "Hyperbolic surfaces") for special bases of eigenfunctions, using ergodic-theoretic methods. These will be discussed in more detail in the next section. His results extend to the noncompact case, that is, to the modular surface where $\Gamma = PSL(2, \mathbb{Z})$. Here he shows that any weak limit of subsequences of $\nu_j$ is of the form $c\mu$, where $c$ is a constant with values in $[0, 1]$. One believes that $c = 1$, but with present techniques it cannot be ruled out that a proportion of the mass of the eigenfunction escapes into the noncompact cusp of the surface. For the modular surface, $c = 1$ can be proved under the assumption of the generalized Riemann hypothesis (see the section "Eigenfunctions and $L$-functions" and Sarnak (2003)). QUE also holds for the continuous part of the spectrum, which is furnished by the Eisenstein series $E(z, s)$, where $s = 1/2 + ir$ is the spectral parameter. Note that the measures associated with the matrix elements

$$\nu_r(a) = \langle Op(a)E(\cdot, 1/2 + ir), E(\cdot, 1/2 + ir)\rangle \qquad [33]$$

are not probability measures but only Radon measures, since $E(z, s)$ is not square-integrable. Luo and Sarnak, and Jakobson have shown that

$$\lim_{r\to\infty} \frac{\nu_r(a)}{\nu_r(b)} = \frac{\mu(a)}{\mu(b)} \qquad [34]$$

for suitable test functions $a, b \in C^\infty(\Gamma\backslash PSL(2, \mathbb{R}))$ (cf. Sarnak (2003)).

## Hecke Operators, Entropy and Measure Rigidity

For compact surfaces, the sequence of probability measures approaching the matrix elements $\nu_j$ is relatively compact. That is, every infinite sequence contains a convergent subsequence. Lindenstrauss' central idea in the proof of QUE is to exploit the presence of Hecke operators to understand the invariance properties of possible quantum limits. We will sketch his argument in the case of the modular surface (ignoring issues related to the noncompactness of the surface), where it is most transparent.

For every positive integer $n$, the Hecke operator $T_n$ acting on continuous functions on $\Gamma\backslash\mathbb{H}$ with $\Gamma = SL(2, \mathbb{Z})$ is defined by

$$T_n f(z) = \frac{1}{\sqrt{n}} \sum_{\substack{a,d=1 \\ ad=n}}^{n} \sum_{b=0}^{d-1} f\left(\frac{az+b}{d}\right) \qquad [35]$$

The set $M_n$ of matrices with integer coefficients and determinant $n$ can be expressed as the disjoint union

$$M_n = \bigcup_{\substack{a,d=1 \\ ad=n}}^{n} \bigcup_{b=0}^{d-1} \Gamma \begin{pmatrix} a & b \\ 0 & d \end{pmatrix} \qquad [36]$$

and hence the sum in [35] can be viewed as a sum over the cosets in this decomposition. We note the product formula

$$T_m T_n = \sum_{d|\gcd(m,n)} T_{mn/d^2} \qquad [37]$$

The Hecke operators are normal, form a commuting family, and in addition they commute with the Laplacian $\Delta$. In the following, we consider an orthonormal basis of eigenfunctions $\varphi_j$ of $\Delta$ that are simultaneously eigenfunctions of all Hecke operators. We will refer to such eigenfunctions as Hecke eigenfunctions. The above assumption is automatically satisfied, if the spectrum of $\Delta$ is simple (i.e., no eigenvalues coincide), a property conjectured by Cartier and supported by numerical computations. Lindenstrauss' work is based on the following two observations. Firstly, all quantum limits of Hecke eigenfunctions are geodesic-flow invariant measures of positive entropy, and secondly, the only such measure of positive entropy that is recurrent under Hecke correspondences is the Lebesgue measure.

The first property is proved by Bourgain and Lindenstrauss (2003) and refines arguments of Rudnick and Sarnak (1994) and Wolpert (2001) on the distribution of Hecke points (see Sarnak (2003) for

references to these papers). For a given point $z \in \mathbb{H}$ the set of Hecke points is defined as

$$T_n(z) := M_n z \quad [38]$$

For most primes, the set $T_{p^k}(z)$ comprises $(p+1)p^{k-1}$ distinct points on $\Gamma\backslash\mathbb{H}$. For each $z$, the Hecke operator $T_n$ may now be interpreted as the adjacency matrix for a finite graph embedded in $\Gamma\backslash\mathbb{H}$, whose vertices are the Hecke points $T_n(z)$. Hecke eigenfunctions $\varphi_j$ with

$$T_n\varphi_j = \lambda_j(n)\varphi_j \quad [39]$$

give rise to eigenfunctions of the adjacency matrix. Exploiting this fact, Bourgain and Lindenstrauss show that for a large set of integers $n$

$$|\varphi_j(z)|^2 \ll \sum_{w\in T_n(z)} |\varphi_j(w)|^2 \quad [40]$$

that is, pointwise values of $|\varphi_j|^2$ cannot be substantially larger than its sum over Hecke points. This, and the observation that Hecke points for a large set of integers $n$ are sufficiently uniformly distributed on $\Gamma\backslash\mathbb{H}$ as $n\to\infty$, yields the estimate of positive entropy with a quantitative lower bound.

Lindenstrauss' proof of the second property, which shows that Lebesgue measure is the only quantum limit of Hecke eigenfunctions, is a result of a currently very active branch of ergodic theory: measure rigidity. Invariance under the geodesic flow alone is not sufficient to rule out other possible limit measures. In fact, there are uncountably many measures with this property. As limits of Hecke eigenfunctions, all quantum limits possess an additional property, namely recurrence under Hecke correspondences. Since the explanation of these is rather involved, let us recall an analogous result in a simpler setup. The map $\times 2 : x \mapsto 2x \bmod 1$ defines a hyperbolic dynamical system on the unit circle with a wealth of invariant measures, similar to the case of the geodesic flow on a surface of negative curvature. Furstenberg conjectured that, up to trivial invariant measures that are localized on finitely many rational points, Lebesgue measure is the only $\times 2$-invariant measure that is also invariant under action of $\times 3 : x \mapsto 3x \bmod 1$. This fundamental problem is still unsolved and one of the central conjectures in measure rigidity. Rudolph, however, showed that Furstenberg's conjecture is true if one restricts the statement to $\times 2$-invariant measures of positive entropy (cf. Lindenstrauss (to appear)). In Lindenstrauss' work, $\times 2$ plays the role of the geodesic flow, and $\times 3$ the role of the Hecke correspondences. Although here it might also be interesting to ask whether an analog of Furstenberg's conjecture holds, it is inessential for the proof of QUE due to the positive entropy of quantum limits discussed in the previous paragraph.

## Eigenfunctions and *L*-Functions

An even eigenfunction $\varphi_j(z)$ for $\Gamma = \mathrm{SL}(2,\mathbb{Z})$ has the Fourier expansion

$$\varphi_j(z) = \sum_{n=1}^{\infty} a_j(n) y^{1/2} K_{\mathrm{i}\rho_j}(2\pi n y)\cos(2\pi n x) \quad [41]$$

We associate with $\varphi_j(z)$ the Dirichlet series

$$L(s,\varphi_j) = \sum_{n=1}^{\infty} a_j(n) n^{-s} \quad [42]$$

which converges for Re $s$ large enough. These series have an analytic continuation to the entire complex plane $\mathbb{C}$ and satisfy a functional equation,

$$\Lambda(s,\varphi_j) = \Lambda(1-s,\varphi_j) \quad [43]$$

where

$$\Lambda(s,\varphi_j) = \pi^{-s}\Gamma\left(\frac{s+\mathrm{i}\rho_j}{2}\right)\Gamma\left(\frac{s-\mathrm{i}\rho_j}{2}\right)L(s,\varphi_j) \quad [44]$$

If $\varphi_j(z)$ is in addition an eigenfunction of all Hecke operators, then the Fourier coefficients in fact coincide (up to a normalization constant) with the eigenvalues of the Hecke operators

$$a_j(m) = \lambda_j(m) a_j(1) \quad [45]$$

If we normalize $a_j(1) = 1$, the Hecke relations [37] result in an Euler product formula for the $L$-function,

$$L(s,\varphi_j) = \prod_{p \text{ prime}} \left(1 - a_j(p)p^{-s} + p^{-1-2s}\right)^{-1} \quad [46]$$

These $L$-functions behave in many other ways like the Riemann zeta or classical Dirichlet $L$-functions. In particular, they are expected to satisfy a Riemann hypothesis, that is, all nontrivial zeros are constrained to the critical line $\mathrm{Im}\, s = 1/2$.

Questions on the distribution of Hecke eigenfunctions, such as QUE or value distribution properties, can now be translated to analytic properties of $L$-functions. We will discuss two examples.

The asymptotics in [6] can be established by proving [6] for the choices $g = \varphi_k, k = 1, 2, \ldots,$ that is,

$$\int_{\mathcal{M}} |\varphi_j|^2 \varphi_k \, \mathrm{d}A \to 0 \quad [47]$$

Watson discovered the remarkable relation (Sarnak 2003)

$$\left|\int_{\mathcal{M}} \varphi_{j_1}\varphi_{j_2}\varphi_{j_3}\,\mathrm{d}A\right|^2 = \frac{\pi^4 \Lambda(\frac{1}{2}, \varphi_{j_1}\times\varphi_{j_2}\times\varphi_{j_3})}{\Lambda(1,\mathrm{sym}^2\varphi_{j_1})\Lambda(1,\mathrm{sym}^2\varphi_{j_2})\Lambda(1,\mathrm{sym}^2\varphi_{j_3})} \quad [48]$$

The $L$-functions $\Lambda(s, g)$ in Watson's formula are more advanced cousins of those introduced earlier (see Sarnak (2003) for details). The Riemann hypothesis for such $L$-functions then implies, via [48], a precise rate of convergence to QUE for the modular surface,

$$\int_{\mathcal{M}} |\varphi_j|^2 g\,\mathrm{d}A = \int_{\mathcal{M}} g\,\mathrm{d}A + O(\lambda_j^{-1/4+\epsilon}) \quad [49]$$

for any $\epsilon > 0$, where the implied constant depends on $\epsilon$ and $g$.

A second example on the connection between statistical properties of the matrix elements $\nu_j(a) = \langle \mathrm{Op}(a)\varphi_j, \varphi_j\rangle$ (for fixed $a$ and random $j$) and values $L$-functions has appeared in the work of Luo and Sarnak (cf. Sarnak (2003)). Define the variance

$$V_\lambda(a) = \frac{1}{N(\lambda)}\sum_{\lambda_j\le\lambda}\left|\nu_j(a) - \mu(a)\right|^2 \quad [50]$$

with $N(\lambda) = \#\{j: \lambda_j \le \lambda\}$; cf. [3]. Following a conjecture by Feingold–Peres and Eckhardt *et al.* (see Sarnak (2003) for references) for "generic" quantum chaotic systems, one expects a central-limit theorem for the statistical fluctuations of the $\nu_j(a)$, where the normalized variance $N(\lambda)^{1/2}V_\lambda(a)$ is asymptotic to the classical autocorrelation function $C(a)$, see eqn [54].

**Conjecture 4** For any bounded function $g: \mathbb{R}\to\mathbb{C}$ we have

$$\frac{1}{N(\lambda)}\sum_{\lambda_j\le\lambda} g\left(\frac{\nu_j(a)-\mu(a)}{\sqrt{V_\lambda(a)}}\right) \to \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} g(t)\mathrm{e}^{-(1/2)t^2}\mathrm{d}t \quad [51]$$

as $\lambda\to\infty$.

Luo and Sarnak prove that in the case of the modular surface the variance has the asymptotics

$$\lim_{\lambda\to\infty} N(\lambda)^{1/2}V_\lambda(a) = \langle Ba, a\rangle \quad [52]$$

where $B$ is a non-negative self-adjoint operator which commutes with the Laplacian $\Delta$ and all Hecke operators $T_n$. In particular, we have

$$B\varphi_j = \tfrac{1}{2}L(\tfrac{1}{2},\varphi_j)C(\varphi_j)\varphi_j \quad [53]$$

where

$$C(a) := \int_{\mathbb{R}}\int_{\Gamma\backslash\mathrm{PSL}(2,\mathbb{R})} a(\Phi^t(g))\overline{a(g)}\,\mathrm{d}\mu(g)\,\mathrm{d}t \quad [54]$$

is the classical autocorrelation function for the geodesic flow with respect to the observable $a$ (Sarnak 2003). Up to the arithmetic factor $(1/2)L(1/2, \varphi_j)$, eqn [53] is consistent with the Feingold–Peres prediction for the variance of generic chaotic systems. Furthermore, recent estimates of moments by Rudnick and Soundararajan (2005) indicate that Conjecture 4 is not valid in the case of the modular surface.

## Quantum Eigenstates of Cat Maps

Cat maps are probably the simplest area-preserving maps on a compact surface that are highly chaotic. They are defined as linear automorphisms on the torus $\mathbb{T}^2 = \mathbb{R}^2/\mathbb{Z}^2$,

$$\Phi_A : \mathbb{T}^2 \to \mathbb{T}^2 \quad [55]$$

where a point $\xi\in\mathbb{R}^2(\mathrm{mod}\,\mathbb{Z}^2)$ is mapped to $A\xi(\mathrm{mod}\,\mathbb{Z}^2)$; $A$ is a fixed matrix in $\mathrm{GL}(2,\mathbb{Z})$ with eigenvalues off the unit circle (this guarantees hyperbolicity). We view the torus $\mathbb{T}^2$ as a symplectic manifold, the phase space of the dynamical system. Since $\mathbb{T}^2$ is compact, the Hilbert space of quantum states is an $N$-dimensional vector space $\mathcal{H}_N$, $N$ integer. The semiclassical limit, or limit of small wavelengths, corresponds here to $N\to\infty$.

It is convenient to identify $\mathcal{H}_N$ with $\mathrm{L}^2(\mathbb{Z}/N\mathbb{Z})$, with the inner product

$$\langle\psi_1,\psi_2\rangle = \frac{1}{N}\sum_{Q \bmod N}\psi_1(Q)\overline{\psi_2(Q)} \quad [56]$$

For any smooth function $f\in\mathrm{C}^\infty(\mathbb{T}^2)$, define a quantum observable

$$\mathrm{Op}_N(f) = \sum_{n\in\mathbb{Z}^2}\widehat{f}(n)T_N(n)$$

where $\widehat{f}(n)$ are the Fourier coefficients of $f$, and $T_N(n)$ are translation operators

$$T_N(n) = \mathrm{e}^{\pi\mathrm{i}n_1n_2/N}t_2^{n_2}t_1^{n_1} \quad [57]$$

$$[t_1\psi](Q) = \psi(Q+1)$$
$$[t_2\psi](Q) = \mathrm{e}^{2\pi\mathrm{i}Q/N}\psi(Q) \quad [58]$$

The operators $\mathrm{Op}_N(a)$ are the analogs of the pseudodifferential operators discussed in the section "Quantum unique ergodicity."

A quantization of $\Phi_A$ is a unitary operator $U_N(A)$ on $L^2(\mathbb{Z}/N\mathbb{Z})$ satisfying the equation

$$U_N(A)^{-1}\mathrm{Op}_N(f)U_N(A) = \mathrm{Op}_N(f \circ \Phi_A) \qquad [59]$$

for all $f \in C^\infty(\mathbb{T}^2)$. There are explicit formulas for $U_N(A)$ when $A$ is in the group

$$\Gamma = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2,\mathbb{Z}): ab \equiv cd \equiv 0 \bmod 2 \right\} \qquad [60]$$

These may be viewed as analogs of the Shale–Weil or metaplectic representation for SL(2). for example, the quantization of

$$A = \begin{pmatrix} 2 & 1 \\ 3 & 2 \end{pmatrix} \qquad [61]$$

yields

$$U_N(A)\psi(Q) = N^{-1/2} \sum_{Q' \bmod N} \exp\left[\frac{2\pi i}{N}(Q^2 - QQ' + Q'^2)\right]\psi(Q') \qquad [62]$$

In analogy with [1], we are interested in the statistical features of the eigenvalues and eigenfunctions of $U_N(A)$, that is, the solutions to

$$U_N(A)\varphi = \lambda\varphi, \quad \|\varphi\|_{L^2(\mathbb{Z}/N\mathbb{Z})} = 1 \qquad [63]$$

Unlike typical quantum-chaotic maps, the statistics of the $N$ eigenvalues

$$\lambda_{N1}, \lambda_{N2}, \ldots, \lambda_{NN} \in S^1 \qquad [64]$$

do not follow the distributions of unitary random matrices in the limit $N \to \infty$, but are rather singular (Keating 1991). In analogy with the Selberg trace formula for hyperbolic surfaces [18], there is an exact trace formula relating sums over eigenvalues of $U_N(A)$ with sums over fixed points of the classical map (Keating 1991).

As in the case of arithmetic surfaces, the eigenfunctions of cat maps appear to behave more generically. The analog of the Schnirelman–Zelditch–Colin de Verdière theorem states that, for any orthonormal basis of eigenfunctions $\{\varphi_{Nj}\}_{j=1}^N$ we have, for all $f \in C^\infty(\mathbb{T}^2)$,

$$\langle \mathrm{Op}(f)\varphi_{Nj}, \varphi_{Nj}\rangle \to \int_{\mathbb{T}^2} f(\xi)\mathrm{d}\xi \qquad [65]$$

as $N \to \infty$, for all $j$ in an index set $J_N$ of full density, that is, $\#J_N \sim N$. Kurlberg and Rudnick (see Rudnick (2001)) have characterized special bases of eigenfunctions $\{\varphi_{Nj}\}_{j=1}^N$ (termed Hecke eigenbases, in analogy with arithmetic surfaces) for which QUE holds, generalizing earlier work of Degli Esposti, Graffi, and Isola (1995). That is, [65] holds for all $j = 1, \ldots, N$. Rudnick and Kurlberg, and more recently Gurevich and Hadani, have established results on the rate of convergence analogous to [49]. These results are unconditional. Gurevich and Hadani use methods from algebraic geometry based on those developed by Deligne in his proof of the Weil conjectures (an analog of the Riemann hypothesis for finite fields).

In the case of quantum-cat maps, there are values of $N$ for which the number of coinciding eigenvalues can be large, a major difference to what is expected for the modular surface. Linear combinations of eigenstates with the same eigenvalue are as well eigenstates, and may lead to different quantum limits. Indeed, Faure, Nonnenmacher, and De Bièvre (see De Bièvre (to appear)) have shown that there are subsequences of values of $N$, so that, for all $f \in C^\infty(\mathbb{T}^2)$,

$$\langle \mathrm{Op}(f)\varphi_{Nj}, \varphi_{Nj}\rangle \to \frac{1}{2}\int_{\mathbb{T}^2} f(\xi)\mathrm{d}\xi + \frac{1}{2}f(0) \qquad [66]$$

that is, half of the mass of the quantum limit localizes on the hyperbolic fixed point of the map. This is the first, and to date the only, rigorous result concerning the existence of scarred eigenfunctions in systems with chaotic classical limit.

# Asymptotic Structure and Conformal Infinity

**J Frauendiener**, Universität Tübingen, Tübingen, Germany

## Introduction

A major motivation for studying the asymptotic structure of spacetimes has been the need for a rigorous description of what should be understood by an "isolated system" in Einstein's theory of gravity. As an example, consider a gravitating system somewhere in our universe (e.g., a galaxy, a cluster of galaxies, a binary system, or a star) evolving according to its own gravitational interaction, and possibly reacting to gravitational radiation impinging on it from the outside. Thereby it will emit gravitational radiation. We are interested in describing these waves because they provide us with important information about the physics governing the system.

To adequately describe this situation, we need to idealize the real situation in an appropriate way, since it is hopeless to try to analyze the behavior of the system in its interaction with the rest of the universe. We are mainly interested in the behavior of the system, and not so much in other processes taking place at large distances from the system. Since we would like to ignore those regions, we need a way to isolate the system from their influence.

The notion of an isolated system allows us to select individual subsystems of the universe and describe their properties regardless of the rest of the universe so that we can assign to each subsystem such physical attributes as its energy–momentum, angular momentum, or its emitted radiation field. Without this notion, we would always have to take into account the interaction of the system with its environment in full detail.

In general relativity (GR) it turns out to be a rather difficult task to describe an isolated system and the reason is – as always in Einstein's theory – the fact that the metric acts both as the physical field and as the background. In other theories, like electrodynamics, the physical field, such as the Maxwell field, is very different from the background field, the flat metric of Minkowski space. The fact that the metric in GR plays a dual role makes it difficult to extract physical meaning from the metric because there is no nondynamical reference point.

Imagine a system alone in the universe. As we recede from the system we would expect its influence to decrease. So we expect that the spacetime which models this situation mathematically will resemble the flat Minkowski spacetime and it will approximate it even better the farther away we go. This implies that one needs to impose fall-off conditions for the curvature and that the manifold will be asymptotically flat in an appropriate sense. However, there is the problem that fall-off conditions necessarily imply the use of coordinates and it is awkward to decide which coordinates should be "good ones." Thus, it is not clear whether the notion of an asymptotically flat spacetime is an invariant concept.

What is needed, therefore, is an invariant definition of asymptotically flat spacetimes. The key observation in this context is that "infinity" is far away with respect to the spacetime metric. This means that geodesics heading away from the system should be able to "run forever," that is, be defined for arbitrary values of their affine parameter $s$. "Infinity" will be reached for $s \to \infty$. However, suppose we do not use the spacetime metric $g$ but a metric $\hat{g}$ which is scaled down with respect to $g$, that is, in such a way that $\hat{g} = \Omega^2 g$ for some function $\Omega$. Then it might be possible to arrange $\Omega$ in such a way that geodesics for the metric $\hat{g}$ cover the same events (strictly speaking, this holds only for null geodesics, but this is irrelevant for the present plausibility argument) as those for the metric $g$ yet that their affine parameter $\hat{s}$ (which is also scaled down with respect to $s$) approaches a finite value $\hat{s}_0$ for $s \to \infty$. Then we could attach a boundary to the spacetime manifold consisting of all the limit points corresponding to the events with $\hat{s} = \hat{s}_0$ on the $\hat{g}$-geodesics.

This boundary would have to be interpreted as "infinity" for the spacetime because it takes infinitely long for the $g$-geodesics to get there.

We arrived at this idea of attaching a boundary by considering the metric structure only "up to arbitrary scaling," that is, by looking at metrics which differ only by a factor. This is the conformal structure of the spacetime manifold in question. By considering the spacetime only from the point of view of its conformal structure we obtain a picture of the spacetime which is essentially finite but which leaves its causal properties unchanged, and hence in particular the properties of wave propagation. This is exactly what is needed for a rigorous treatment of radiation emitted by the system.

## Infinity for Minkowski Spacetime

The above discussion suggests that we should consider the spacetime metric only up to scale, that is, to focus on the conformal structure of the spacetime in question. Since we are interested in systems which approach Minkowski spacetime at large distances from the source, it is illuminating to study Minkowski spacetime as a preliminary example. So consider the manifold $\mathbb{M} = \mathbb{R}^4$ equipped with the flat metric

$$g = \mathrm{d}t^2 - \mathrm{d}r^2 - r^2 \mathrm{d}\sigma^2 \qquad [1]$$

where $r$ is the standard radial coordinate defined by $r^2 = x^2 + y^2 + z^2$ and

$$\mathrm{d}\sigma^2 = \mathrm{d}\theta^2 + \sin^2\theta \mathrm{d}\phi^2$$

is the standard metric on the unit sphere $S^2$. We now introduce retarded and advanced time coordinates, which are adapted to the null cone and hence to the conformal structure of $g$ by the definition

$$u = t - r, \qquad v = t + r$$

and obtain the metric in the form

$$g = \mathrm{d}u\,\mathrm{d}v - \tfrac{1}{4}(v - u)^2 \mathrm{d}\sigma^2$$

The coordinates $u$ and $v$ both take arbitrary real values but they are restricted by the relation $v - u = 2r \geq 0$. In order to see what happens "at infinity," we introduce the coordinates $U$ and $V$ by the relations

$$u = \tan\, U, \qquad v = \tan\, V$$

Then $U$ and $V$ both take values in the open interval $(-\pi/2, \pi/2)$ with $V \geq U$ and the metric is transformed to

$$g = \frac{1}{4\cos^2 U \cos^2 V}\left[4\mathrm{d}U\,\mathrm{d}V - \sin^2(V - U)\,\mathrm{d}\sigma^2\right] \qquad [2]$$

Clearly, the metric is undefined at events with $\cos U = 0$ or $\cos V = 0$. These would correspond to events with $u = \pm\infty$ or $v = \pm\infty$ which do not lie in $\mathbb{M}$. However, by defining the function

$$\Omega = 2\cos U \cos V$$

we find that the metric $\hat{g} = \Omega^2 g$ with

$$\hat{g} = 4\mathrm{d}U\,\mathrm{d}V - \sin^2(V - U)\,\mathrm{d}\sigma^2 \qquad [3]$$

is conformally equivalent to $g$ and is regular for all values of $U$ and $V$ (keeping $V \geq U$). In fact, by defining the coordinates

$$T = V + U, \qquad R = V - U$$

this metric takes the form

$$\hat{g} = \mathrm{d}T^2 - \mathrm{d}R^2 - \sin^2 R\,\mathrm{d}\sigma^2 \qquad [4]$$

the metric of the static Einstein universe $\mathbb{E}$. Thus, we may regard the Minkowski spacetime as the part of the Einstein cylinder defined by restricting the coordinates $T$ and $R$ to the region $|T| + R < \pi$ as illustrated in Figure 1. Although $\mathbb{M}$ can be considered as being diffeomorphic to the shaded part in Figure 1, these two manifolds are not isometric. This is obvious from considering the properties of the events lying on

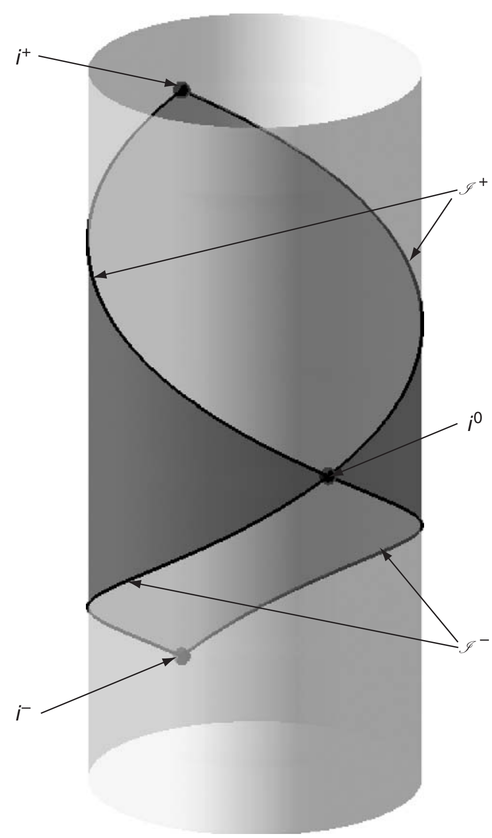

**Figure 1** The embedding of Minkowski spacetime into the Einstein cylinder.

the boundary $\partial\mathbb{M}$ of $\mathbb{M}$ in $\mathbb{E}$. Fix a point $P$ inside $\mathbb{M}$ and follow a null geodesic with respect to the metric $\hat{g}$ from $P$ toward the future. It will intersect $\partial\mathbb{M}$ after a finite amount of its affine parameter has elapsed. When we follow a null geodesic with respect to $g$ from $P$ in the same direction, we find that it does not reach $\partial\mathbb{M}$ for any value of its affine parameter. Thus, the boundary is at infinity for the metric $g$ but at a finite location with respect to the metric $\hat{g}$. When we consider all possible kinds of geodesics for the metric $g$ we find that $\partial\mathbb{M}$ consists of five qualitatively different pieces. The future pointing timelike geodesics all approach the point $i^+$ given by $(T, R) = (\pi, 0)$, while the past-pointing geodesics approach $i^-$ with coordinates $(-\pi, 0)$. All spacelike geodesics come arbitrarily close to a point $i^0$ with coordinates $(0, \pi)$ (located on the front of the cylinder in Figure 1). Null geodesics, however, are different. For any point $(T, \pi - |T|)$ with $T \neq 0, \pm\pi$ on $\partial\mathbb{M}$ there are $g$-null-geodesics which come arbitrarily close.

In this sense, we may regard $\partial\mathbb{M}$ as consisting of limit points obtained by tracing-geodesics for infinite values of their affine parameters. According to the causal character of the geodesics the set of their respective limit points is called future/past timelike infinity $i^\pm$, spacelike infinity $i^0$ or future/past null-infinity, denoted by $\mathscr{I}^\pm$. These two parts of null-infinity are three-dimensional regular submanifolds of the embedding manifold $\mathbb{E}$, while the points $i^\pm, i^0$ are regular points in $\mathbb{E}$ in the sense that the metric $\hat{g}$ is regular there. This is not automatic, considering the fact that infinitely many geodesics converge to a single point. However, the flatness of Minkowski spacetime guarantees that the geodesics approach at just the appropriate rate for the limit points to be regular.

This example shows that the structure of the boundary is determined entirely by the metric $g$ of Minkowski spacetime. If we had chosen a different function $\Omega' = \omega\Omega$ with $\omega > 0$ then we would not have obtained the Einstein cylinder but some different Lorentzian manifold $(\mathcal{M}', g')$. Yet, the boundary of $\mathbb{M}$ in $\mathcal{M}'$ would have had the same properties.

## Asymptotically Flat Spacetimes

The physical idea of an isolated system is captured mathematically by an asymptotically flat spacetime. Since such a spacetime $\mathcal{M}$ is expected to approach Minkowski spacetime asymptotically, the asymptotic structure of $\mathcal{M}$ is also expected to be similar to that of $\mathbb{M}$. This expectation is expressed in

**Definition 1** A spacetime $(\mathcal{M}, g_{ab})$ is called "asymptotically simple" if there exists a manifold-with-boundary $\widehat{\mathcal{M}}$ with metric $\hat{g}_{ab}$ and scalar field $\Omega$ on $\widehat{\mathcal{M}}$ and boundary $\mathcal{I} = \partial\mathcal{M}$ such that the following conditions hold:

1. $\mathcal{M}$ is the interior of $\widehat{\mathcal{M}}$: $\mathcal{M} = \text{int}\ \widehat{\mathcal{M}}$;
2. $\hat{g}_{ab} = \Omega^2 g_{ab}$ on $\mathcal{M}$;
3. $\Omega$ and $\hat{g}_{ab}$ are smooth on all of $\bar{\mathcal{M}}$;
4. $\Omega > 0$ on $\mathcal{M}$; $\Omega = 0, \nabla_a\Omega \neq 0$ on $\mathscr{I}$; and
5. each null geodesic acquires both future and past endpoints on $\mathscr{I}$.

This definition formalizes the construction which was explicitly performed above, by which one attaches a regular (nonempty) boundary to a spacetime after suitably rescaling its metric. Asymptotically simple spacetimes are exactly those for which this process of conformal compactification is possible. The purpose of condition 5 is to exclude pathological cases. There are spacetimes which do not satisfy this condition (e.g., the Schwarzschild spacetime, where some of the null geodesics enter the event horizon and cannot escape to infinity). Yet, one would like to include them as being asymptotically simple in a sense, because they clearly describe isolated systems. For these cases, there exists the notion of weakly asymptotically simple spacetimes.

In order to arrive at asymptotically flat spacetimes, one needs to make certain assumptions about the behavior of the curvature near the boundary, thus:

**Definition 2** An asymptotically simple spacetime is called "asymptotically flat" if its Ricci tensor Ric[$g$] vanishes in a neighborhood of $\mathscr{I}$.

Note that this definition imposes a rather strong restriction on the Ricci curvature; less restrictive assumptions are possible. This condition applies only near $\mathscr{I}$. Thus, it is possible to consider spacetimes which contain matter fields as long as these fields do not extend to infinity.

Other asymptotically simple spacetimes which are not asymptotically flat are the de Sitter and anti-de Sitter spacetimes which are solutions of the Einstein equations with nonvanishing cosmological constant $\lambda$. It is a simple consequence of the definition that the boundary $\mathscr{I}$ is a regular three-dimensional hypersurface of the embedding spacetime $\widehat{\mathcal{M}}$ which is timelike, spacelike, or null depending on the sign of $\lambda$. In particular, for the Minkowski spacetime $(\lambda = 0)$ the boundary is necessarily a null hypersurface, as noted above.

The requirement that the vacuum Einstein equations hold near $\mathscr{I}$ has several important

consequences. First, $\mathscr{I}$ is a null hypersurface with the special property of being shear-free. This means that any cross section of a bundle of its null generators does not suffer any distortions when moved along the generators. Only expansion or contraction can occur. The global structure of $\mathscr{I}$ is the same as the one from the example above. Null infinity consists of two connected components, $\mathscr{I}^{\pm}$, each of which is diffeomorphic to $S^2 \times \mathbb{R}$. Thus, topologically, $\mathscr{I}^{\pm}$ are cylinders. The cone-like appearance as seen in Figure 1 is artificial. It depends on the particular conformal factor $\Omega$ chosen for the conformal compactification. Furthermore, it is only in very exceptional cases that the metric $\hat{g}$ is regular at $i^0$ or $i^{\pm}$.

The most important consequence, however, concerns the conformal Weyl tensor $C^a{}_{bcd}$. This is the part of the full Riemann curvature tensor $R^a{}_{bcd}$ which is trace-free. It is invariant under conformal rescalings of the metric. Thus, on $\mathcal{M}$, $C^a{}_{bcd} = \hat{C}^a{}_{bcd}$. When the vanishing of the Ricci tensor near $\mathscr{I}$ is assumed then it turns out that the Weyl tensor necessarily vanishes on $\mathscr{I}$. This is the ultimate justification for calling such manifolds asymptotically flat because the entire curvature vanishes on $\mathscr{I}$.

## Some Consequences

There are several consequences of the existence of the conformal boundary $\mathscr{I}$. They all can be traced back to the fact that this boundary can be used to separate the geometric fields into a universal background field and dynamical fields which propagate on it. The background is given by the boundary points attached to an asymptotically flat spacetime which always form a three-dimensional null hypersurface $\mathscr{I}$ with two connected components (in the sequel, we restrict our attention to $\mathscr{I}^+$ only; $\mathscr{I}^-$ is treated similarly), each with the topology of a cylinder. And in each case, $\mathscr{I}$ is shear-free.

### The BMS Group

Since the structure of null-infinity is universal over all asymptotically flat spacetimes, it is obvious that its symmetry group should also possess a universal meaning. This group, the so-called Bondi–Metzner–Sachs (BMS) group is in many respects similar to the Poincaré group, the symmetry group of $\mathbb{M}$. It is the semidirect product of the Lorentz group with an abelian group which, however, is not the four-dimensional translation group but an infinite-dimensional group of supertranslations. This group is a normal subgroup, so the factor group is isomorphic to the Lorentz group.

In physical terms, the supertranslations arise because there are infinitely many directions from which observers at infinity (whose world lines coincide with the null generators of $\mathscr{I}$ in a certain limit) can observe the system and because each observer is free to choose its own origin of proper time $u$. The observers surrounding the system are not synchronized, because under the assumptions made there is no natural way to fix a unique common origin. Hence, a supertranslation is a shift of the parameter along each null generator of $\mathscr{I}^+$ corresponding to a change of origin for each individual observer. It can be given as a map $S^2 \to \mathbb{R}$. A choice of origin on each null generator of $\mathscr{I}^+$ is referred to as a "cut" of $\mathscr{I}^+$. It is a two-dimensional surface of spherical topology which intersects each null generator exactly once. It is an open question whether one can always synchronize the observers by imposing canonical conditions at $i^0$ or $i^{\pm}$, thereby reducing the BMS group to the smaller Poincaré group.

The supertranslations contain a unique four-dimensional normal subgroup. In $\mathbb{M}$ these special supertranslations are the ones which are induced by the translations of Minkowski spacetime in the following way. Take the future light cone of some event $P$ and follow it out to $\mathscr{I}^+$, where its intersection defines an origin for each observer located there. Now consider the light cone of another event $Q$ obtained from $P$ by a translation in a spatial direction. Then the light emitted from $Q$ will arrive at $\mathscr{I}^+$ earlier than that from $P$ for observers in the direction of the translation, while it will be delayed for observers in the opposite direction. This change in arrival time defines a specific supertranslation. Similarly, for a translation in a temporal direction, the light from $Q$ will arrive later than that from $P$ for all observers. Thus, every translation in $\mathbb{M}$ defines a particular supertranslation on $\mathscr{I}^+$. These can be characterized in a different way, which is intrinsic to $\mathscr{I}^+$ and which can be used in the general case even though there will be no Killing vectors present in a general asymptotically flat spacetime. In an appropriate coordinate system, the asymptotic translations are given as linear combinations of the first four spherical harmonics $Y_{00}, Y_{10}, Y_{1\pm1}$. The space of asymptotic translations $\mathbb{T}$ is in a natural way isometric to $\mathbb{M}$.

### The Peeling Property

Now consider the Weyl tensor $C^a{}_{bcd}$ on $\widehat{\mathcal{M}}$. Since it vanishes on $\mathscr{I}$ where $\Omega = 0$ we may form the quotient

$$K^a{}_{bcd} = \Omega^{-1} C^a{}_{bcd}$$

which can be shown to be smooth on $\mathscr{I}^+$. The physical interpretation of this tensor field is based on the following properties. In source-free regions the field satisfies the spin-2 zero-rest-mass equation

$$\widehat{\nabla}_a K^a{}_{bcd} = 0$$

which is very similar to the Maxwell equations for the electromagnetic (spin-1) Faraday tensor. Thus, $K^a{}_{bcd}$ is interpreted as the gravitational field, which describes the gravitational waves contained inside the system. The zero-rest-mass equation for $K^a{}_{bcd}$ and the fact that the field is smooth on $\mathscr{I}$ implies that the Weyl tensor satisfies the "peeling" property. This is a characteristic conspiracy between the fall-off behavior of certain components of the Weyl tensor along outgoing $g$-null-geodesics approaching $\mathscr{I}^+$ in $\mathcal{M}$ with respect to an affine parameter $s$ for $s \to \infty$ and their algebraic type. Symbolically, the Weyl tensor has the following behavior as $s \to \infty$ along the null geodesic:

$$C = \frac{[4]}{s} + \frac{[31]}{s^2} + \frac{[211]}{s^3} + \frac{[1111]}{s^4} + O(s^{-5}) \qquad [5]$$

where the numerator of each component indicates its Petrov type. The repeated principal null direction (PND) in the first three components and one of the PNDs in the fourth component are aligned with the tangent vector of the geodesic. This implies that the farthest reaching component of the Weyl tensor, which is $O(1/s)$, has the Petrov type of a radiation field. It is customary to combine the components which are $O(1/s^i)$ into one complex function and denote it by $\psi_{5-i}$. When expressed in terms of the field $K^a{}_{bcd}$ on $\widehat{\mathcal{M}}$, this fall-off behavior implies that of all components of $K^a{}_{bcd}$ only $\psi_4$ does not necessarily vanish on $\mathscr{I}^+$.

In special cases like the Minkowski, Schwarzschild, Kerr, and more generally in all asymptotically flat stationary spacetimes, even $\psi_4$ vanishes on $\mathscr{I}^+$. For these reasons, $\psi_4$ is called the radiation field of the system, that is, that part of the gravitational field which can be registered by the observers at infinity. It describes the outgoing radiation which is being emitted by the system during its evolution.

### The Bondi–Sachs Mass-Loss Formula

Gravitational waves carry away energy from the system. This is a consequence of the Bondi–Sachs mass-loss formula. The Bondi–Sachs energy–momentum is related to a weighted integral over a cut $\mathcal{C}$,

$$P_{\mathcal{C}}[W] = -\frac{1}{4\pi G}\int_{\mathcal{C}} W[\psi_2 + \sigma\dot{\bar{\sigma}}]\,\mathrm{d}^2S \qquad [6]$$

The quantity in brackets, the mass aspect, is a combination of the scalar $\psi_2$ which in a sense measures the strength of the Coulomb-like part of the gravitational field on $\mathscr{I}^+$ and the complex quantity $\sigma$. In a so-called Bondi coordinate system, this quantity is related to the radiation field $\psi_4$ by the relation

$$\psi_4 = -\ddot{\bar{\sigma}}$$

the dot indicating differentiation with respect to the affine parameter along the null generators. Thus, $\sigma$ is essentially the second time integral of the radiation field. The mass aspect is integrated against a function $W$ which is an asymptotic translation, that is, a linear combination of the first four spherical harmonics. Thus, one can view the expression [6] as defining a linear map $\mathbb{T} \to \mathbb{R}$. Since $\mathbb{T}$ and $\mathbb{M}$ are isometric this defines a covector $P_a$ on $\mathbb{M}$, which can always be shown to be timelike, $P_aP^a \geq 0$. This positivity property together with the fact that in the special cases of Schwarzschild and Kerr spacetimes the integral yields the mass parameters when evaluated for a time translation ($W = 1$) motivates the interpretation of $P_{\mathcal{C}}$ as the energy–momentum 4-vector of the spacetime at the instant defined by the cut $\mathcal{C}$. In particular, for $W = 1$ the integral gives the time component of $P_{\mathcal{C}}$, the Bondi–Sachs energy $E$.

The interpretation of [6] as energy–momentum is strengthened by the fact that $P_{\mathcal{C}}$ arises as dual to the translations which is familiar from Lagrangian field theories where energy and momentum appear as generators for time and space translations. In fact, one can set up a Hamiltonian framework where the role of the Bondi–Sachs energy–momentum as generator of asymptotic translations is made explicit.

This point of view suggests that one should also be able to define a notion of angular momentum for asymptotically flat spacetimes because angular momentum arises as the generator of rotations, which can also be defined asymptotically. However, while there is a unique notion of translation on $\mathscr{I}^+$, this is not the case for rotations (and boosts). The reason is hidden in the structure of the BMS group where the Lorentz group appears naturally as a factor group but not as a unique subgroup. In physical terms, the angular momentum depends on an origin but there is no natural way to choose an origin on $\mathscr{I}^+$. This ambiguity in the choice of origin leads to several nonequivalent expressions for angular momentum in the literature.

Consider now two cuts $\mathcal{C}$ and $\mathcal{C}'$, with $\mathcal{C}'$ later than $\mathcal{C}$. Then we may compute the difference $\Delta E = E - E'$ of the Bondi–Sachs energies with respect to the two

cuts. It turns out that this difference can be expressed as an integral over the (three-dimensional) piece $\Sigma$ of $\mathscr{I}^+$ which is bounded by the two cuts (i.e., $\partial\Sigma = \mathcal{C}' - \mathcal{C}$):

$$E' - E = -\frac{1}{4\pi G}\int_\Sigma \dot{\sigma}\dot{\bar{\sigma}}\, \mathrm{d}^3 V \qquad [7]$$

This result means that the Bondi–Sachs energy of the system decreases, since $E' < E$ and the rate of decrease is given by the (positive-definite) amount of gravitational radiation which leaves the system during the period defined by the two cuts.

It is necessary to point out that in this article the structure of null infinity has been postulated based on physical reasonings. The Einstein equations have been used only in a very weak sense, namely only in a neighborhood of $\mathscr{I}$. It is an entirely different question whether the field equations are compatible with this postulated structure. To answer it, one needs to show that there are global solutions of the Einstein equations which exhibit the postulated behavior in the asymptotic region. This question has been settled recently in the affirmative: there are many global spacetimes which are asymptotically flat in the sense described here.

This article discussed has the notion of null infinity, that is, of spacetimes which are asymptotically flat in lightlike directions. Spacetimes which are asymptotically flat in spacelike directions have not been covered. The latter is a notion which has been developed largely independently of null infinity since it is essentially a property of an initial data set and not of the entire four-dimensional spacetime. Ultimately, these two notions should coincide, in the sense that if one has an initial data set which is asymptotically flat in spatial directions in an appropriate sense then its Cauchy development will be an asymptotically flat spacetime. However, as of yet, it is not clear what the appropriate conditions should be because the structure of the gravitational field in the neighborhood of spacelike infinity $i^0$ is not sufficiently well understood so far.

# Averaging Methods

**A I Neishtadt**, Russian Academy of Sciences, Moscow, Russia

## Introduction

Averaging methods are the methods of perturbation theory that are based on the averaging principle and the idea of dividing the dynamics into slow drift and fast oscillations. The most common field of applications of averaging methods is the analysis of the behavior of dynamical systems that differ from integrable systems by small perturbations.

## Averaging Principle

Equations of motion of a system that differ from an integrable system by small perturbations often can be written in the form

$$\dot{I} = \varepsilon g(I, \varphi, \varepsilon), \quad \dot{\varphi} = \omega(I) + \varepsilon f(I, \varphi, \varepsilon)$$
$$I = (I_1, \ldots, I_n) \in \mathbb{R}^n \qquad [1]$$
$$\varphi = (\varphi_1, \ldots, \varphi_m) \in \mathbb{T}^m \bmod 2\pi, 0 < \varepsilon \ll 1$$

The small parameter $\varepsilon$ characterizes the amplitude of the perturbation. For $\varepsilon = 0$ one gets the unperturbed system. The equation $I = \text{const.}$ singles out an invariant $m$-dimensional torus of the unperturbed system. The motion on this torus is quasiperiodic with frequency vector $\omega(I)$; components of vector $I$ are called "slow variables" whereas components of vector $\varphi$ are called "fast variables" or "phases." The right-hand sides of system [1] are $2\pi$-periodic with respect to all $\varphi_j$. It is assumed that they are smooth enough functions of all arguments. It is also assumed that components of the frequency vector are not linearly dependent over the ring of integer numbers identically with respect to $I$. System [1] is called a "system with rotating phases."

In applications, one is often interested mainly in the behavior of slow variables. The "averaging principle" (or method) consists in replacing the system of perturbed equations [1] by the "averaged system"

$$\dot{J} = \varepsilon G(J), \quad G(J) = (2\pi)^{-m} \oint_{\mathbb{T}^m} g(J, \varphi, 0)\, d\varphi \qquad [2]$$

for the purpose of providing an approximate description of the evolution of the slow variables over time intervals of order $1/\varepsilon$ or longer. Here, $d\varphi = d\varphi_1 \cdots d\varphi_m$. System [2] contains only slow variables and, therefore, is much simpler for investigation than system [1]. When passing from system [1] to system [2], one ignores the terms $g(I, \varphi, 0) - G(I)$ on the right-hand side of [1]. The averaging principle is based on the idea that these terms oscillate and lead only to small oscillations which are superimposed on the drift described by the averaged system. To justify the averaging principle, one should establish a relation between the behavior of the solutions of systems [1] and [2]. This problem is still far from being completely solved.

Another version of the averaging principles is used in the case when frequencies are approximately in resonance. This means that one or several relations of the form $(k, \omega) = 0$ approximately are valid with irreducible integer coefficient vectors $k \neq 0$; here, $(k, \omega)$ is the standard scalar product in $\mathbb{R}^m$. Let $\Gamma$ be a sublattice of the integer lattice $\mathbb{Z}^m$ generated by these vectors. Let $r = \operatorname{rank} \Gamma$ and $k^{(1)}, k^{(2)}, \ldots, k^{(m)}$ be a basis in $\mathbb{Z}^m$, the first $r$ vectors of which belong to $\Gamma$. Instead of $\varphi$, one can introduce new variables:

$$\vartheta = (\vartheta_1, \ldots, \vartheta_r) \in \mathbb{T}^r \bmod 2\pi$$
$$\chi = (\chi_1, \ldots, \chi_{m-r}) \in \mathbb{T}^{m-r} \bmod 2\pi$$
$$\vartheta_i = (k^{(i)}, \varphi), \qquad \chi_j = (k^{(r+j)}, \varphi)$$

Let $R$ be an $r \times m$ matrix whose rows are vectors $k^{(i)}, 1 \leq i \leq r$. For an approximate description of the behavior of variables $I, \vartheta$, the averaging principle prescribes replacing system [1] by the system

$$\dot{J} = \varepsilon G_\Gamma(J, \gamma), \quad \dot{\gamma} = R\omega(J) + \varepsilon R F_\Gamma(J, \gamma)$$
$$G_\Gamma(J, \vartheta) = (2\pi)^{-(m-r)} \oint_{\mathbb{T}^{m-r}} g(J, \varphi, 0)\, d\chi \qquad [3]$$
$$F_\Gamma(J, \vartheta) = (2\pi)^{-(m-r)} \oint_{\mathbb{T}^{m-r}} f(J, \varphi, 0)\, d\chi$$

(one should express $g, f$ through $\vartheta, \chi$ and then integrate over $\chi, d\chi = d\chi_1 \cdots d\chi_{m-r}$). System [3] is called "partially averaged system" for resonances in $\Gamma$. Functions $G_\Gamma, F_\Gamma$ can be obtained from Fourier series expansions of functions $g$, $f$ for $\varepsilon = 0$ by throwing away harmonics $\exp(i(k, \varphi)), k \notin \Gamma$ (nonresonant harmonics). Passing from system [1] to system [3] is based on the idea that the ignored nonresonant harmonics oscillate fast and do not affect essentially the evolution of the slow variables.

Now let system [1] be a Hamiltonian system close to an integrable one. The Hamiltonian function has the form

$$H = H_0(p) + \varepsilon H_1(p, \varphi, y, x, \varepsilon)$$

where $\varphi, x$ are coordinates and $p, y$ are conjugated to them. The equations of motion have the same form as [1], with $I = (p, y, x)$:

$$\dot{p} = -\varepsilon \frac{\partial H_1}{\partial \varphi}, \quad \dot{y} = -\varepsilon \frac{\partial H_1}{\partial x}$$
$$\dot{x} = \varepsilon \frac{\partial H_1}{\partial y}, \qquad \dot{\varphi} = \frac{\partial H_0}{\partial I} + \varepsilon \frac{\partial H_1}{\partial I} \qquad [4]$$

The averaging principle in the case when there are no resonant relations leads to the system

$$\dot{p} = 0, \quad \dot{y} = -\varepsilon \frac{\partial \mathcal{H}_1}{\partial x}, \quad \dot{x} = \varepsilon \frac{\partial \mathcal{H}_1}{\partial y}$$
$$\mathcal{H}_1 = (2\pi)^{-m} \oint_{\mathbb{T}^m} H_1(p, \varphi, y, x, 0)\, d\varphi \qquad [5]$$

Therefore, in this case there is no drift in $p$, and the behavior of $y, x$ is described by the Hamiltonian system, which contains $p$ as a parameter. Equations of motion of planets around the Sun can be reduced to the form [4]. The issue of the absence of the evolution of momenta $p$ is known in this problem as

the Lagrange–Laplace theorem, about the absence of the evolution of semimajor axes of planetary orbits.

## Elimination of Fast Variables, Decoupling of Slow and Fast Motions

The basic role in the averaging method is played by the idea that the exact system can be in the principal approximation transformed into the averaged system by means of a transformation of variables close to the identical one. The extension of this idea is the idea that similar transformation of variables allows one to eliminate, up to an arbitrary degree of accuracy, the fast phases from the right-hand sides of the equations of perturbed motion and in this way decouple the slow motion from the fast one. For system [1], provided there are no resonant relations between frequencies, the elimination of fast variables is performed as follows. The desirable transformation of variables $(I, \varphi) \mapsto (J, \psi)$ is sought as a formal series

$$\begin{aligned} I &= J + \varepsilon u_1(J, \psi) + \varepsilon^2 u_2(J, \psi) + \cdots \\ \varphi &= \psi + \varepsilon v_1(J, \psi) + \varepsilon^2 v_2(J, \psi) + \cdots \end{aligned} \qquad [6]$$

where functions $u_j, v_j$ are $2\pi$-periodic in $\psi$. The transformation [6] should be chosen in such a way that in the new variables the right-hand sides of equations of motion do not contain fast variables, that is, the equations of motion should have the form

$$\begin{aligned} \dot{J} &= \varepsilon G_0(J) + \varepsilon^2 G_1(J) + \cdots \\ \dot{\psi} &= \omega(J) + \varepsilon F_0(J) + \varepsilon^2 F_1(J) + \cdots \end{aligned} \qquad [7]$$

Substituting [6] into [7], taking into account [1], and equating the terms of the same order in $\varepsilon$, we obtain the following set of relations:

$$\begin{aligned} G_0(J) &= g(J, \psi, 0) - \frac{\partial u_1}{\partial \psi}\omega \\ F_0(J) &= f(J, \psi, 0) + \frac{\partial \omega}{\partial J}u_1 - \frac{\partial v_1}{\partial \psi}\omega \\ G_i(J) &= X_i(J, \psi) - \frac{\partial u_{i+1}}{\partial \psi}\omega \\ F_i(J) &= Y_i(J, \psi) + \frac{\partial \omega}{\partial J}u_{i+1} - \frac{\partial v_{i+1}}{\partial \psi}\omega, \quad i \geq 1 \end{aligned} \qquad [8]$$

The functions $X_i, Y_i$ are uniquely determined by the terms $u_1, v_1, \ldots, u_i, v_i$ in expansion [6]. The first equation in [8] implies that

$$\begin{aligned} G_0(J) &= g_0(J) = G(J) \\ u_1(J, \psi) &= \sum_{k \neq 0} \frac{g_k}{\mathrm{i}(k,\ \omega)} \exp(\mathrm{i}(k, \psi)) + u_1^0(J) \end{aligned} \qquad [9]$$

where $g_k, k \in \mathbb{Z}^m$, are Fourier coefficients of function $g$ at $\varepsilon = 0$, and $u_1^0$ is an arbitrary function of $J$. It is assumed that the denominators in [9] do not vanish, and that the series in [9] converges and determines a smooth function. In the same way, from the other equations in [8] one can sequentially determine $F_0, v_1, \ldots, G_i, u_{i+1}, F_i, v_{i+1}, i \geq 1$.

On truncating the series in [6] and [7] at the terms of order $\varepsilon^l$, we obtain a truncated system of the $l$th approximation. The equation for $J$ is decoupled from the other equations and can be solved separately. Then the behavior of $\psi$ is determined by means of quadrature. The behavior of original variable $I$ in this approximation is a slow drift (described by the equation for $J$), on which small oscillations (described by transformation of variables) are superimposed. The behavior of $\varphi$ can be represented as a rotation with slowly varying frequency, on which oscillations are also superimposed. For $l = 1$, the truncated system coincides with the averaged system [2].

If the sublattice $\Gamma \subset \mathbb{Z}^m$ specifying possible resonant relations is given, then in an analogous manner one can construct a formal transformation of variables $(I, \varphi) \mapsto (J, \psi)$ such that, in the new variables, the fast phase $\psi$ will appear on the right-hand sides of the differential equations for the new variables only in combinations $(k, \psi)$, with $k \in \Gamma$ (see, e.g., Arnol'd *et al.* (1988)). Again, on truncating the series on the right-hand sides of the differential equations for the new variables at the terms of order $\varepsilon^l$, we obtain a truncated system of the $l$th approximation. At $l = 1$, this truncated system coincides with the partially averaged system [3] (for some special choice of arbitrary functions that are contained in the formulas for transformation of variables). If the original system is a Hamiltonian system of the form [4], then the transformation of variables eliminating the fast phases from the right-hand sides of the differential equations can be chosen to be symplectic. The corresponding procedures are called "Lindstedt method" and "Newcomb method" (nonresonant case for $n = m$), "Delaunay method" (resonant case for $n = m$), and "von Zeipel method" (resonant case for $n \geq m$) (see Poincaré (1957) and Arnol'd *et al.* (1988)).

The calculation of high-order terms in the procedures of elimination of fast variables is rather cumbersome. There are versions of these procedures which are convenient for symbolic processors (especially for Hamiltonian systems, e.g., the Deprit–Hori method; Giacaglia 1972).

The averaging method consists in using the averaged system for the description of motion in the first approximation and the truncated systems

obtained by means of the procedures of elimination of fast variables in the higher approximations, together with the corresponding transformations of variables.

## Justification of the Averaging Method

To justify the averaging method, one should establish conditions under which the deviation of the slow variables along the solutions of the exact system from the solutions of the averaged system with appropriate initial data on time intervals of order $1/\varepsilon$ or longer tends to 0 as $\varepsilon \to 0$. It is desirable to have estimates from the above for these deviations. The estimates of deviations of the solutions of the exact system from the solutions of the truncated systems obtained by means of the procedure of elimination of fast phases are important as well. It can happen that there are "bad" initial data for which the slow component of the solution of the exact system deviates from the solution of the averaged system by a value of order 1 over time of order $1/\varepsilon$. In this case, one should have estimates from above for the measure of the set of such "bad" initial data; on the complementary set of initial data, one should have estimates from above for the deviation of slow variables along the solutions of the exact system from the solution of the averaged system. These problems are currently far from being completely solved. Some general results are described in the following.

Let functions $\omega, f, g$ on the right-hand side of system [1] be defined and bounded together with a sufficient number of derivatives in the domain $D\{I\} \times \mathbb{T}^m\{\varphi\} \times [0, \varepsilon_0]$. Let $J(t)$ be the solution of the averaged system [2] with initial condition $I_0 \in D$. Let $(I(t), \varphi(t))$ be the solution of the exact system [1] with initial conditions $(I_0, \varphi_0)$. So, $I(0) = J(0)$. It is assumed that the solution $J(t)$ is defined and stays at a positive distance from the boundary of $D$ on the time interval $0 \le t \le K/\varepsilon, K = \text{const} > 0$.

If system [1] is a one-frequency system ($m = 1$), and the frequency $\omega$ does not vanish in $D$, then for $0 \le t \le K/\varepsilon$ the solution $(I(t), \varphi(t))$ is well defined, and $|I(t) - J(t)| < C\varepsilon, C = \text{const.} > 0$. For $\omega = 1$, this assertion was proved by P Fatou (1928) and, by a different method, by L I Mandel'shtam and L D Papaleksi (1934). This was historically the first result on the justification of the averaging method (Mintropol'skii 1971). There is a proof based on the elimination of fast variables (see, e.g., Arnol'd (1983)). For a one-frequency system, higher approximations of the procedure of elimination of fast variables allow the description of the dynamics with an accuracy of the order of any power in $\varepsilon$ on time intervals of order $1/\varepsilon$ (Bogolyubov and Mitropol'skii 1961).

If system [1] is a multifrequency system ($m \ge 2$), but the vector of frequencies is constant and nonresonant, then for any $\rho > 0$ and small enough $\varepsilon < \varepsilon_0(\rho)$ it holds that $|I(t) - J(t)| < \rho$ for $0 \le t \le K/\varepsilon$ (Bogolyubov 1945, Bogolyubov and Mitropol'skii 1961). If, in addition, the frequencies satisfy the Diophantine condition $|(k, \omega)| > \text{const}\,|k|^{-\nu}$ for all $k \in \mathbb{Z}^m \backslash \{0\}$ and some $\nu > 0$, then one can choose $\rho = O(\varepsilon)$. In this case, higher approximations of the procedure of elimination of fast variables allow one to describe the dynamics with an accuracy of the order of any power in $\varepsilon$ on time intervals of order $1/\varepsilon$ (see, e.g., Arnol'd *et al.* (1988)).

If the system is a multifrequency system, and frequencies are not constant (but depend on the slow variables $I$), then due to the evolution of slow variables the frequencies themselves are evolving slowly. At certain time moments, they can satisfy certain resonant relations. One of the phenomena that can take place here is a capture into a resonance; this capture leads to a large deviation of the solutions of the exact and averaged systems. However, the general Anosov averaging theorem (Anosov 1960) implies that if the frequencies $\omega$ are nonresonant for almost all $I$, then for any $\rho > 0$, the inequality $|I(t) - J(t)| < \rho$ is satisfied for $0 \le t \le K/\varepsilon$ for all initial data outside a set $E(\rho, \varepsilon)$ whose measure tends to 0 as $\varepsilon \to 0$. In many cases, it turns out that $\text{mes}\, E(\rho, \varepsilon) = O(\sqrt{\varepsilon}/\rho)$ (in particular, the sufficient condition for the last estimate is that $\text{rank}(\partial\omega/\partial I) = m$) (Arnol'd *et al.* (1988)).

The knowledge about averaging in two-frequency systems ($m = 2$) on time intervals, of order of $1/\varepsilon$, is relatively more complete (see Arnol'd (1983), Arnol'd *et al.* (1988), and Lochak and Meunier (1988)). For Hamiltonian and reversible systems, the justification of the averaging method is a by-product of Kolmogorov–Arnold–Moser (KAM) theory. The KAM theory provides estimates of the difference between the solutions of the exact and averaged systems for majority of initial data on infinite time interval $-\infty < t < +\infty$. For remaining data this difference can grow because of Arnol'd diffusion, but, in general, very slowly. According to the Nekhoroshev theorem, this difference is small on time intervals whose length grows exponentially when the perturbation decays linearly (for an analytic Hamiltonian if the unperturbed Hamiltonian is a generic function, the so-called steep function).

Another aspect of justification of the averaging method is establishing relations between invariant manifolds of the exact and averaged systems. Consider, in particular, the case of a one-frequency

system and a multifrequency system with constant Diophantine frequencies. Suppose that the averaged system has an equilibrium such that real parts of all its eigenvalues are different from 0, or a limit cycle such that the absolute values of all but one of its multipliers are different from 1. Then the exact system has an invariant torus, respectively, $m$- or $(m+1)$-dimensional, whose projection onto the space of the slow variables is $O(\varepsilon)$-close to the equilibrium (cycle) of the averaged system. This torus is stable or unstable together with the equilibrium (cycle) of the averaged system. For Hamiltonian and reversible systems, the problem of invariant manifolds is considered in the framework of the KAM theory.

## Averaging in Bogolyubov's Systems

Systems in the standard form of Bogolyubov (1945) are of the form

$$\dot{x} = \varepsilon X(t, x, \varepsilon), \quad x \in \mathbb{R}^p,\ 0 < \varepsilon \ll 1 \qquad [10]$$

It is assumed that the function $X$, besides the usual smoothness conditions, satisfies the condition of uniform average: the limit (time average)

$$X_0(x) = \lim_{T\to\infty} \frac{1}{T} \int_0^T X(t, x, 0)\,\mathrm{d}t \qquad [11]$$

exists uniformly in $x$. The averaging principle of Bogolyubov consists of the replacement of the original system in standard form by the averaged system

$$\dot{\xi} = \varepsilon X_0(\xi) \qquad [12]$$

with a goal to provide an approximate description of the behavior of $x$. This approach generalizes the approach of the section "Averaging principle" for the case of constant frequencies ($\omega = \text{const}$). Upon introducing in the given system with constant frequencies the deviation from uniform rotation $\alpha = \varphi - \omega t$ and denoting $x = (I, \alpha)$, we obtain a system in the standard form [10]. Here the condition of uniform average is fulfilled because $X(t, x, 0)$ is a quasiperiodic function of time $t$. The averaged system [12] for nonresonant frequencies coincides with the averaged system [2]; for resonant frequencies, it coincides with the partially averaged system [3] (one should only supply systems [2] and [3] with equations for some components of the vector $\varphi - \omega t$ that do not enter into the right-hand side of the averaged system).

The averaging principle of Bogolyubov is justified by three Bogolyubov theorems. According to the first theorem, if $\xi(t), 0 \le t \le K/\varepsilon$, is a solution of the averaged system, and $x(t)$ is a solution of the exact system with initial condition $x(0) = \xi(0)$, then for any $\rho > 0$ there exists $\varepsilon_0(\rho) > 0$ such that $|x(t) - \xi(t)| < \rho$ for $0 \le t \le K/\varepsilon$ and $0 < \varepsilon < \varepsilon_0(\rho)$. The second and the third Bogolyubov theorems describe the motion in the neighborhoods of equilibria and the limit cycles of the averaged system. In particular, if for an equilibrium real parts of all its eigenvalues are different from 0, or, for a limit cycle, the absolute values of all but one multipliers are different from 1, then the exact system has a solution which eternally stays near this equilibrium (cycle). The stability properties of this solution are the same as the stability properties of the corresponding equilibrium (cycle) of the averaged system.

For systems of the form [10] a procedure exists that, similarly to the procedure in the section "Elimination of fast variables, decoupling of slow and fast motions," allows us to eliminate time $t$ from the right-hand side of the system with an accuracy of the order of any power in $\varepsilon$ by means of a transformation of variables. (To perform this procedure, one should assume that the conditions of uniform average are satisfied for functions that arise in the process of constructing higher approximations in this procedure (Bogolyubuv and Mitropol'skii 1961).) In the first approximation, such a transformation of variables transforms the original system into the averaged one.

The condition of uniform average is very important for theory. If the limit in [11] exists, but convergence is nonuniform in $x$, then the time average $X_0$ could be, for example, a discontinuous function of $x$, and the averaged system would not be well defined.

## Averaging in Slow–Fast Systems

Systems of the form [1] are particular cases of the systems of the form

$$\dot{x} = f(x, y, \varepsilon), \qquad \dot{y} = \varepsilon g(x, y, \varepsilon) \qquad [13]$$

which are called "slow–fast systems" (or systems with slow and fast motions, with slow and fast variables). The generalization of the approach of the section "Averaging principle" for these systems is the following averaging principle of Anosov (1960). In the system [6], let $x \in M, y \in \mathbb{R}^n$, where $M$ is a smooth compact $m$-dimensional manifold. At $\varepsilon = 0$, the system for fast variables $x$ contains slow variables $y$ as parameters. Assume that this system (which is called "fast system") has a finite smooth

invariant measure $\mu_y$ and is ergodic for almost all values of $y$. Introduce the averaged system

$$\dot{Y} = \varepsilon G(Y), \quad G(Y) = \frac{1}{\mu_Y(M)} \int_M g(x, Y, 0) \mathrm{d}\mu_Y$$

According to the averaging principle, one should use the solution $Y(t)$ of the averaged system with initial condition $Y(0) = y(0)$ for approximate description of slow motion $y(t)$ in the original system. This averaging principle is justified by the following Anosov theorem [1]: *for any positive $\rho$ the measure of the set $E(\rho, \varepsilon)$ of initial data (from a compact in the phase space) such that*

$$\max_{0 \le t \le 1/\varepsilon} |y(t) - Y(t)| > \rho$$

*tends to* $0$ *as* $\varepsilon \to 0$.

The particular case when the original system is a Hamiltonian system depending on slowly varying parameter $\lambda = \varepsilon t$, and for almost all values of $\lambda$ the motion of the system with $\lambda = \text{const}$ is ergodic on almost all energy levels, is considered in Kasuga (1961).

For the case when the has strong mixing properties, see Bakhtin (2004) and Kifer (2004).

For slow–fast systems, there is also a generalization of approach of the previous section that uses time averaging and the condition of uniform average (Volosov 1962).

## Applications of the Averaging Method

The averaging method is one of the most productive methods of perturbation theory, and its applications are immense. It is widely used in celestial mechanics and space flight dynamics for the description of the evolution of motions of celestial bodies, in plasma physics and theory of accelerators for description of motion of charged particles, and in radio engineering for the description of nonlinear oscillatory regimes. There are also applications in hydrodynamics, physics of lasers, optics, acoustics, etc. (see Arnol'd *et al.* (1988), Bogolyubov and Mitropol'skii (1961), Lochak and Meunier (1988), Mitropol'skii (1971), and Volosov (1962)).

# Axiomatic Approach to Topological Quantum Field Theory

**C Blanchet**, Université de Bretagne-Sud, Vannes, France
**V Turaev**, IRMA, Strasbourg, France

## Introduction

The idea of topological invariants defined via path integrals was introduced by A S Schwartz (1977) in a special case and by E Witten (1988) in its full power. To formalize this idea, Witten (1988) introduced a notion of a topological quantum field theory (TQFT). Such theories, independent of Riemannian metrics, are rather rare in quantum physics. On the other hand, they admit a simple axiomatic description first suggested by M Atiyah (1989). This description was inspired by G Segal's (1988) axioms for a two-dimensional conformal field theory. The axiomatic formulation of TQFTs makes them suitable for a purely mathematical research combining methods of topology, algebra, and mathematical physics. Several authors explored axiomatic foundations of TQFTs (see Quinn (1995) and Turaev (1994).

## Axioms of a TQFT

An $(n+1)$-dimensional TQFT $(\boldsymbol{V}, \tau)$ over a scalar field $\boldsymbol{k}$ assigns to every closed oriented $n$-dimensional manifold $X$ a finite-dimensional vector space $\boldsymbol{V}(X)$ over $\boldsymbol{k}$ and assigns to every cobordism $(M, X, Y)$ a $\boldsymbol{k}$-linear map

$$\tau(M) = \tau(M, X, Y) : \boldsymbol{V}(X) \to \boldsymbol{V}(Y)$$

Here a cobordism $(M, X, Y)$ between $X$ and $Y$ is a compact oriented $(n+1)$-dimensional manifold $M$ endowed with a diffeomorphism $\partial M \approx \overline{X} \amalg Y$ (the overline indicates the orientation reversal). All manifolds and cobordisms are supposed to be smooth. A TQFT must satisfy the following axioms.

1. *Naturality* Any orientation-preserving diffeomorphism of closed oriented $n$-dimensional manifolds $f : X \to X'$ induces an isomorphism $f_\sharp : \boldsymbol{V}(X) \to \boldsymbol{V}(X')$. For a diffeomorphism $g$ between the cobordisms $(M, X, Y)$ and $(M', X', Y')$, the following diagram is commutative:

$$\begin{array}{ccc} \boldsymbol{V}(X) & \xrightarrow{(g|_X)_\sharp} & \boldsymbol{V}(X') \\ {\scriptstyle \tau(M)}\downarrow & & \downarrow{\scriptstyle \tau(M')} \\ \boldsymbol{V}(Y) & \xrightarrow{(g|_Y)_\sharp} & \boldsymbol{V}(Y') \end{array}$$

2. *Functoriality* If a cobordism $(W, X, Z)$ is obtained by gluing two cobordisms $(M, X, Y)$ and $(M', Y', Z)$ along a diffeomorphism $f : Y \to Y'$, then the following diagram is commutative:

$$\begin{array}{ccc} \boldsymbol{V}(X) & \xrightarrow{\tau(W)} & \boldsymbol{V}(Z) \\ {\scriptstyle \tau(M)}\downarrow & & \downarrow{\scriptstyle \tau(M')} \\ \boldsymbol{V}(Y) & \xrightarrow{f_\sharp} & \boldsymbol{V}(Y') \end{array}$$

3. *Normalization* For any $n$-dimensional manifold $X$, the linear map

$$\tau([0,1] \times X) : \boldsymbol{V}(X) \to \boldsymbol{V}(X)$$

is identity.

4. *Multiplicativity* There are functorial isomorphisms

$$\boldsymbol{V}(X \amalg Y) \approx \boldsymbol{V}(X) \otimes \boldsymbol{V}(Y)$$
$$\boldsymbol{V}(\emptyset) \approx \boldsymbol{k}$$

such that the following diagrams are commutative:

$$\begin{array}{ccc} \boldsymbol{V}((X \amalg Y) \amalg Z) & \approx & (\boldsymbol{V}(X) \otimes \boldsymbol{V}(Y)) \otimes \boldsymbol{V}(Z) \\ \downarrow & & \downarrow \\ \boldsymbol{V}(X \amalg (Y \amalg Z)) & \approx & \boldsymbol{V}(X) \otimes (\boldsymbol{V}(Y) \otimes \boldsymbol{V}(Z)) \end{array}$$

$$\begin{array}{ccc} \boldsymbol{V}(X \amalg \emptyset) & \approx & \boldsymbol{V}(X) \otimes \boldsymbol{k} \\ \downarrow & & \downarrow \\ \boldsymbol{V}(X) & = & \boldsymbol{V}(X) \end{array}$$

Here $\otimes = \otimes_{\boldsymbol{k}}$ is the tensor product over $\boldsymbol{k}$. The vertical maps are respectively the ones induced by the obvious diffeomorphisms, and the standard isomorphisms of vector spaces.

5. *Symmetry* The isomorphism

$$\boldsymbol{V}(X \amalg Y) \approx \boldsymbol{V}(Y \amalg X)$$

induced by the obvious diffeomorphism corresponds to the standard isomorphism of vector spaces

$$\boldsymbol{V}(X) \otimes \boldsymbol{V}(Y) \approx \boldsymbol{V}(Y) \otimes \boldsymbol{V}(X)$$

Given a TQFT $(\boldsymbol{V}, \tau)$, we obtain an action of the group of diffeomorphisms of a closed oriented $n$-dimensional manifold $X$ on the vector space $\boldsymbol{V}(X)$. This action can be used to study this group.

An important feature of a TQFT $(\boldsymbol{V}, \tau)$ is that it provides numerical invariants of compact oriented $(n+1)$-dimensional manifolds without boundary. Indeed, such a manifold $M$ can be considered as a cobordism between two copies of $\emptyset$ so that $\tau(M) \in Hom_{\boldsymbol{k}}(\boldsymbol{k}, \boldsymbol{k}) = \boldsymbol{k}$. Any compact oriented $(n+1)$-dimensional manifold $M$ can be considered as a

cobordism between $\emptyset$ and $\partial M$; the TQFT assigns to this cobordism a vector $\tau(M)$ in $\mathrm{Hom}_{\boldsymbol{k}}(\boldsymbol{k}, \boldsymbol{V}(\partial M)) = \boldsymbol{V}(\partial M)$ called the vacuum vector.

The manifold $[0,1] \times X$, considered as a cobordism from $\overline{X} \amalg X$ to $\emptyset$ induces a nonsingular pairing

$$\boldsymbol{V}(\overline{X}) \otimes \boldsymbol{V}(X) \to \boldsymbol{k}$$

We obtain a functorial isomorphism $\boldsymbol{V}(\overline{X}) = \boldsymbol{V}(X)^* = \mathrm{Hom}_{\boldsymbol{k}}(\boldsymbol{V}(X), \boldsymbol{k})$.

We now outline definitions of several important classes of TQFTs.

If the scalar field $\boldsymbol{k}$ has a conjugation and all the vector spaces $\boldsymbol{V}(X)$ are equipped with natural nondegenerate Hermitian forms, then the TQFT $(\boldsymbol{V}, \tau)$ is Hermitian. If $\boldsymbol{k} = \boldsymbol{C}$ is the field of complex numbers and the Hermitian forms are positive definite, then the TQFT is unitary.

A TQFT $(\boldsymbol{V}, \tau)$ is nondegenerate or cobordism generated if for any closed oriented $n$-dimensional manifold $X$, the vector space $\boldsymbol{V}(X)$ is generated by the vacuum vectors derived as above from the manifolds bounded by $X$.

Fix a Dedekind domain $D \subset \boldsymbol{C}$. A TQFT $(\boldsymbol{V}, \tau)$ over $\boldsymbol{C}$ is almost $D$-integral if it is nondegenerate and there is $d \in \boldsymbol{C}$ such that $d\tau(M) \in D$ for all $M$ with $\partial M = \emptyset$. Given an almost integral TQFT $(\boldsymbol{V}, \tau)$ and a closed oriented $n$-dimensional manifold $X$, we define $S(X)$ to be the $D$-submodule of $\boldsymbol{V}(X)$ generated by all the vacuum vectors. This module is preserved under the action of self-diffeomorphisms of $X$ and yields a finer "arithmetic" version of $\boldsymbol{V}(X)$.

The notion of an $(n+1)$-dimensional TQFT over $\boldsymbol{k}$ can be reformulated in the categorical language as a symmetric monoidal functor from the category of $n$-manifolds and $(n+1)$-cobordisms to the category of finite-dimensional vector spaces over $\boldsymbol{k}$. The source category is called the $(n+1)$-dimensional cobordism category. Its objects are closed oriented $n$-dimensional manifolds. Its morphisms are cobordisms considered up to the following equivalence: cobordisms $(M, X, Y)$ and $(M', X, Y)$ are equivalent if there is a diffeomorphism $M \to M'$ compatible with the diffeomorphisms $\partial M \approx \overline{X} \amalg Y \approx \partial M'$.

## TQFTs in Low Dimensions

TQFTs in dimension $0 + 1 = 1$ are in one-to-one correspondence with finite-dimensional vector spaces. The correspondence goes by associating with a one-dimensional TQFT $(\boldsymbol{V}, \tau)$ the vector space $\boldsymbol{V}(pt)$ where $pt$ is a point with positive orientation.

Let $(\boldsymbol{V}, \tau)$ be a two-dimensional TQFT. The linear map $\tau$ associated with a pair of pants (a 2-disk with two holes considered as a cobordism between two circles $S^1 \amalg S^1$ and one circle $S^1$) defines a commutative multiplication on the vector space $\mathcal{A} = \boldsymbol{V}(S^1)$. The 2-disk, considered as a cobordism between $S^1$ and $\emptyset$, induces a nondegenerate trace on the algebra $\mathcal{A}$. This makes $\mathcal{A}$ into a commutative Frobenius algebra (also called a symmetric algebra). This algebra completely determines the TQFT $(\boldsymbol{V}, \tau)$. Moreover, this construction defines a one-to-one correspondence between equivalence classes of two-dimensional TQFTs and isomorphism classes of finite dimensional commutative Frobenius algebras (Kock 2003).

The formalism of TQFTs was to a great extent motivated by the three-dimensional case, specifically, Witten's Chern–Simons TQFTs. A mathematical definition of these TQFTs was first given by Reshetikhin and Turaev using the theory of quantum groups. The Witten–Reshetikhin–Turaev three-dimensional TQFTs do not satisfy exactly the definition above: the naturality and the functoriality axioms only hold up to invertible scalar factors called framing anomalies. Such TQFTs are said to be projective. In order to get rid of the framing anomalies, one has to add extra structures on the three-dimensional cobordism category. Usually one endows surfaces $X$ with Lagrangians (maximal isotropic subspaces in $H_1(X; \boldsymbol{R})$). For 3-cobordisms, several competing – but essentially equivalent – additional structures are considered in the literature: 2-framings (Atiyah 1989), $p_1$-structures (Blanchet *et al.* 1995), numerical weights (K Walker, V Turaev).

Large families of three-dimensional TQFTs are obtained from the so-called modular categories. The latter are constructed from quantum groups at roots of unity or from the skein theory of links. *See* Quantum 3-Manifold Invariants.

## Additional Structures

The axiomatic definition of a TQFT extends in various directions. In dimension 2 it is interesting to consider the so-called open–closed theories involving 1-manifolds formed by circles and intervals and two-dimensional cobordisms with boundary (G Moore, G Segal). In dimension 3 one often considers cobordisms including framed links and graphs whose components (resp. edges) are labeled with objects of a certain fixed category $\mathcal{C}$. In such a theory, surfaces are endowed with finite sets of points labeled with objects of $\mathcal{C}$ and enriched with tangent directions. In all dimensions one can study manifolds and cobordisms endowed with homotopy classes of mappings to a fixed space (homotopy quantum field theory, in the sense of Turaev). Additional structures on the tangent bundles – spin

structures, framings, etc. – may be also considered provided the gluing is well defined.

# Axiomatic Quantum Field Theory

**B Kuckert**, Universität Hamburg, Hamburg, Germany

## Introduction

The term "axiomatic quantum field theory" subsumes a collection of research branches of quantum field theory analyzing the general principles of relativistic quantum physics. The content of the results typically is structural and retrospective rather than quantitative and predictive.

The first axiomatic activities in quantum field theory date back to the 1950s, when several groups started investigating the notion of scattering and *S*-matrix in detail (Lehmann, Symanzik, and Zimmermann 1955 (LSZ-approach), Bogoliubov and Parasiuk 1957, Hepp and Zimmermann (BPHZ-approach), Haag 1957–59 and Ruelle 1962 (Haag–Ruelle theory) (*see* Scattering, Asymptotic Completeness and Bound States and Scattering in Relativistic Quantum Field Theory: Fundamental Concepts and Tools).

Wightman (1956) analyzed the properties of the vacuum expectation values used in these approaches and formulated a system of axioms that the vacuum expectation values ought to satisfy in general. Together with Gårding (1965), he later formulated a system of axioms in order to characterize general quantum fields in terms of operator-valued functionals, and the two systems have been found to be equivalent.

A couple of spectacular theorems such as the PCT theorem and the spin–statistics theorem have been obtained in this setting, but no interacting quantum fields satisfying the axioms have been found so far (in $1+3$ spacetime dimensions). So, the development of alternatives and modifications of the setting got into the focus of the theory, and the axioms themselves became the objects of research. Their role as axioms – understood in the common sense – turned into the role of mere properties of quantum fields. Today, the term "axiomatic quantum field theory" is widely avoided for this reason.

In a long list of publications spread over the 1960s, Araki, Borchers, Haag, Kastler, and others worked out an algebraic approach to quantum field theory in the spirit of Segal's "postulates for general quantum Mechanics" (1947) (*see* Algebraic Approach to Quantum Field Theory).

The Wightman setting was the basis of a framework into which the causal construction of the *S*-matrix developed by Stückelberg (1951) and Bogoliubov and Shirkov (1959) has been fitted by Epstein and Glaser (1973). The causality principle fixes the time-ordered products up to a finite number of parameters at each order, which are to be put in as the renormalization constants.

Already in 1949, Dyson had seen that problems in the formulation of quantum electrodynamics (QED) could be avoided by "just" multiplying the time variable and, correspondingly, the energy variable by the imaginary unit constant ("Wick rotation"). Schwinger then investigated time-ordered Green functions of QED in this Euclidean setting. This approach was formulated in terms of axioms by Osterwalder and Schrader (1973, 1975) (*see* Euclidean Field Theory).

Other extensions of the aforementioned settings are objects of current research (*see* Indefinite Metric,

Quantum Field Theory in Curved Spacetime, Symmetries in Quantum Field Theory of Lower Spacetime Dimensions, and Thermal Quantum Field Theory).

## Quantum Fields

Gårding and Wightman characterized operator-valued quantum fields on the Minkowski spacetime $\mathbb{R}^{1+3}$ by a couple of axioms. Given additional assumptions concerning the high-energy behavior, the Gårding–Wightman fields are in one–one correspondence with algebraic field theories.

Without specifying or presupposing these additional assumptions, the axioms will now be formulated and discussed in detail and compared to the corresponding conditions in the algebraic setting. Adjoint operators are marked by an asterisk, and Einstein's summation convention is used.

**Operator-valued functionals** *The components of a field* $\boldsymbol{F}$ *are an n-tuple* $F_1 \cdots F_n$ *of linear maps that assign to each test function* $\varphi \in C_0^\infty(\mathbb{R}^{1+3})$ *linear operators* $F_1(\varphi) \cdots F_n(\varphi)$ *in a Hilbert space* $\mathcal{H}$ *with domains of definition* $D(F_1(\varphi)) \cdots D(F_n(\varphi))$. *There exists a dense subspace* $\mathcal{D}$ *of* $\mathcal{H}$ *with* $\mathcal{D} \subset D(F_\nu(\varphi)) \cap D(F_\nu(\varphi)^*)$ *and* $F_\nu(\varphi)\mathcal{D} \cup F_\nu(\varphi)^*\mathcal{D} \subset \mathcal{D}$ *for all indices* $\nu$. *Consider* $m$ *such fields* $\boldsymbol{F}^1 \cdots \boldsymbol{F}^m$ *with components* $F_\nu^a, 1 \le a \le m, \; 1 \le \nu \le n_a$. *Assume there to be an involution* $* : (1 \cdots m) \to (1 \cdots m)$ *such that* $F_\nu^{a^*}(\varphi) = F_\nu^a(\overline{\varphi})^*$, *where* $\overline{\varphi}(x) := \overline{\varphi(x)}$.

Quantum fields cannot be operator-valued functions on $\mathbb{R}^{1+3}$ if one wants them to exhibit (part of) the properties to follow. But point fields can be quadratic forms; typically this is the case for fields in a Fock space.

For each component $F_\nu^a$ and each open region $\mathcal{O} \subset \mathbb{R}^{1+3}$, the field operators $F_\nu^a(\varphi)$ with $\operatorname{supp} \varphi \subset \mathcal{O}$ generate a $^*$-algebra $\mathcal{F}_\nu^a(\mathcal{O})$ of operators defined on $\mathcal{D}$. These operators typically are unbounded, which is one of the differences with the traditional setting of the algebraic approach. There a $C^*$-algebra $\mathfrak{A}(\mathcal{O})$ is assigned to each open region $\mathcal{O}$ in such a way that $\mathcal{O} \subset \mathcal{P}$ implies $\mathfrak{A}(\mathcal{O}) \subset \mathfrak{A}(\mathcal{P})$. Each $C^*$-algebra is a $^*$-algebra, but in contrast to a $C^*$-algebra, a$^*$-algebra does not need to be endowed with a norm. The fundamental observables in quantum theory are bounded positive operators (typically, but not always, projections), and these generate a $C^*$-algebra.

There is no fundamental physical motivation for confining the setting to fields with a finite number of components, except that it includes most of the fields known from "daily life."

**Continuity as a distribution** *For all* $\Phi, \Psi \in \mathcal{D}$, *the linear functionals* $T_{\Phi,\Psi,\nu}$ *on* $C_0^\infty(\mathbb{R}^{1+3})$ *defined by*

$$T^a_{\nu,\Phi,\Psi}(\varphi) := \langle \Phi, F^a_\nu(\varphi)\Psi \rangle$$

*are distributions. They can be extended to tempered distributions.*

The Fourier transform of a tempered distribution is well defined as a tempered distribution. It is mainly due to the importance of Fourier transformations that the preceding assumption is convenient. Bogoliubov *et al.* (1975) remark that the assumption is not a mere technicality, since it rules out nonrenormalizable quantum fields.

**Microcausality (Bose–Fermi alternative)** *If* $\varphi$ *and* $\psi$ *are test functions with spacelike separated support, then*

$$F^a_\nu(\varphi)F^b_\mu(\psi)|_{\mathcal{D}} = \pm F^b_\mu(\psi)F^a_\nu(\varphi)|_{\mathcal{D}}.$$

The sign depends on the statistics of the fields, it is "−" if and only if both $\boldsymbol{F}^a$ and $\boldsymbol{F}^b$ are fermion fields.

Microcausality is closely related to Einstein causality. Einstein causality requires that any two observables located in spacelike separated regions commute in the strong sense, that is, their spectral measures commute. But fields with Fermi–Dirac statistics are not observables, and not even for Bose–Einstein fields with self-adjoint field operators does the above condition imply that the spectral projections commute, which is the criterion for commensurability. The sign on the right-hand side does, however, specify the statistics of the field.

This is a crucial difference with the algebraic approach. If $\mathcal{O}$ and $P$ are spacelike separated open regions and if $A \in \mathfrak{A}(\mathcal{O})$ and $B \in \mathfrak{A}(P)$, then one assumes, like in the above case, that $AB = BA$ (locality). But being elements of $C^*$-algebras, $A$ and $B$ are bounded operators (or can be represented accordingly), so if $A$ and $B$ are self-adjoint, they are, indeed, commensurable.

Doplicher, Haag, and Roberts (1974) and Buchholz and Fredenhagen (1984) have derived from this input of observables a field structure of *localized particle states*, and they showed that the statistics of these fields is Bose–Einstein, Fermi–Dirac, or some corresponding parastatistics (which is, *a priori*, forbidden if one assumes microcausality).

Recall that the unimodular group $SL(2,\mathbb{C})$ is isomorphic to the universal covering group of the restricted Lorentz group $L_+^\uparrow$ (the connected component containing the unit element). Denote by $\Lambda : SL(2,\mathbb{C}) \to L_+^\uparrow$ a covering map.

**Covariance** *There exist strongly continuous unitary representations U and T of* $\mathrm{SL}(2,\mathbb{C})$ *and* $(\mathbb{R}^{1+3},+)$, *respectively, and representations* $\boldsymbol{D}^1\cdots\boldsymbol{D}^m$ *of* $\mathrm{SL}(2,\mathbb{C})$ *in* $\mathbb{C}^{n_1}\cdots\mathbb{C}^{n_m}$, *respectively, such that*

$$U(g)F^a_\nu(\varphi)U(g)^* = D^a(g^{-1})^\mu_\nu F^a_\mu(\varphi(\Lambda(g)^{-1}\cdot))$$

*and*

$$T(y)F^a_\nu(\varphi)T(y)^* = F^a_\mu(\varphi(\cdot - y)),$$

*where* $D^a(g^{-1})^\mu_\nu$ *are the elements of the matrix* $\boldsymbol{D}^a(g^{-1})$. *Dropping coordinate indices, this reads*

$$U(g)\boldsymbol{F}^a(\varphi)U(g)^* = \boldsymbol{D}^a(g^{-1})\boldsymbol{F}^a(\varphi(\Lambda(g)^{-1}\cdot))$$

*and*

$$T(y)\boldsymbol{F}^a(\varphi)T(y)^* = \boldsymbol{F}^a(\varphi(\cdot - y)).$$

*The representations U and T generate a representation of the universal covering of the restricted Poincaré group.*

As it stands, this assumption is a very strong one, since it manifestly fixes the action of the representation on the field operators. In the algebraic approach, the covariance assumption is more modestly formulated. Namely, it is assumed that $U(g)\mathfrak{A}(\mathcal{O})U(g)^* = \mathfrak{A}(\Lambda(g)\mathcal{O})$ and $T(y)\mathfrak{A}(\mathcal{O})T(y)^* = \mathfrak{A}(\mathcal{O}+y)$, leaving open how the representation acts on the single local observables.

**Vacuum vector** *There exists a unique (up to a multiple) vector* $\Omega\in\mathcal{D}$ *that is invariant under the representations U and T and cyclic with respect to the algebra* $\mathcal{F}(\mathbb{R}^{1+3})$ *generated by all field operators* $F^a_\nu(\varphi)$, *that is,* $\overline{\mathcal{F}(\mathbb{R}^{1+3})\Omega} = \mathcal{H}$.

**Spectrum condition** *The joint spectrum of the components of the 4-momentum, i.e., of the generators of the spacetime translations, has support in the closed forward light cone* $\overline{V}_+$, *that is, the set* $\{k^2 \geq 0, k_0 \geq 0\}$.

The existence of an invariant ground state called the vacuum is standard in algebraic quantum field theory as well.

## *N*-Point Functions

Consider the above fields $\boldsymbol{F}^1\cdots\boldsymbol{F}^m$. For each $N\in\mathbb{N}$ and each $N$-tuple $(a_1\cdots a_N)$ of natural numbers $\leq m$ (labeling fields), define families $(\boldsymbol{F}^{a_1\cdots a_N}) := (F^{a_1\cdots a_N}_{\nu_1\cdots\nu_N})_{\nu_i\leq n_{a_i}}$ and $\boldsymbol{w}^{a_1\cdots a_N} := (w^{a_1\cdots a_N}_{\nu_1\cdots\nu_N})_{\nu_i\leq n_{a_i}}$ of distributions on $(\mathbb{R}^{1+3})^N$ by

$$F^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(\varphi_1\otimes\cdots\otimes\varphi_N) := F^{a_1}_{\nu_1}(\varphi_1)\cdots F^{a_N}_{\nu_N}(\varphi_N)$$

(using the nuclear theorem) and

$$w^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(\psi) := \langle\Omega, F^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(\psi)\Omega\rangle. \qquad [1]$$

These distributions are called the "$N$-point functions" of the fields $\boldsymbol{F}^1\cdots\boldsymbol{F}^m$ and yield the vacuum expectation values of the theory. It is straightforward to deduce the following properties from the Gårding–Wightman axioms.

**Microcausality (Bose–Fermi alternative)** *If* $\varphi_i$ *and* $\varphi_{i+1}$ *have spacelike separated supports, then*

$$\begin{aligned}&w^{a_1\cdots a_i a_{i+1}\cdots a_N}_{\nu_1\cdots\nu_i\nu_{i+1}\cdots\nu_N}(\varphi_1\otimes\cdots\otimes\varphi_i\otimes\varphi_{i+1}\otimes\cdots\otimes\varphi_N)\\&\quad = \pm w^{a_1\cdots a_{i+1}a_i\cdots a_N}_{\nu_1\cdots\nu_{i+1}\nu_i\cdots\nu_N}(\varphi_1\otimes\cdots\otimes\varphi_{i+1}\otimes\varphi_i\otimes\cdots\otimes\varphi_N).\end{aligned}$$

*or dropping coordinate indices,*

$$\begin{aligned}&\boldsymbol{w}^{a_1\cdots a_i a_{i+1}\cdots a_N}(\varphi_1\otimes\cdots\otimes\varphi_i\otimes\varphi_{i+1}\otimes\cdots\otimes\varphi_N)\\&\quad = \pm \boldsymbol{w}^{a_1\cdots a_{i+1}a_i\cdots a_N}(\varphi_1\otimes\cdots\otimes\varphi_{i+1}\otimes\varphi_i\otimes\cdots\otimes\varphi_N).\end{aligned}$$

**Invariance** *For all* $g\in\mathrm{SL}(2,\mathbb{C})$ *and* $y\in\mathbb{R}^{1+3}$, *one has*

$$\begin{aligned}&w^{a_1\cdots a_N}_{\mu_1\cdots\mu_N}(\varphi_1\otimes\cdots\otimes\varphi_N)\\&\quad = D^{a_1}(g^{-1})^{\nu_1}_{\mu_1}\cdots D^{a_N}(g^{-1})^{\nu_N}_{\mu_N}\\&\qquad \times w^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(\Lambda(g)\varphi_1\otimes\cdots\otimes\Lambda(g)\varphi_N)\\&\quad = w^{a_1\cdots a_N}_{\mu_1\cdots\mu_N}(\varphi_1(\cdot - y)\otimes\cdots\otimes\varphi_N(\cdot - y))\end{aligned}$$

*or dropping coordinate indices,*

$$\begin{aligned}&\boldsymbol{w}^{a_1\cdots a_N}(\varphi_1\otimes\cdots\otimes\varphi_N)\\&\quad = \left(\boldsymbol{D}^{a_1}(g^{-1})\otimes\cdots\otimes\boldsymbol{D}^{a_N}(g^{-1})\right)\\&\qquad \times \boldsymbol{w}^{a_1\cdots a_N}(\Lambda(g)\varphi_1\otimes\cdots\otimes\Lambda(g)\varphi_N)\\&\quad = \boldsymbol{w}^{a_1\cdots a_N}(\varphi_1(\cdot - y)\otimes\cdots\otimes\varphi_N(\cdot - y)).\end{aligned}$$

By translation invariance, the $N$-point functions $w^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(x_1\cdots x_N)$ only depend on the $N-1$ *relative*-position vectors $\xi_1 := x_1 - x_2$, $\xi_2 := x_2 - x_3, \ldots,$ $\xi_{N-1} := x_{N_1} - x_N$. This means that there are distributions $W^{a_1\cdots\nu_N}_{\nu_1\cdots\nu_N}$ on $(\mathbb{R}^{1+3})^{N-1}$ related to the $N$-point functions by the symbolic condition

$$w^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(x_1\cdots x_N) = W^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(\xi_1\cdots\xi_{N-1}).$$

In precise notation, this reads

$$w^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(\varphi) = \int_{1+3} W^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}(\varphi_x)\,dx,$$

where

$$\varphi_x(\xi_1\cdots\xi_{N-1}) := \varphi(x, x-\xi_1, x-\xi_1-\xi_2, \ldots, x-\xi_1 - \cdots - \xi_{N-1}).$$

The functions $W^{a_1\cdots a_N}_{\nu_1\cdots\nu_N}$ are called the *Wightman functions*, and they have the following property because of the spectrum condition of the field.

**Spectrum condition** *The support of the Fourier transform of each* $W^{a_1 \cdots a_N}_{\nu_1 \cdots \nu_N}$ *is contained in* $(\overline{V}_+)^{N-1}$.

The uniqueness of the vacuum vector (up to a phase) is equivalent to the following condition.

**Cluster property** *For* $N \geq 2$, *let* $x$ *be a spacelike vector in* $\mathbb{R}^{1+3}$, *let* $L$ *be a natural number* $< N$, *and let* $\varphi$ *and* $\psi$ *be tempered test functions on* $(\mathbb{R}^{1+3})^L$ *and* $(\mathbb{R}^{1+3})^{N-L}$, *respectively. then*

$$\lim_{0<\lambda\to\infty} w^{a_1 \cdots a_N}_{\nu_1 \ldots \nu_N}(\varphi \otimes \psi(\cdot - \lambda x)) = w^{a_1 \cdots a_L}_{\nu_1 \cdots \nu_L}(\varphi) w^{a_{L+1} \cdots a_N}_{\nu_{L+1} \cdots \nu_N}(\psi).$$

On the one hand, these properties have been deduced from the Gårding–Wightman axioms via eqn [1]. Conversely, a family of distributions labeled in the above fashion and satisfying the above properties may be used to construct a Gårding–Wightman field theory provided that two more conditions – which hold for all systems of $N$-point functions – are satisfied. This requires some elementary notation.

Define the index sets

$$\mathcal{I}_N := \left\{ \begin{pmatrix} a_1 \cdots a_N \\ \nu_1 \cdots \nu_N \end{pmatrix} : 1 \leq a_i \leq m, 1 \leq \nu_i \leq n_{a_i} \text{ for all } 1 \leq i \leq N \right\}, \quad N \in \mathbb{N}$$

$\mathcal{I}_0 := \{\emptyset\}$, and $\mathcal{I} := \bigcup_{N \in \mathbb{N}_0} \mathcal{I}_N$. On $\mathcal{I}$ a concatenation $\circ$ is defined by

$$\begin{pmatrix} a_1 \cdots a_N \\ \nu_1 \cdots \nu_N \end{pmatrix} \circ \begin{pmatrix} b_1 \cdots b_M \\ \mu_1 \cdots \mu_M \end{pmatrix} := \begin{pmatrix} a_1 \cdots a_N \, b_1 \cdots b_M \\ \nu_1 \cdots \nu_N \, \mu_1 \cdots \mu_M \end{pmatrix}$$

and

$$\emptyset \circ \kappa := \kappa \circ \emptyset := \kappa$$

and an involution $*$ by

$$\begin{pmatrix} a_1 \cdots a_N \\ \nu_1 \cdots \nu_N \end{pmatrix}^* := \begin{pmatrix} a_N^* \cdots a_1^* \\ \nu_N \cdots \nu_1 \end{pmatrix} \quad \text{and} \quad \emptyset^* := \emptyset.$$

Define an antilinear involution $*$ on $\mathcal{S}^N := \mathcal{S}((\mathbb{R}^{1+3})^N)$ by

$$\psi(x_1 \cdots x_N) := \overline{\psi(x_N \cdots x_1)}$$

for each $N \in \mathbb{N}$. Put $\mathcal{S}^0 := \mathbb{C}$ and $z^* := \overline{z}$ for all $z \in \mathbb{C}$.

Define $\mathcal{S}^{\mathcal{I}_N} := \mathcal{S}^N \times \mathcal{I}_N$, and $\mathcal{S}^{\mathcal{I}} := \bigcup_N \mathcal{S}^{\mathcal{I}_N}$. For each $\kappa \in \mathcal{I}_N$, the set $\mathcal{S}^\kappa := \mathcal{S}((\mathbb{R}^{1+3})^N) \times \{\kappa\}$ is a linear space. On the direct sum $\mathcal{B}^{\mathcal{I}} := \bigoplus_{\kappa \in \mathcal{I}} \mathcal{S}^\kappa$ define an associative product by

$$(\psi, \kappa)(\chi, \lambda) := (\psi \otimes \chi, \kappa \circ \lambda)$$

and an antilinear involution $*$ by $(\psi, \kappa)^* := (\psi^*, \kappa^*)$. This endows $\mathcal{B}^{\mathcal{I}}$ with the structure of a nonabelian $*$-algebra with unit element $1 = (1, \emptyset)$ (Borchers algebra).

If one defines $F_\emptyset(z) := z\mathbf{1}$, then $w_\emptyset(z) = z$, and the Wightman functions induce a $\mathbb{C}$-linear functional $\omega$ on $\mathcal{B}^{\mathcal{I}}$ by

$$\omega(\psi, \kappa) := w_\kappa(\psi) \qquad [2]$$

$\omega$ exhibits the following two properties, which are the announced additional conditions required for reconstructing the fields from the $N$-point functions.

**Hermiticity** $\omega(\xi^*) = \overline{\omega(\xi)}$.

**Positivity** $\omega(\xi^* \xi) \geq 0$.

To see Hermiticity, compute

$$\begin{aligned} \omega(\psi^*, \kappa^*) &= \langle \Omega, F_{\kappa^*}(\psi^*)\Omega \rangle \\ &= \langle F_\kappa(\psi)\Omega, \Omega \rangle = \overline{\omega(\psi, \kappa)} \end{aligned}$$

and use $\mathbb{C}$-linearity to prove the statement for arbitrary $\xi \in \mathcal{B}$. For positivity, write any $\xi$ as a finite sum $\xi = (\psi_1, \kappa_1) + \cdots + (\psi_M, \kappa_M)$, and compute

$$\begin{aligned} \omega(\xi^* \xi) &= \omega\left( \sum_{i,j=1}^M (\psi_i, \kappa_i)^* (\psi_j, \kappa_j) \right) \\ &= \omega\left( \sum_{ij} (\psi_i^* \otimes \psi_j, \kappa_i^* \circ \kappa_j) \right) \\ &= \sum_{ij} w_{\kappa_i^* \circ \kappa_j}(\psi_i^* \otimes \psi_j) \\ &= \sum_{ij} \langle \Omega, F_{\kappa_i^* \circ \kappa_j}(\psi_i^* \otimes \psi_j)\Omega \rangle \\ &= \sum_{ij} \langle \Omega, F_{\kappa_i^*}(\psi_i^*) F_{\kappa_j}(\psi_j)\Omega \rangle \\ &= \sum_{ij} \langle F_{\kappa_i}(\psi_i)\Omega, F_{\kappa_j}(\psi_j)\Omega \rangle \\ &= \left\| \sum_i F_{\kappa_i}(\psi_i)\Omega \right\|^2 \geq 0. \end{aligned}$$

**Theorem 1** (Wightman's reconstruction theorem). *Let* $m$ *and* $n_1 \cdots n_m$ *be natural numbers, let* $\mathcal{I}_0, \mathcal{I}_1, \mathcal{I}_2, \ldots,$ *and* $\mathcal{I}$ *be the above index sets, and let* $\mathcal{B}^{\mathcal{I}}$ *be the above Borchers algebra. Let* $D_1 \cdots D_m$ *be matrix representations of* SL(2, $\mathbb{C}$) *in* $\mathbb{C}^{n_1} \cdots \mathbb{C}^{n_m}$, *respectively.*

*For each natural number* $N$, *let* $(w_\kappa)_{\kappa \in \mathcal{I}_N}$ *be a family of distributions on* $(\mathbb{R}^{1+3})^N$. *Suppose the family* $(w_\kappa)_{\kappa \in \mathcal{I}}$ *defined this way satisfies microcausality, covariance, spectrum condition, and the cluster property. If the linear functional* $\omega$ *defined on* $\mathcal{B}^{\mathcal{I}}$ *by eqn [2] is Hermitian and positive, then*

*there is (up to unitary equivalence) a unique family* $F^1 \cdots F^m$ *of Gårding–Wightman fields with* $n_1 \cdots n_m$ *components such that eqn [1] holds.*

The proof uses the GNS construction known from the theory of operator algebras. The Borchers algebra plays several roles. On the one hand, it is a linear space with an inner product. The Hilbert space $\mathcal{H}$ and the invariant space $\mathcal{D}$ of the field theory are constructed from this structure. On the other hand, the Borchers algebra acts on itself as an algebra of linear operators by its own algebra multiplication. This is the structure the $*$-algebra of field operators is constructed from.

## Results

The mathematical and structural analysis of quantum fields has improved the understanding of scattering theory in the different approaches mentioned above; see Bogoliubov *et al.* (1975) and the relevant articles in this encyclopedia. Apart from this, the following results deserve to be mentioned. Evidently, many others have to be omitted for practical reasons.

### PCT Symmetry

An early famous result was Lüders's proof (1957) that all fields in the above setting exhibit PCT symmetry, that is, the symmetry under reflections in all space and time variables combined with a charge conjugation. This symmetry is exhibited by all particle reactions observed so far. The proof, like several of the main results, made extensive use of the fact that the $N$-point functions are boundary values of analytic functions due to the spectrum condition, and that a fundamental theorem by Bargmann, Hall, and Wightman (1957) yields invariant analytic extensions.

### Reeh–Schlieder Theorem

For each field $F^a_\nu$ and each bounded open region $\mathcal{O} \subset \mathbb{R}^{1+3}$, the vacuum vector is cyclic with respect to $\mathcal{F}^a_\nu(\mathcal{O})$ (Reeh and Schlieder 1961). So excitations of the vacuum vector by field operators located in $\mathcal{O}$ are not to be considered as state vectors of a particle localized in $\mathcal{O}$, since they are not perpendicular to the excitations by field operators located outside $\mathcal{O}$.

### Unruh Effect and Modular $P_1CT$ Symmetry

In the 1970s, Bisognano and Wichmann (1975, 1976) discovered a surprising link of symmetries to the intrinsic algebraic structure of quantum fields, which is established by the Tomita–Takesaki modular theory (*see* Tomita–Takesaki Modular Theory). Namely, the unitary operators implementing the Lorentz boosts on the fields are elements of modular groups. This means that a uniformly accelerated observer perceives the vacuum as a thermal state with a temperature proportional to its acceleration, corresponding to the famous Unruh effect.

In addition, it was shown that $P_1CT$ symmetries (i.e., PCT combined with rotations by the angle $\pi$) are implemented by modular conjugations (modular $P_1CT$ symmetry). Modular $P_1CT$ symmetry is a consequence of the Unruh effect (Guido and Longo 1995).

### Spin and Statistics

Immediately following Lüders's PCT theorem, the spin–statistics theorem was proved for the $N$-point functions of the Wightman setting (Lüders and Zumino 1958, Burgoyne 1958, Dell'Antonio 1961). This was a remarkable and widely acknowledged progress. But as remarked earlier, the confinement to finite-component fields, which is used in the proof, cannot be motivated by physical first principles (i.e., in a truly axiomatic fashion). The representation $D$ of $SL(2, \mathbb{C})$ acting on the components, however, is forced to be finite dimensional by this assumption, and since the representations $D^a$ are objects of investigation, a considerable part of the result is assumed this way from the outset. Even more so, there are examples of fields with a "wrong" spin–statistics connection and infinitely many components.

This was one reason to continue working on the subject. At the beginning of the 1990s, it was found that the spin–statistics theorem can be derived from the symmetries discovered by Bisognano and Wichmann, and Unruh. Two approaches not referring to the number of internal degrees of freedom have been worked out: one assumes the Unruh effect (Guido and Longo 1995), the other modular $P_1CT$ symmetry (Kuckert 1995, 2005, Kuckert and Lorenzen 2005). The first approach has been generalized to conformal fields, the second to the case that the symmetry group's homogeneous part is not $SL(2, \mathbb{C})$, but only $SU(2)$.

Both approaches can be applied to infinite-component fields. They yield existence theorems; a distinguished representation is constructed from the modular symmetries, and this representation exhibits Pauli's spin–statistics connection. As mentioned before, nothing more can be expected at this level of generality. The line of argument works in both the algebraic and the Wightman setting.

### A Dynamical Property of the Vacuum

One can derive the spectrum condition, the Bisognano–Wichmann symmetries/the Unruh effect, and

covariance from the condition that no (inertial or) uniformly accelerated observer can extract mechanical energy from the field *in vacuo* by means of a cyclic process (Kuckert 2002).

#### Interacting Fields

The examples of interacting quantum fields that fit into the above settings live in one or two spatial dimensions only, and their relevance for physics mainly consists in being such examples. This has contributed to some frustration and to doubts on whether one is not, in fact, proving theorems on pretty empty sets, or in other words, working on "the most sophisticated theory of the free field."

The computations in quantum field theory are, like most of the computations in physics, perturbative. In order to be successful, they need to yield good agreement with experiment with reasonable computational efforts, that is, by evolution up to the second or third order. This asymptotic convergence is more important than convergence of the series as a whole. There are low-dimensional examples of interacting Wightman fields (e.g., $(\varphi^4)_2$; cf. the monograph by Glimm and Jaffe (1987)), and time will tell whether four-dimensional interacting Wightman fields exist. But there is no reason to expect convergence for general interacting fields; for example, QED does not fit into the Wightman framework.

The appropriate extension of the Wightman setting has been formulated by Epstein and Glaser (1973). It defines the *S-matrix* rather than the field itself as a (in general divergent) formal power series of operator-valued distributions.

The above results apply to this somewhat more modest setting as well, so the "axiomatic" approaches do help in understanding the known high-energy physics interactions. This even includes gauge theories (*see* Perturbative Renormalization Theory and BRST). The high-precision results of QED can be reproduced within this setting, and there occur no UV singularities: renormalization amounts to the need to extend distributions by fixing some parameters, that is, the renormalization constants. The infrared problem is circumvented by considering the *S*-matrix as a (position-dependent) distribution taking values in the unitary formal power series of distributions rather than as a single (global) unitary operator (or unitary power series).

#### Quantum Energy Inequalities

Energy densities of Wightman fields admit negative expectation values (Epstein, Glaser, and Jaffe 1965). This is in contrast to the positivity conditions that the energy–momentum tensors of classical general (and, hence, also special) relativity have to satisfy to ensure causality. But the conflict can be solved by smearing the densities out in space or time, as has first been realized by Ford (1991). The extent to which the energy density can become negative depends on the extent to which it is smeared out: "more smearing means less violation of positivity," so the classical positivity conditions are restored at medium and large scales. There are many ways to make this principle concrete. Quantum energy inequalities hold for thermodynamically well-behaved quantum fields on causally well-behaved classical spacetime backgrounds.

## Bibliographic Notes

Important monographs on axiomatic quantum field theory are those by Streater and Wightman (1964), Jost (1965), Bogoliubov *et al.* (1975), and Bogoliubov *et al.* (1990). Note that the books of Bogoliubov *et al.* differ in setup fundamentally and that neither replaces the other. For a lecture notes volume, see also Völkel (1977), and for a review article, see Streater (1975). A valuable discussion of the Wightman axioms can also be found in the second volume of the series by Reed and Simon (1970).

The first monograph on the algebraic approach to quantum field theory is due to Haag (1992), a more recent one has been written by Araki (1999). Concerning the sufficient conditions for "switching" between the Gårding–Wightman and the algebraic approach, see Wollenberg (1988) and the Ph.D. thesis of Bostelmann (2000) and references given there. Dynamical and thermodynamical foundation of standard axioms, the Bisognano–Wichmann symmetries (Unruh effect), and the spin–statistics theorem, have been investigated by Kuckert (2002, 2005), see also the references given there for related work.

In different formulations and at differing degrees of mathematical sophistication, the causal approach to perturbation theory can be found in the monographs by Bogoliubov and Shirkov (1959), Scharf (1989, 2001), and Steinmann (2000). Two modern review articles have been written by Brunetti and Fredenhagen (2000) and by Dütsch and Fredenhagen (2004).

The reference original articles on the Euclidean axioms are those of Osterwalder and Schrader (1973, 1975). Note that the first one contains an error. (cf. also Zinoviev (1995)). A monograph on Euclidean field theory and its relations to the other axiomatic settings of quantum field theory and to statistical mechanics is that by Glimm and Jaffe (1987).

A recent review on quantum energy inequalities is due to Fewster (2003).

## Bäcklund Transformations

**D Levi**, Università "Roma Tre", Rome, Italy

### Introduction

Bäcklund transformations appeared for the first time in the work of the geometers of the end of the nineteenth century, for instance, Bianchi, Lie, Bäcklund, and Darboux, when studying surfaces of constant curvature. If on a surface in three-dimensional Euclidean space, the asymptotic directions are taken as coordinate directions, then the surface metric may be written as

$$\mathrm{d}s^2 = \mathrm{d}x^2 + 2\cos(w)\,\mathrm{d}x\,\mathrm{d}y + \mathrm{d}y^2 \qquad [1]$$

where $w(x,y)$ is a function of the surface coordinates $x, y$. A necessary and sufficient condition for the surface to be of constant curvature is that $w$ satisfies the nonlinear partial differential equation

$$w_{,xy} = \sin(w) \qquad [2]$$

where the subscript denotes partial derivative. Equation [2] is nowadays called the sine Gordon (sG) equation. Bianchi (1879), Lie (1888, 1890, 1893), and Bäcklund (1874) introduced a transformation which allows one to pass from a solution of eqn [2] to a new solution, that is, from a surface of constant curvature to a new one. Starting from the work of Clarin (1903), this transformation has been referred to as Bäcklund transformation (BT). The BT for eqn [2] reads

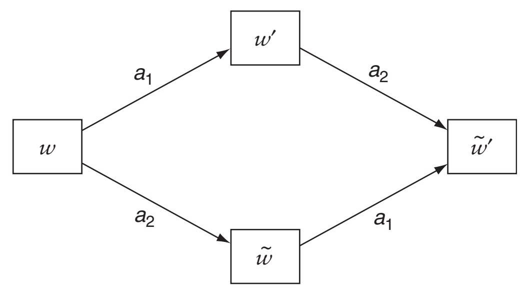
$$\tilde{w}_{,x} = w_{,x} + 2a\sin\left(\frac{\tilde{w}+w}{2}\right) \qquad [3a]$$

$$\tilde{w}_{,y} = -w_{,y} + \frac{2}{a}\sin\left(\frac{\tilde{w}-w}{2}\right) \qquad [3b]$$

where $a$ is a nonzero constant parameter and $\tilde{w}$ is a different solution of eqn [2]. It is immediate to prove by appropriate differentiation of eqns [3] with respect to $y$ and $x$ that both $w$ and $\tilde{w}$ must satisfy eqn [2]. The BT [3] provides a denumerable set of exact solutions once a solution $w$ is known. Bianchi showed that four such solutions can be related in an algebraic way:

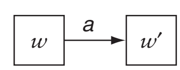
$$\tan\left(\frac{\tilde{w}'-w}{4}\right) = \frac{a_1+a_2}{a_1-a_2}\tan\left(\frac{w'-\tilde{w}}{4}\right) \qquad [4]$$

Equation [4] is derived using the permutability theorem proved by Bianchi in his Ph.D. thesis in 1879:



[5]

whereby the diagram



we mean a BT from $w$ to $w'$ with parameter $a$.

For sG equation [2] a trivial solution is given, for example, by $w(x,y) = \pi$. Then, from eqn [3a] we get

$$\tilde{w}(x,y) = 2\arcsin\left(\frac{1-\mathrm{e}^{-2[ax+\alpha(y)]}}{1+\mathrm{e}^{-2[ax+\alpha(y)]}}\right)$$

Introducing this result in eqn [3b], we get $\alpha_{,y} = -1/a$. So, the application of the BT [3] to sG equation gives the nontrivial solution

$$\boxed{w=\pi} \longrightarrow \boxed{\tilde{w} = 4\arctan\left(\frac{1-\mathrm{e}^{-[ax-y/a]}}{1+\mathrm{e}^{-[ax-y/a]}}\right)} \qquad [6]$$

Clarin (1903) extended the results of Bäcklund to the case of a generic partial differential equation of second order,

$$F(x, y, w, w_{,x}, w_{,y}, w_{,xx}, w_{,xy}, w_{,yy}) = 0 \qquad [7]$$

by assuming that

$$\begin{aligned} w_{,x} &= f(w, \tilde{w}, \tilde{w}_{,x}, \tilde{w}_{,y}) \\ w_{,y} &= g(w, \tilde{w}, \tilde{w}_{,x}, \tilde{w}_{,y}) \end{aligned} \qquad [8]$$

If the compatibility of eqns [8]

$$f_{,y} - g_{,x} = 0 \qquad [9]$$

is identically satisfied by eqn [7] for the variable $\tilde{w}(x, y)$, then we say that eqns [8] are an auto-Bäcklund transformation for eqn [7]. In this case, eqns [8] transform a solution of eqn [7] into a new solution of the same equation. Thus, eqns [8] simplify the problem of finding solutions of eqn [7]. Given one solution $w(x, y)$ of eqn [7], the existence of a BT reduces the problem of integrating eqn [7] into that of solving two first-order ordinary differential equations. From this point of view, the Cauchy–Riemann relations

$$w_{,x} = \tilde{w}_{,y}, \qquad w_{,y} = -\tilde{w}_{,x} \qquad [10]$$

for the Laplace equation

$$w_{,xx} + w_{,yy} = 0 \qquad [11]$$

are a BT *ante litteram* (however, without a free parameter).

Consider the case when $\tilde{w}(x, y)$ satisfies a different partial differential equation,

$$G(x, y, \tilde{w}, \tilde{w}_{,x}, \tilde{w}_{,y}, \tilde{w}_{,xx}, \tilde{w}_{,xy}, \tilde{w}_{,yy}) = 0 \qquad [12]$$

In this case, one still has a BT, but not an auto-BT. The best-known cases are when $F_1 = w_{,y} + w_{,xxx} + ww_{,x}$ and $G_1 = \tilde{w}_{,y} + \tilde{w}_{,xxx} + \tilde{w}^2\tilde{w}_{,x}$, and $F_2 = w_{,xy} - e^w$ and $G_2 = \tilde{w}_{,xy}$ (Lamb 1976). In the first case, the BT relates the Korteweg–de Vries (KdV) equation to the modified KdV equation and this transformation paved the way to the discovery of the complete integrability of the KdV equation by Gardner *et al.* (1967). In the second case, the BT relates the Liouville equation to the wave equation, and can be used to solve it completely. Due to the first example, often a non-auto-BT is denoted as Miura transformation.

One can now state an operative definition of BT, extending the results of Bäcklund and Clarin to more general equations.

**Definition 1** Consider two partial differential equations of order $m_1$ and $m_2$:

$$F_1(\boldsymbol{x}, \boldsymbol{u}, \underset{(1)}{\boldsymbol{u}}, \underset{(2)}{\boldsymbol{u}}, \ldots, \underset{(m_1)}{\boldsymbol{u}}) = 0 \qquad [13a]$$

$$F_2(\boldsymbol{x}, \tilde{\boldsymbol{u}}, \underset{(1)}{\tilde{\boldsymbol{u}}}, \underset{(2)}{\tilde{\boldsymbol{u}}}, \ldots, \underset{(m_2)}{\tilde{\boldsymbol{u}}}) = 0 \qquad [13b]$$

where $\boldsymbol{x} \in \mathbb{R}^n$ and $(\boldsymbol{u}, \tilde{\boldsymbol{u}}) \in \mathbb{C}^p$, and $\underset{(k)}{\boldsymbol{u}}$ is the set of $k$-order derivative of $\boldsymbol{u}$. The set of $n$ equations

$$G_j(\boldsymbol{x}, \boldsymbol{u}, \underset{(1)}{\boldsymbol{u}}, \ldots, \underset{(s_1)}{\boldsymbol{u}}; \tilde{\boldsymbol{u}}, \underset{(1)}{\tilde{\boldsymbol{u}}}, \ldots, \underset{(s_2)}{\tilde{\boldsymbol{u}}}) = 0$$
$$j = 1, 2, \ldots, n \qquad [14]$$

with $s_1 < m_1$ and $s_2 < m_2$, represents the BT of eqns [13] iff the compatibility of eqns [14] is identically satisfied on the solutions of eqns [13] and $G_j$ depends on a set of essential arbitrary constant parameters.

The Clarin formulation [8] and the classical BT for the sG [3] are clearly special subcases of this definition. When a solution of $F_1 = 0$ is known, a solution of $F_2 = 0$ is obtained by solving a set of lower-order partial differential equations. By a proper choice of the BT parameters, once a new solution is obtained by solving the BT [14], one can use the obtained solution as a starting point to construct another one, and so on. In this way, one can construct a whole ladder of solutions, *a priori* a denumerable set of solutions. This same construction has been applied also to the case of functional equations. In particular, it has been considered for the case of differential–difference and difference–difference equations both for finite (dynamical systems (Wojciechowski 1982)) and infinite lattices (Toda 1989).

In the case when $F_1$ and $F_2$ represent the same equation, $s_1 = s_2 = 1$ and the BTs $G_j = 0$ are linear in $\underset{(1)}{\boldsymbol{u}}$, then Definition 1 is strictly related to the notion of nonclassical symmetry or conditional symmetry (Levi and Winternitz 1989, Olver 1993), an extension of the concept of Lie symmetry used to reduce and integrate a differential equation. In the case of the nonclassical symmetries, the known solution $\tilde{\boldsymbol{u}}$ is included in the arbitrary $\boldsymbol{x}$-dependent coefficients of the transformation. In this case, the BT is just a way to construct an explicit solution of the differential equation [7].

Definition 1 is often too general to be able to get explicit results. It is constructive for any partial differential equation, linear or nonlinear, but if one is not able to get a nontrivial BT this does not mean that a BT does not exist. As noted later, the existence of an auto-BT is associated to the existence of an infinity of symmetries, and this is a condition for the exact integrability of eqn [13] (Fokas 1980, Ibragimov and Shabat 1980). So, the existence of a BT is closely related to the integrability of eqn [13].

## Bäcklund via Integrability

One can derive the BT from the integrability properties of eqn [13a]. Equation [13a] is said to be integrable if it can be written as the compatibility condition of an overdetermined system of linear partial differential equations for an auxiliary function depending on a free parameter belonging to the

complex $C$ plane. The prototype of such a situation is given by the Lax pair for the KdV equation

$$u_{,t} + u_{,xxx} - 6uu_{,x} = 0 \quad [15]$$

introduced by Lax (1968):

$$L\psi = k^2\psi, \quad L = -\partial_x^2 + u(x,t) \quad [16a]$$

$$\psi_{,t} = -M\psi, \quad M = 4\partial_{xxx} - 3(u\partial_x + \partial_x u) \quad [16b]$$

where $k$ is a free parameter and $\psi = \psi(x,t;k)$. As eqn [16a] is nothing else but the stationary Schrödinger equation, the function $\psi$ can be interpreted as a wave function, and $k^2$ is the spectral parameter corresponding to the potential $u(x,t)$. The condition for the existence of a solution $\psi$ of the overdetermined system of eqns [16] is given by the operator equation

$$L_{,t} = [L, M] \quad [17]$$

the so-called Lax equation. In the case of asymptotically bounded potentials, eqn [16a] defines the spectrum unique. Introducing the following asymptotic boundary conditions for the wave function $\psi$,

$$\begin{aligned} \psi(x,t;k) &\underset{x\to-\infty}{\longrightarrow} T(k,t)e^{-ikx} \\ \psi(x,t;k) &\underset{x\to+\infty}{\longrightarrow} e^{-ikx} + R(k,t)e^{ikx} \end{aligned} \quad [18]$$

where $R(k,t)$ and $T(k,t)$ are, respectively, the reflection and the transmission coefficient, the spectrum is defined in the complex plane of the variable $k$ by

$$S[u] \equiv \{R(k,t),\ -\infty < k < \infty;\ p_n, c_n(t),\ j = 1,2,\ldots,N\} \quad [19]$$

where $p_n$ are the bound state parameters corresponding to isolated singularities of the reflection coefficients on the imaginary positive $k$-axis corresponding to a solution $\phi_n(x,t;p_n)$ of the spectral problem vanishing for $x \to -\infty$ and such that

$$\lim_{x\to+\infty} [e^{p_n x}\phi_n(x,t;p_n)] = 1 \quad [20]$$

and $c_n$ are some functions of $t$ related to the residues of $R(k,t)$ at the poles $p_n$. There is a one-to-one correspondence between the evolution of the potential $u(x,t)$ in eqn [15] and that of the spectrum $S[u]$ of the Schrödinger spectral problem [16a]. In particular, for the KdV, taking into account eqn [16b], the evolution of the reflection coefficient $R(k,t)$ is given by

$$\frac{dR(k,t)}{dt} = 8ik^3 R(k,t) \quad [21]$$

In eqn [21] and henceforth, $d/dt$ denotes the total derivative with respect to $t$.

In the following, for the sake of the simplicity of exposition and for the concreteness of the presentation, all the results presented on the BT will be derived for the KdV equation. Similar results can be obtained and have been obtained in the literature for many classes of integrable partial differential equations in two and three dimensions and for differential–difference and difference–difference equations. For a partial review of the available recent literature on the subject, see Rogers and Shadwick (1982) and Coley *et al.* (2001)

A more general form of introducing the nonlinear partial differential equation as a compatibility of an overdetermined system of linear equations has been provided by Zaharov and Shabat (1979) with the dressing method (DM). In the DM, the differential equations [16] are substituted by a matrix system of linear equations

$$\Psi_{,x} = U(u(x,t),k)\Psi \quad [22a]$$

$$\Psi_{,t} = V(u(x,t),k)\Psi \quad [22b]$$

where $\Psi = \Psi(x,t;k)$ and $U$ and $V$ are matrix functions. The existence of a nonsingular solution of the system of linear equations [22] requires that the matrix functions $U$ and $V$ satisfy the equation

$$U_{,t} - V_{,x} + [U,V] = 0 \quad [23]$$

often called zero-curvature condition. The KdV equation [15] in the DM is obtained by choosing

$$\begin{aligned} U(u(x,t),k) &= \begin{pmatrix} ik & u(x,t) \\ 1 & -ik \end{pmatrix} \\ V(u(x,t),k) & \\ &= \begin{pmatrix} 2u + 4k^2 & -u_x - 2iku - 4ik^3 \\ u_x + 2iku + 4ik^3 & 2u(u+2k^2) - 2iku_x - u_x x \end{pmatrix} \end{aligned} \quad [24]$$

The existence of an auto-BT implies the existence of a differential equation (see Definition 1) which relates two solutions of the same nonlinear equation. The new solution $\tilde{u}(x,t)$ of eqn [15] will be associated to a different Lax operator and a different spectral problem (but of the same operational form)

$$\tilde{L} = -\partial_{xx} + \tilde{u}(x,t) \quad [25a]$$

$$\tilde{L}\tilde{\psi} = k^2\tilde{\psi} \quad [25b]$$

The existence of a relation between the potentials $u(x,t)$ and $\tilde{u}(x,t)$ thus implies that there must be a $(u,\tilde{u};k)$-dependent operator $D$ such that

$$\tilde{\psi} = D\psi \qquad [26]$$

The compatibility of eqns [16a], [25b], and [26] implies that $\tilde{L}D\psi = Dk^2\psi$, that is,

$$\tilde{L}D = DL \qquad [27]$$

Equation [27] is the auto-BT in the Lax formalism. If $\tilde{L}$ and $L$ are two different spectral problems related to two different nonlinear partial differential equations, then eqn [27] will provide a Miura transformation. In the DM, the requirement of the existence of a BT is given again by eqn [26] with $\psi$ and $\tilde{\psi}$ substituted by $\Psi$ and $\tilde{\Psi}$ and the operator $D$ substituted by a matrix function $\mathcal{D}$. The BT in the DM is given by

$$\mathcal{D}_{,x} = U(\tilde{u}(x,t),k)\mathcal{D} - \mathcal{D}U(u(x,t),k) \qquad [28a]$$

$$\mathcal{D}_{,t} = V(\tilde{u}(x,t),k)\mathcal{D} - \mathcal{D}V(u(x,t),k) \qquad [28b]$$

In the particular case of the Hilbert–Riemann problem with zeros, providing the soliton solutions, the matrix $\mathcal{D}$ can be expressed as a function of $\Psi$. In this way, one derives the Moutard or Darboux transformation (DT) (Moutard 1878, Levi *et al.* 1984), the most efficient way to get soliton solutions of the nonlinear partial differential equation.

Given a linear ordinary differential equation for the unknown $\psi$, depending on a set of arbitrary functions $u(x)$ and parameters $k$, the DT provides a discrete transformation which leaves the equation invariant. In the particular case of the KdV equation associated with the stationary Schrödinger spectral problem [16a], we have

$$\tilde{u}(x,t) = u(x,t) - 2(\log F(x,t))_{,xx} \qquad [29a]$$

$$\tilde{\psi}(x,t;k) = -\frac{\mathrm{i}}{k+\mathrm{i}p}\psi_{,x}(x,t;k) - \frac{F_x(x,t)}{F(x,t)}\psi(x,t;k) \qquad [29b]$$

where the intermediate wave function

$$F(x,t) = \psi(x,t;k=\mathrm{i}p) + a\psi(x,t;k=-\mathrm{i}p)$$

is a linear combination of the Jost solution of the Schrödinger spectral problem with $p$ a real parameter and $a$ an arbitrary constant. If one looks for an equation involving only the potentials $u$ and $\tilde{u}$, from eqns [29], one gets the BT for the KdV equation. Given a trivial solution of the KdV equation, together with the corresponding solution of the spectral problem, eqn [29a] provides a new solution of the KdV, while eqn [29b] gives a new solution of the spectral problem. This procedure can be carried out recursively and gives a ladder of explicit solutions for the KdV equation.

The DM is a particularly simple setting in which one can derive DTs. In fact, expressing the matrix $\mathcal{D}$ in terms of $\Psi$, eqn [28a] gives a relation between the potentials of the type given by eqn [29a], while eqn [26] gives eqn [29b]. Depending on the form of the matrix $\mathcal{D}$ in terms of $k$, one can introduce more parameters in the DT. The classical DT [29] depends on just one parameter; however, in the case of the Schrödinger spectral problem [16a], one can also have DTs depending on two parameters, a TDT.

A more general DT, which can provide solutions even when the initial solution is not bounded asymptotically, can be obtained for many equations and, in particular, also for the KdV equation. This is obtained in a particular limit of the TDT when the parameters coincide (Levi 1988) and it is often referred to as binary DT (Matveev and Salle 1991). The binary DT for the KdV is given by

$$\tilde{u}(x,t) = u(x,t) - 2(\log F(x,t))_{,xx} \qquad [30a]$$

$$\tilde{\psi}(x,t;k) = \frac{1}{k^2-\mu^2}\left\{\left(k^2-\mu^2-\frac{F(x,t)_{,xx}}{2F(x,t)}\right)\psi_{,x}(x,t;k) - \frac{F_x(x,t)}{F(x,t)}\psi(x,t;k)\right\} \qquad [30b]$$

where $\mu$ is a value of $k$ for which the function $\psi(x,t;k)$ is asymptotically bounded at $+\infty$ and the function $F(x,t)$ is given by

$$F(x,t) = 1 + \rho\int_x^{+\infty}\psi(y,t;\mu)^2\,\mathrm{d}y \qquad [31]$$

with $\rho$ an arbitrary constant. The corresponding BT obtained eliminating the function $F$ from eqns [30] reads

$$\tilde{q}_{,xx} - q_{,xx} = -\frac{1}{8}(\tilde{q}-q)^3 - [\tilde{q}_x + q_x - 2g(x) + 2\mu](\tilde{q}-q) + \frac{1}{2}\frac{(\tilde{q}_x - q_x)^2}{\tilde{q}-q} \qquad [32]$$

where $q = \int_x^\infty u_0(y,t)\,\mathrm{d}y$ with $u_0(x,t) = u(x,t) - g(x)$, the asymptotically bounded part of $u(x,t)$, and $g(x)$ its asymptotic behavior, and $\tilde{q} = \int_x^\infty \tilde{u}_0(y,t)\,\mathrm{d}y$ with $\tilde{u}_0(x,t) = \tilde{u}(x,t) - g(x)$.

Once the Lax operator $L$ is given, we can obtain in a constructive way the operators $M$ which give the admissible nonlinear partial differential

equations and the operators $D$ which give the admissible BT. A technique to do so is provided by the so-called Lax technique introduced by Bruschi and Ragnisco (1980a–c). Using the Lax technique, we can easily obtain the nonlinear partial differential equations and BT associated with the Lax operator [16a] both in the isospectral and nonisospectral case (when $k_{,t}=0$ and when $k_{,t}\neq 0$) and the corresponding evolution of the spectrum. We have

$$u_{,t} = f(\mathcal{L},t)u_x + g(\mathcal{L},t)[xu_x + 2u] \qquad [33a]$$

$$k_{,t} = kg(-4k^2,t) \qquad \frac{dR(k,t)}{dt} = 2ikf(-4k^2,t)R(k,t) \qquad [33b]$$

$$F(\Lambda)(\tilde{u}-u) + G(\Lambda)\Gamma\ 1 = 0 \qquad [33c]$$

$$\tilde{R}(k,t) = \frac{F(-4k^2) - 2ikG(-4k^2)}{F(-4k^2)+2ikG(-4k^2)}R(k,t) \qquad [33d]$$

where the functions $f$, $g$, $F$, and $G$ are entire functions of their first argument and the recursive operators $\mathcal{L}$ and $\Lambda$ are given by

$$\mathcal{L}f(x) = f_{,xx}(x) - 4u(x,t)f(x) + 2u_{,x}(x,t)\int_x^{+\infty} f(y)\,dy \qquad [34a]$$

$$\Lambda f(x) = f_{,xx}(x) - 2[\tilde{u}(x,t)+u(x,t)]f(x) + \Gamma\int_x^{+\infty} f(y)\,dy \qquad [34b]$$

$$\Gamma f(x) = [\tilde{u}_{,x}(x,t)+u_{,x}(x,t)]f(x) + [\tilde{u}(x,t)-u(x,t)] \times \int_x^{+\infty}[\tilde{u}(y,t)-u(y,t)]f(y)\,dy \qquad [34c]$$

In the limit when $\tilde{u}\to u$ the operator $\Lambda\to\mathcal{L}$. A BT is obtained by choosing the functions $F$ and $G$ in eqn [33c]. The simplest BT is obtained by setting $F=\sigma$ and $G=1$:

$$\tilde{v}_{,x} + v_{,x} + (\tilde{v}-v)\left[\sigma - \tfrac{1}{2}(\tilde{v}-v)\right] = 0 \qquad [35]$$

with $u(x,t) = -v_{,x}(x,t)$ and $\sigma$ is the Bäcklund parameter. By combining together BT of the form [35] with different parameters as in eqn [5], we get the permutability theorem for the KdV BTs:

$$\tilde{v}' = v - \frac{(\sigma_1+\sigma_2)[v'-\tilde{v}]}{\sigma_1-\sigma_2+(1/2)(v'-\tilde{v})} \qquad [36]$$

Its proof is immediate from the point of view of the spectrum.

## Bäcklund and Symmetries

A symmetry of the nonlinear equation [15] is given by a flow commuting with it, that is, by an equation

$$u_{,\epsilon} = f(u,u_x,u_t,\ldots) \qquad [37]$$

where $\epsilon$ is the group parameter, $u=u(x,t;\epsilon)$, and the $\epsilon$ derivative of [15] is zero on its set of solutions. A group transformation is obtained by integrating it. Usually this is possible only when eqn [37] is a quasilinear partial differential equation of the first order. Taking into account the evolution of the spectrum of the KdV equation [15], it is easy to prove that its symmetries are given by

$$u_{,\epsilon} = \left\{\sum_{n=0}^{+\infty}\alpha_n\mathcal{L}^n - 3\sum_{n=0}^{+\infty}\beta_n t\mathcal{L}^n\right\}u_{,x} + \left\{\sum_{n=0}^{+\infty}\beta_n\mathcal{L}^n\right\}[xu_{,x}+2u] \qquad [38]$$

where $\alpha_n$ and $\beta_n$ are a set of constant parameters. For each choice of the parameters $\alpha_n$ and $\beta_n$, one gets a symmetry of the KdV equation [15]. With eqn [38] one can associate the following evolution of the reflection coefficient $R(k,t;\epsilon)$:

$$\frac{dR}{d\epsilon} = 2ik\left\{\sum_{n=0}^{+\infty}\alpha_n(-4k^2)^n - 3\sum_{n=0}^{+\infty}\beta_n t(-4k^2)^{n+1}\right\}R \qquad [39]$$

and of the spectral parameter $k$

$$k_{,\epsilon} = \sum_{n=0}^{+\infty}\beta_n(-4k^2)^n k \qquad [40]$$

As $-(1/2)\mathcal{L}\ 1 = xu_{,x}+2u$, one can add to the symmetries [38] the exceptional one (which has no spectral counterpart as $u$ is not bounded asymptotically):

$$u_{,\epsilon} = 1 + 6tu_{,x} \qquad [41]$$

By a proper natural choice of the constant parameters $\alpha_n$ and $\beta_n$, one can define two infinite series of symmetries. The first one is obtained by choosing $\beta_n=0$ and $\alpha_n=\delta_{n,m}$ with $m=1,2,\ldots,\infty$ and can be denoted as the isospectral series as $k_{,\epsilon}=0$. This is formed by commuting symmetries. The second one is given by $\alpha_n=0$ and $\beta_n=\delta_{n,m}$ with $m=1,2,\ldots,\infty$ and can be denoted as the nonisospectral series as $k_{,\epsilon}\neq 0$. The nonisospectral symmetries have a nonzero commutation relation among themselves and with the isospectral ones.

Except for a few Lie point symmetries (given by eqn [41] and by choosing inside the series [38] those with different from zero only $\beta_0$ or $\alpha_0$ or $\alpha_1$) they are all generalized symmetries (Olver 1993). By analyzing their spectrum, it is easy to prove that the choice [38] is such that they are all independent. For the isospectral class, the evolution of the spectrum is simple and can be integrated to provide the group transformation of the spectrum

$$R(k,t;\epsilon) = R(k,t) \times \exp\left[2\mathrm{i}k\left\{\sum_{n=0}^{+\infty}\alpha_n(-4k^2)^n\right\}\epsilon\right] \qquad [42]$$

Let us now consider the simplest BT obtained by choosing, in eqn [33c], $F(\Lambda)=\sigma$ and $G(\Lambda)=1$, where $\sigma$ is an arbitrary parameter. In the spectral space, this corresponds to the following change of the spectrum:

$$\tilde{R}(k,t) = \frac{\sigma - 2\mathrm{i}k}{\sigma + 2\mathrm{i}k}R(k,t) \qquad [43]$$

Defining $\tilde{R}(k,t)=R(k,t;\epsilon)$, eqn [42] is equal to eqn [43] iff

$$\alpha_n = -\frac{2}{\epsilon\sigma^{2n+1}(2n+1)}, \quad n = 0,1,\ldots,\infty \qquad [44]$$

So we need an infinite number of symmetries to be able to reconstruct the change of the spectrum given by the BT. This shows that the existence of a BT is strictly connected to the existence of an infinity of symmetries which is a condition for the exact integrability of the nonlinear partial differential equation (Fokas 1980, Ibragimov and Shabat 1980).

## Discretization via Bäcklund

BTs, apart from providing classes of exact solutions to nonlinear equations, play a very important role in the discretization of partial differential equations. As noted earlier, an auto-BT is a differential relation between two different solutions of the same nonlinear partial differential equation. If it is assumed that the new solution $\tilde{u}$ is just the old solution $u$ computed in a different point of a lattice, then the BT becomes just a differential–difference equation (Chiu and Ladik 1977, Levi and Benguria 1980). This can be carried out also at the level of the associated compatibility condition and in such a way one is able to also obtain its Lax pair. This demonstrates the integrability of the differential–difference equation

$$v(n+1,t)_{,t} + v(n,t)_{,t} + [v(n+1,t) - v(n,t)] \times \left\{\sigma - \tfrac{1}{2}[v(n+1,t) - v(n,t)]\right\} = 0 \qquad [45]$$

which is an integrable differential–difference approximation to the KdV equation or

$$w(n+1,t)_{,t} = w(n,t)_{,t} + 2a\sin\left[\frac{w(n+1,t)+w(n,t)}{2}\right] \qquad [46]$$

a discrete integrable differential–difference approximation to the sG equation (Hirota 1977, Orfanidis 1978).

As the nonlinear superposition formulas are purely algebraic relations involving potentials associated with integrable nonlinear partial differential equations, one can interpret them as difference–difference equations. In the case of the sG equation from eqn [7], we have

$$w_{n+1,m+1} - w_{n,m} = 4\arctan^{-1}\left(\frac{a_1+a_2}{a_1-a_2}\tan\frac{w_{n,m+1}-w_{n+1,m}}{4}\right) \qquad [47]$$

where $w(x,t)=w_{n,m}$, $\tilde{w}(x,t)=w_{n+1,m}$, $w'(x,t)=w_{n,m+1}$, and $\tilde{w}'(x,t)=w_{n+1,m+1}$. In a similar manner, from [36], one gets

$$v_{n+1,m+1} = v_{n,m} - \frac{(\sigma_1+\sigma_2)[v_{n+1,m} - v_{n,m+1}]}{\sigma_1 - \sigma_2 + \frac{1}{2}[v_{n+1,m} - v_{n,m+1}]} \qquad [48]$$

The continuous limit of eqn [47], obtained by setting $x=\epsilon_1 n$ and $y=\epsilon_2 m$ and choosing

$$\frac{a_1}{a_2} = \frac{\epsilon_1\epsilon_2}{4}$$

gives back eqn [2] (Rogers and Schief 1997). It is worth mentioning that one can also use known nonlinear lattice equations to construct BT for nonlinear partial differential equations (Levi 1981).

# Batalin–Vilkovisky Quantization

**A C Hirshfeld**, Universität Dortmund, Dortmund, Germany

## Introduction

The Batalin–Vilkovisky formalism for quantizing gauge theories has a long history of development. It begins with the Faddeev–Popov procedure for quantizing Yang–Mills theory, involving the Faddeev–Popov ghost fields (Faddeev and Popov 1967). It continued with the discovery of BRST symmetry by Becchi *et al.* (1976). Then Zinn-Justin (1975) introduced sources for these transformations, and a symmetric structure in the space of fields and sources in his study of renormalizability of these theories. Finally, Batalin and Vilkovisky (1981) systematized and generalized these developments. A more detailed account of this history can be found in Gomis *et al.* (1994), where many worked examples of the Batalin–Vilkovisky formalism are given. At the present time, it is the most general treatment available. Alexandrov, Kontsevich, Schwarz, and Zabaronsky (AKSZ 1997) have presented a geometric interpretation for the case in which the action is topologically invariant.

## Structure of the Set of Gauge Transformations

Consider a system whose dynamics is governed by a classical action $S[\phi^i]$ which depends on the fields $\phi^i(x), i=1,\ldots,n$. We employ a compact notation in which the multi-index $i$ may denote the various fields involved, the discrete indices on which they depend, and the dependence on the spacetime variables as well. The generalized summation convention then means that a repeated index may denote not only a sum over discrete variables, but also integration over the spacetime variables. $\epsilon_i=\epsilon(\phi^i)$ denotes the

Grassmann parity of the fields. Fields with $\epsilon_i = 0$ are called bosonic, with $\epsilon_i = 1$ fermionic. The graded commutation rule is

$$\phi^i(x)\phi^j(y) = (-1)^{\epsilon_i\epsilon_j}\phi^j(y)\phi^i(x) \qquad [1]$$

For a gauge theory the action is invariant under a set of gauge transformations with infinitesimal form

$$\delta\phi^i = R^i_\alpha \varepsilon^\alpha, \quad \alpha = 1 \text{ or } 2 \text{ or} \ldots m \qquad [2]$$

The $\varepsilon^\alpha$ are the infinitesimal gauge parameters and $R^i_\alpha$ the generators of the gauge transformations. When $\epsilon_\alpha = \epsilon(\varepsilon^\alpha) = 0$ we have an ordinary symmetry, when $\epsilon_\alpha = 1$ the equation is characteristic of a supersymmetry. The Grassmann parity of $R^i_\alpha$ is $\epsilon(R^i_\alpha) = \epsilon_i + \epsilon_\alpha \pmod 2$.

A subscript after a comma denotes the right derivative with respect to the corresponding field, that is, the field is to be commutated to the far right and then dropped. The field equations may then be written as

$$S_{0,i} = 0 \qquad [3]$$

where $S_0$ is the classical action. Let $\Sigma$ denote the surface in the space of solutions where the field equations are satisfied:

$$S_{0,i}|_\Sigma = 0 \qquad [4]$$

If the gauge transformations are "independent" on-shell, that is,

$$\operatorname{rank} R^i_\alpha|_\Sigma = m \qquad [5]$$

the gauge theory is said to be "irreducible." We assume here that this is the case. When it is not, the theory is "reducible." For details of the treatment in that case, see Gomis, Paris, and Samuel. The classical solutions are $\phi_0 \in \Sigma$.

The Noether identities are

$$S_{0,i}R^i_\alpha = 0 \qquad [6]$$

The general solution to the Noether identity is

$$\lambda^i = R^i_\alpha T^\alpha + S_{0,j}E^{ji} \qquad [7]$$

The commutator of two gauge transformations is

$$[\delta_1, \delta_2]\phi^i = \left(R^i_{\alpha,j}R^j_\beta - (-1)^{\epsilon_\alpha\epsilon_\beta}R^i_{\beta,j}R^j_\alpha\right)\varepsilon^\beta_1\varepsilon^\alpha_2 \qquad [8]$$

Since this commutator is a symmetry of the action, it satisfies the Noether identity

$$S_{0,i}\left(R^i_{\alpha,j}R^j_\beta - (-1)^{\epsilon_\alpha\epsilon_\beta}R^i_{\beta,j}R^j_\alpha\right) = 0 \qquad [9]$$

which by eqn [7] implies that

$$R^i_{\alpha,j}R^j_\beta - (-1)^{\epsilon_\alpha\epsilon_\beta}R^i_{\beta,j}R^j_\alpha = R^i_\gamma T^\gamma_{\alpha\beta} + S_{0,j}E^{ji}_{\alpha\beta} \qquad [10]$$

Equations [8] and [10] lead to the following condition:

$$[\delta_1, \delta_2]\phi^i = \left(R^i_\gamma T^\gamma_{\alpha\beta} - S_{0,j}E^{ji}_{\alpha\beta}\right)\varepsilon^\beta_1\varepsilon^\alpha_2 \qquad [11]$$

The tensors $T^\gamma_{\alpha\beta}$ are called the structure constants of the gauge algebra, although they depend, in general, on the fields of the theory. When $E^{ij}_{\alpha\beta} = 0$, the gauge algebra is said to be "closed," otherwise it is "open." Equation [11] defines a Lie algebra if the algebra is closed and the $T^\gamma_{\alpha\beta}$ are independent of the fields.

The gauge tensors have the following graded symmetry properties:

$$\begin{aligned} T^\gamma_{\alpha\beta} &= -(-1)^{\epsilon_\alpha\epsilon_\beta}T^\gamma_{\beta\alpha} \\ E^{ij}_{\alpha\beta} &= -(-1)^{\epsilon_\alpha\epsilon_\beta}E^{ji}_{\alpha\beta} = -(-1)^{\epsilon_\alpha\epsilon_\beta}E^{ij}_{\beta\alpha} \end{aligned} \qquad [12]$$

The Grassmann parities are

$$\epsilon(T^\gamma_{\alpha\beta}) = \epsilon_\alpha + \epsilon_\beta + \epsilon_\gamma \pmod 2 \qquad [13]$$

and

$$\epsilon(E^{ij}_{\alpha\beta}) = \epsilon_i + \epsilon_j + \epsilon_\alpha + \epsilon_\beta \pmod 2 \qquad [14]$$

Various restrictions are imposed by the Jacobi identity

$$\sum_{\text{cyclic}(123)} [\delta_1, [\delta_2, \delta_3]] = 0 \qquad [15]$$

These restrictions are

$$\sum_{\text{cyclic}(123)} \left(R^i_\delta A^\delta_{\alpha\beta\gamma} - S_{0,j}B^{ji}_{\alpha\beta\gamma}\right)\varepsilon^\gamma\varepsilon^\beta\varepsilon^\alpha = 0 \qquad [16]$$

where

$$\begin{aligned} 3A^\delta_{\alpha\beta\gamma} \equiv & \left(T^\delta_{\alpha\beta k}R^k_\gamma - T^\delta_{\alpha\eta}T^\eta_{\beta\gamma}\right) + (-1)^{\epsilon_\alpha(\epsilon_\beta+\epsilon_\gamma)} \\ & \times\left(T^\delta_{\beta\gamma k}R^k_\gamma - T^\delta_{\beta\eta}T^\eta_{\gamma\alpha}\right) \\ & + (-1)^{\epsilon_\gamma(\epsilon_\alpha+\epsilon_\beta)}\left(T^\delta_{\gamma\alpha k}R^k_\beta - T^\delta_{\gamma\eta}T^\eta_{\alpha\beta}\right) \end{aligned}$$

and

$$\begin{aligned} 3B^{ji}_{\alpha\beta\gamma} \equiv & \Big(E^{ji}_{\alpha\beta k}R^k_\alpha - E^{ji}_{\alpha\delta}T^\delta_{\beta\gamma} - (-1)^{\epsilon_i\epsilon_\alpha} \\ & \times R^j_{\alpha,k}E^{ki}_{\beta\gamma} + (-1)^{\epsilon_j(\epsilon_i+\epsilon_\alpha)}R^i_{\alpha,k}E^{kj}_{\beta\gamma}\Big) \\ & + (-1)^{\epsilon_\alpha(\epsilon_\beta+\epsilon_\gamma)}(\alpha \to \beta \to \gamma) + (-1)^{\epsilon_\gamma(\epsilon_\alpha+\epsilon_\beta)} \\ & \times (\alpha \to \gamma \to \beta) \end{aligned}$$

As in the familiar Faddeev–Popov procedure, it is useful to introduce ghost fields $C^\alpha$ with opposite Grassmann parities to the gauge parameters $\varepsilon^\alpha$:

$$\epsilon(C^\alpha) = \epsilon_\alpha + 1 \pmod 2 \qquad [17]$$

and to replace the gauge parameters by ghost fields. One must then modify the graded symmetry properties of the gauge structure tensors according to

$$T_{\alpha_1\alpha_2\alpha_3\alpha_4\ldots} \to (-1)^{\epsilon_{\alpha_2+\alpha_4+\cdots}} T_{\alpha_1\alpha_2\alpha_3\alpha_4\ldots} \qquad [18]$$

The Noether identities then take the form

$$S_{0,i} R^i_\alpha C^\alpha = 0 \qquad [19]$$

and the structure relations [10] become

$$(2R^i_{\alpha,j} R^j_\beta - R^i_\gamma T^\gamma_{\alpha\beta} + S_{0,j} E^{ji}_{\alpha\beta}) C^\beta C^\alpha = 0 \qquad [20]$$

## Introducing the Antifields

We incorporate the ghost fields into the field set $\Phi^A = \{\phi^i, C^\alpha\}$, where $i = 1, \ldots, n$ and $\alpha = 1, \ldots, m$. Clearly $A = 1, \ldots, N$, where $N = n + m$. One then further increases the set by introducing an antifield $\Phi^*_A$ for each field $\Phi^A$. The Grassmann parity of the antifields is

$$\epsilon\left(\Phi^*_A\right) = \epsilon(\Phi^A) + 1 \ (\mathrm{mod}\, 2) \qquad [21]$$

Each field is assigned a ghost number, with

$$\begin{aligned} \mathrm{gh}[\phi^i] &= 0 \\ \mathrm{gh}[C^\alpha] &= 1 \\ \mathrm{gh}\left[\Phi^*_A\right] &= -\mathrm{gh}[\Phi^A] - 1 \end{aligned} \qquad [22]$$

In the space of fields and antifields, the antibracket is defined by

$$(X, Y) = \frac{\partial_r X}{\partial \Phi^A} \frac{\partial_l Y}{\partial \Phi^*_A} - \frac{\partial_r X}{\partial \Phi^*_A} \frac{\partial_l Y}{\partial \Phi^A} \qquad [23]$$

where $\partial_r$ denotes the right, $\partial_l$ the left derivative. The antibracket is graded antisymmetric:

$$(X, Y) = -(-1)^{(\epsilon_X+1)(\epsilon_Y+1)} (Y, X) \qquad [24]$$

It satisfies a graded Jacobi identity

$$((X, Y), Z) + (-1)^{(\epsilon_X+1)(\epsilon_Y+1)} \times ((Y, Z), X) + (-1)^{(\epsilon_Z+1)(\epsilon_X+\epsilon_Y)} ((Z, X), Y) = 0 \qquad [25]$$

It is a graded derivation

$$\begin{aligned} (X, YZ) &= (X, Y)Z + (-1)^{\epsilon_X \epsilon_Y} (X, Z) Y \\ (XY, Z) &= X(Y, Z) + (-1)^{\epsilon_X \epsilon_Y} Y(X, Z) \end{aligned} \qquad [26]$$

It has ghost number

$$\mathrm{gh}[(X, Y)] = \mathrm{gh}[X] + \mathrm{gh}[Y] + 1 \qquad [27]$$

and Grassmann parity

$$\epsilon((X, Y)) = \epsilon(X) + \epsilon(Y) + 1 \ (\mathrm{mod}\, 2) \qquad [28]$$

For bosonic fields

$$(B, B) = 2 \frac{\partial B}{\partial \Phi^A} \frac{\partial B}{\partial \Phi^*_A} \qquad [29]$$

for fermionic fields

$$(F, F) = 0 \qquad [30]$$

and for any $X$

$$((X, X), X) = 0 \qquad [31]$$

If one groups the fields and the antifields together into the set

$$z^a = \{\Phi^A, \Phi^*_A\}, \quad a = 1, \ldots, 2N \qquad [32]$$

then the antibracket is seen to define a symplectic structure on the space of fields and antifields

$$(X, Y) = \frac{\partial_r X}{\partial z^a} \omega^{ab} \frac{\partial_l Y}{\partial z^b} \qquad [33]$$

with

$$\omega^{ab} = \begin{pmatrix} 0 & \delta^A_B \\ -\delta^A_B & 0 \end{pmatrix} \qquad [34]$$

The antifields can be thought of as conjugate variables to the fields, since

$$\left(\Phi^A, \Phi^*_B\right) = \delta^A_B \qquad [35]$$

## The Classical Master Equation

Let $S[\Phi^A, \Phi^*_A]$ be a functional of the fields and antifields with the dimension of an action, vanishing ghost number and even Grassmann parity. The equation

$$(S, S) = 2 \frac{\partial S}{\partial \Phi^A} \frac{\partial S}{\partial \Phi^*_A} = 0 \qquad [36]$$

is the classical master equation. Solutions of the classical master equation with suitable boundary conditions turn out to be generating functionals for the gauge structure of the theory. $S$ is also the starting point for the quantization. One denotes by $\Sigma$ the subspace of stationary points of the action in the space of fields and antifields:

$$\Sigma = \left\{ z^a \left| \frac{\partial S}{\partial z^a} = 0 \right. \right\} \qquad [37]$$

Given a classical solution $\phi_0$ of $S_0$ one stationary point is

$$\phi^i = \phi^i_0, \quad C^a = 0, \quad \Phi^*_A = 0 \qquad [38]$$

An action which satisfies the classical master equation has its own set of invariances:

$$\frac{\partial S}{\partial z^a} R^a_b = 0 \qquad [39]$$

with

$$R^a_b = \omega^{ac} \frac{\partial_l \partial_r S}{\partial z^c \partial z^b} \qquad [40]$$

This equation implies

$$R^a_c R^a_b \big|_\Sigma = 0 \qquad [41]$$

One says that $R^a_b$ is invariant on-shell. A nilpotent $2N \times 2N$ matrix has rank $\leq N$. Let $r$ be the rank of the hessian of $S$ at the stationary point:

$$r = \operatorname{rank} \frac{\partial_l \partial_r S}{\partial z^a \partial z^b}\bigg|_\Sigma \qquad [42]$$

We then have $r \leq N$. The relevant solutions of the classical master equation are those for which $r = N$. In this case the number of independent gauge invariances of the type in eqn [39] equals the number of antifields. When at a later stage the gauge is fixed, the nonphysical antifields are eliminated.

To ensure the correct classical limit, the proper solution must contain the classical action $S_0$ in the sense that

$$S\left[\Phi^A, \Phi^*_A\right]\big|_{\Phi^*_A = 0} = S_0[\phi^i] \qquad [43]$$

The action $S[\Phi^A, \Phi^*_A]$ can be expanded in a series in the antifields, while maintaining vanishing ghost number and even Grassmann parity:

$$\begin{aligned} S[\Phi, \Phi^*] = {} & S_0 + \phi^*_i R^i_\alpha C^\alpha + C^*_a \tfrac{1}{2} T^\alpha_{\beta\gamma} (-1)^{\epsilon_\beta} C^\gamma C^\beta \\ & + \phi^*_i \phi^*_j (-1)^{\epsilon_i} \tfrac{1}{4} E^{ji}_{\alpha\beta} (-1)^{\epsilon_\alpha} C^\beta C^\alpha + \cdots \end{aligned} \qquad [44]$$

When this is inserted into the classical master equation, one finds that this equation implies the gauge structure of the classical theory.

## Gauge Fixing and Quantization

Equation [39] shows that the action $S$ still possesses gauge invariances, and hence is not yet suitable for quantization via the path integral approach: a gauge-fixing procedure is necessary. In the Batalin–Vilkovisky approach the gauge is fixed, and the antifields eliminated, by use of a gauge-fixing fermion $\Psi$ which has Grassmann parity $\epsilon(\Psi) = 1$ and $\text{gh}[\Psi] = -1$. It is a functional of the fields $\Phi^A$ only; its relation to the antifields is

$$\Phi^*_A = \frac{\partial \Psi}{\partial \Phi^A} \qquad [45]$$

We define a surface in functional space

$$\Sigma_\Psi = \left\{ \left(\Psi^A, \Psi^*_A\right) | \Psi^*_A = \frac{\partial \Psi}{\partial \Phi^A} \right\} \qquad [46]$$

so that for any functional $X[\Phi, \Phi^*]$

$$X|_{\Sigma_\Psi} = X\left[\Psi, \frac{\partial \Psi}{\partial \Phi}\right] \qquad [47]$$

To construct a gauge-fixing fermion $\Psi$ of ghost number –1, one must again introduce additional fields. The simplest choice utilizes a trivial pair $\bar{C}_\alpha, \bar{\pi}_\alpha$ with

$$\begin{aligned} \epsilon(\bar{C}_\alpha) &= \epsilon_\alpha + \mathbf{1}, & \epsilon(\bar{\pi}_\alpha) &= \epsilon_\alpha \\ \text{gh}[\bar{C}_\alpha] &= -1, & \text{gh}[\bar{\pi}_\alpha] &= 0 \end{aligned} \qquad [48]$$

The fields $\bar{C}_\alpha$ are the Faddeev–Popov antighosts. Along with these fields we include the corresponding antifields $\bar{C}^{*\alpha}, \bar{\pi}^{*\alpha}$. Adding the term $\bar{\pi}_\alpha \bar{C}^{*\alpha}$ to the action $S$ does not spoil its properties as a proper solution to the classical master equation, and one gets the nonminimal action

$$S^{\text{non}} = S + \bar{\pi}_\alpha \bar{C}^{*\alpha} \qquad [49]$$

The simplest possibility for $\Psi$ is

$$\Psi = \bar{C}_\alpha \chi^\alpha(\phi) \qquad [50]$$

where $\chi^\alpha$ are the gauge-fixing conditions for the fields $\psi$. The gauge-fixed action is denoted by

$$S_\Psi = S^{\text{non}}|_{\Sigma_\psi} \qquad [51]$$

Quantization is performed using the path integral to calculate a correlation function $X$, with the constraint [45] implemented by a $\delta$-function:

$$\begin{aligned} I_\Psi(X) = {} & \int D\Phi D\Phi^* \delta\left(\Phi^*_A - \frac{\partial \Psi}{\partial \Phi^A}\right) \\ & \times \exp\left(\frac{\mathrm{i}}{\hbar} W[\Phi, \Phi^*]\right) X[\Phi, \Phi^*] \end{aligned} \qquad [52]$$

Here $W$ is the quantum action, which reduces to $S$ in the limit $\hbar \to 0$. An admissible $\Psi$ leads to well-defined propagators when the path integral is expressed as a perturbation series expansion.

The results of a calculation should be independent of the gauge fixing. Consider the integrand in eqn [52],

$$I[\Phi, \Phi^*] = \exp\left(\frac{\mathrm{i}}{\hbar} W[\Phi, \Phi^*]\right) X[\Phi, \Phi^*] \qquad [53]$$

Under an infinitesimal change in $\Psi$

$$I_{\Psi + \delta\Psi}(X) - I_\Psi(X) \approx \int D\Phi \, \Delta I \delta\Psi \qquad [54]$$

where the Laplacian $\Delta$ is

$$\Delta = (-1)^{\epsilon_A+1} \frac{\partial}{\partial \Phi^A} \frac{\partial}{\partial \Phi^*_A} \quad [55]$$

Obviously, the integral $I_\Psi(X)$ is independent of $\Psi$ if $\Delta I = 0$. For $X = 1$ one gets the requirement

$$\Delta \exp\left(\frac{i}{\hbar} W\right) = \exp\left(\frac{i}{\hbar} W\right) \times \left(\frac{i}{\hbar}\Delta W - \frac{1}{2\hbar^2}(W, W)\right) = 0 \quad [56]$$

The formula

$$\tfrac{1}{2}(W, W) = i\hbar \Delta W \quad [57]$$

is the quantum master equation. A gauge-invariant correlation function satisfies

$$(X, W) = i\hbar \Delta X \quad [58]$$

The terms of higher order in $\hbar$ by which the quantum action $W$ may differ from the solution of the classical master equation $S$ correspond to the counter-terms of the renormalizable gauge theory if

$$\Delta S = 0 \quad [59]$$

One must, of course, use a regularization scheme which respects the symmetries of the theory. For $W = S + O(\hbar)$ the quantum master equation [57] reduces in this case to the classical master equation

$$(S, S) = 0 \quad [60]$$

Hence, up to possible counter-terms, one may simply choose $W = S$.

To implement the gauge fixing, one uses for the action $W = S^{\text{non}}$. For the path integral $Z = I_\Psi(X = 1)$, the integration over the antifields in eqn [52] is performed by using the $\delta$-function. The result is

$$Z = \int D\Phi \exp\left(\frac{i}{\hbar} S_\Psi\right) \quad [61]$$

## Geometrical Interpretation of Topological Field Theories

The Batalin–Vilkovisky formalism for topological field theories has been given a geometrical interpretation by AKSZ (1997).

A supermanifold equipped with an odd vector field satisfying $Q^2 = 0$ is called a $Q$-manifold. A $Q$-manifold provided with an odd symplectic structure $\omega$ (P-structure) is called a QP-manifold if the odd symplectic structure is $Q$-invariant, that is, $L_Q \omega = 0$. Every solution to the classical master equation determines a QP-structure on $M$ and vice versa. The geometric object corresponding to a classical mechanical system in the Batalin–Vilkovisky formalism is a QP-manifold.

The nondegenerate closed 2-form $\omega$ is written as

$$\omega = dz^a \zeta_{ab} dz^b \quad [62]$$

where $z^a$ are local coordinates in the supermanifold $M$. For functions on $M$, an (odd) Poisson bracket is defined as in eqn [33], where $\omega^{ab}$ stands for the inverse matrix of $\omega_{ab}$. An even function $S$ on $M$ satisfies the classical master equation if $(S, S) = 0$. The correspondence between vector fields and functions on $M$ is given by $K_F G = (G, F)$, where $K_F$ is the vector field, $F$ the given function, and $G$ an arbitrary function. The function $F$ is called the Hamiltonian of the vector field $K_F$.

Geometrically, equivalent QP-manifolds describe the same physics. In particular, one can consider an even Hamiltonian vector field $K_F$ corresponding to an odd function $F$. This vector field determines an infinitesimal transformation preserving P-structure. It transforms a solution $S$ to the classical master equation into the physically equivalent solution $S + \epsilon(S, F)$, where $\epsilon$ is an infinitesimally small parameter.

A submanifold $L$ of a P-manifold $M$ is called a Lagrangian submanifold if the restriction of the form $\omega$ to $L$ vanishes. In the particular case when $M = \Pi T^*N$ (the cotangent bundle to $N$ with reversed parity of fibres) with standard P-structure, one can construct many examples of Lagrangian submanifolds in the following way. Fix an odd function $\Psi$ on $N$, the gauge fermion. The submanifold $L_\Psi \in M$ determined by the equation

$$\xi^a = \frac{\partial \Psi}{\partial x^a} \quad [63]$$

where $\{x^a, \xi_a\}$ are coordinates corresponding to the identification of $M$, will be a Lagrangian submanifold of $M$.

The P-manifold M in the neighborhood of $L$ can be identified with $\Pi T^*L$. In other words, one can find such a neighborhood $U$ of $L$ in $M$ and a neighborhood $V$ of $L$ in $\Pi T^*L$ that there exists an isomorphism of P-manifolds $U$ and $V$ leaving $L$ intact. Using this isomorphism a function $\Psi$ defined on a Lagrangian submanifold $L \subset M$ determines another Lagrangian submanifold $L_\Psi \subset M$.

Consider a solution $S$ to the classical master equation on $M$. In the Batalin–Vilkovisky formalism we have to restrict $S$ to a Lagrangian submanifold $L \in M$, then the quantization of $S$ can be performed by integration of $\exp(iS/\hbar)$ over $L$. One may construct an odd vector field $Q$ on $L$ in such a

way that the functional $S$ restricted to $L$ is $Q$-invariant. This invariance is BRST invariance.

AKSZ apply these geometric constructions to obtain in a natural way the action functionals of two-dimensional sigma-models (Witten 1998) and to show that the Chern–Simons theory (Axelrod and Singer 1991) in Batalin–Vilkovisky formalism arises as a sigma-model with target space $\Pi\mathcal{G}$, where $\mathcal{G}$ stands for a Lie algebra and $\Pi$ denotes parity inversion.

## The Poisson-Sigma Model

The quantization of the Poisson-sigma model was performed by Hirshfeld and Schwarzweller (2000) and by Cattaneo and Felder (2001). The Poisson-sigma model is the simplest topological field theory in two dimensions. It is a field theory on a two-dimensional world sheet without boundary (Schaller and Strobl 1994). It involves a set of bosonic scalar fields, which can be seen as a set of maps $X^i : M \to N$, where $N$ is a Poisson manifold. In addition, one has a 1-form $A$ on the world sheet $M$ which takes values in $T^*(N)$, for $x$ coordinates on $M$ we have $A = A_{\mu i}\mathrm{d}x^i \wedge \mathrm{d}X^i$. Its action is

$$S_0[X,A] = \int_M \mu\big(\epsilon^{\mu\nu}(A_{\mu i}\partial_\nu X^i + P^{ij}(X)A_{\mu i}A_{\nu j}\big) \quad [64]$$

where $\epsilon^{\mu\nu}$ is the antisymmetric tensor and $\mu$ is the volume form on $M$. The gauge transformations of the model are

$$\delta X^i = P^{ij}(X)\varepsilon_j, \qquad \delta A_{\mu i} = D^j_{\mu i}\varepsilon_j \quad [65]$$

where $D^j_{\mu i} = \partial_\mu \delta^j_i + P^{kj}{}_{,i}A_{\mu k}$. The equations of motion are

$$\epsilon^{\mu\nu} D^j_{\mu i} A_{\nu j} = 0 \quad [66]$$

and

$$\epsilon^{\mu\nu}(\partial_\nu X^i + P^{ij}A_{\nu j}) = \epsilon^{\mu\nu}D_\nu X^i = 0 \quad [67]$$

The gauge algebra is given by

$$\begin{aligned}
[\delta(\varepsilon_1), \delta(\varepsilon_2)]X^i &= P^{ji}(P^{mn}{}_{,j}\varepsilon_{1n}\varepsilon_{2m}) \\
[\delta(\varepsilon_1), \delta(\varepsilon_2)]A_{\mu i} &= D^j_{\mu i}(P^{mn}{}_{,j}\varepsilon_{1n}\varepsilon_{2m}) \\
&\quad - (\epsilon^{\nu\rho}D_\rho X^j)\epsilon_{\nu\mu}P^{mn}{}_{,ji}\varepsilon_{1n}\varepsilon_{2m}
\end{aligned} \quad [68]$$

In our general notation the generators of the gauge transformations $R$ are here $P^{ij}$ and $D^j_{\mu i}$. The gauge tensors $T$ and $E$ are $P^{ij}{}_{,k}$ and $\epsilon_{\nu\mu}P^{mn}{}_{,ji}$. The higher-order gauge tensors $A$ and $B$ vanish.

The ghost fields are again denoted by $C^i$. The Noether identities are then

$$\int_M \mu\Big(\epsilon^{\mu\nu}D^j_{\mu i}A_{\nu j}P^{ki} + (\epsilon^{\mu\nu}D_\nu X^i)D^k_{\mu i}\Big)C_k = 0 \quad [69]$$

Considering the commutator of two gauge transformations leads to (see eqns [8]–[11])

$$\begin{aligned}
&\int_M \mu\big(2P^{mi}{}_{,j}P^{nj} - P^{ji}P^{mn}{}_{,j}\big)C_mC_n = 0 \\
&\int_M \mu\Big(2(P^{jk}{}_{,i}D^l_{\mu j} + P^{mk}{}_{,ij}A_{\mu m}P^{jl}) \\
&\quad - D^m_{\mu i}P^{kl}{}_{,m} + (\epsilon^{\rho\nu}D_\rho X^i)\epsilon_{\mu\nu}P^{kl}{}_{,ji}\Big)C_lC_k = 0
\end{aligned} \quad [70]$$

The Jacobi identity is

$$P^{ij}{}_{,m}P^{mk}C_iC_jC_k = 0 \quad [71]$$

The fields and antifields of the model are

$$\Phi^A = \{A^{\mu i}, X^i, C_i\} \quad \text{and} \quad \Phi^*_A = \{A^{\mu i *}, X^*_i, C^{i*}\} \quad [72]$$

The extended action is

$$\begin{aligned}
\mathcal{S} = \int_M \mu\Big(&\epsilon^{\mu\nu}(A_{\mu i}\partial_\nu X^i + P^{ij}(X)A_{\mu i}A_{\nu j}) \\
&+ A^{\mu i*}D^j_{\mu i}C_j + X^*_i P^{ji}(X)C_j + \frac{1}{2}C^{i*}P^{jk}{}_{,i}(X)C_jC_k \\
&+ \frac{1}{4}A^{\mu i*}A^{\nu j*}\epsilon_{\mu\nu}P^{kl}{}_{,ij}(X)C_kC_l\Big)
\end{aligned} \quad [73]$$

The gauge-fixing conditions are taken to be of the form $\chi_i(A,X)$, so that the gauge fermion [50] becomes $\Psi = \bar{C}^i\chi_i(A,X)$. The antifields are then fixed to be

$$\begin{aligned}
A^*_{\mu i} &= \bar{C}_j \frac{\partial \chi_j(A,X)}{\partial A_{\mu i}} \\
X^*_i &= \bar{C}_j \frac{\partial \chi_j(A,X)}{\partial X^i} \\
C^*_i &= 0 \\
\bar{C}^*_i &= \chi_i(A,X)
\end{aligned} \quad [74]$$

The gauge-fixed action is

$$\begin{aligned}
S_\Psi = \int_M \mu\Big(&\epsilon^{\mu\nu}(A_{\mu i}\partial_\nu X^i + P^{ij}(X)A_{\mu i}A_{\nu j}) \\
&+ \bar{C}^k \frac{\partial \chi_k(A,X)}{\partial A_{\mu i}}D^j_{\mu i}C_j + \bar{C}^k\frac{\partial\chi_k(A,X)}{\partial X^i}P^{ij}C_j \\
&+ \frac{1}{4}\bar{C}^m\frac{\partial\chi_m(A,X)}{\partial A_{\mu i}}\bar{C}^n\frac{\partial\chi_n(A,X)}{\partial A_{\nu j}}\epsilon_{\mu\nu}P^{kl}{}_{,ij}(X) \\
&\times C_kC_l + \bar{\pi}^i\chi_i(A,X)\Big)
\end{aligned} \quad [75]$$

Now consider different gauge conditions:

1. First, the Landau gauge for the gauge potential $\chi_i = \partial^\mu A_{\mu i}$, so that the gauge fermion becomes $\Psi = \bar{C}^i\partial^\mu A_{\mu i}$. The antifields are fixed to be

$$\begin{aligned}
A^{*\mu i} &= \partial^\mu \bar{C}^i \\
X^*_i &= C^{*i} = 0 \\
\bar{C}^*_i &= \partial^\mu A_{\mu i}
\end{aligned} \quad [76]$$

for this gauge choice the gauge-fixed action is

$$S_\Psi = \int_M \mu\Big(\epsilon^{\mu\nu}(A_{\mu i}\partial_\nu X^i + P^{ij}(X)A_{\mu i}A_{\nu j}) + \bar{C}^i\partial^\mu D^j_{\mu i}C_j + \frac{1}{4}(\partial^\mu\bar{C}^i)(\partial^\nu\bar{C}^j)\epsilon_{\mu\nu}P^{kl}{}_{,ij}(X) \times C_k C_l - \bar{\pi}^i(\partial^\mu A_{\mu i})\Big) \quad [77]$$

Translating this action into the notation of Cattaneo and Felder, one sees that it is exactly the expression they use to derive the perturbation series.

2. Now consider the temporal gauge $\chi_i = A_{0i}$. The gauge fermion is given by $\Psi = \bar{C}^i A_{0i}$. The antifields are fixed to

$$A^{*0i} = \bar{C}^i \quad A^{*1i} = 0 \quad X^*_i = C^{*i} = 0 \quad \bar{C}^*_i = A_{0i} \quad [78]$$

The gauge-fixed action is

$$S_\Psi = \int_M \mu\Big(\epsilon^{\mu\nu}(A_{\mu i}\partial_\nu X^i + P^{ij}(X)A_{\mu i}A_{\nu j}) + \bar{C}^i D^j_{0i}C_j - \bar{\pi}^i(A_{0i})\Big) \quad [79]$$

3. Finally consider the Schwinger–Fock gauge $\chi_i = x^\mu A_{\mu i}$. Then the antifields are fixed to be

$$A^{*\mu i} = x^\mu\bar{C}^i \quad X^*_i = C^{*i} = 0 \quad \bar{C}^*_i = x^\mu A_{\mu i} \quad [80]$$

for this gauge choice the gauge-fixed action is

$$S_\Psi = \int_M \mu\Big(\epsilon^{\mu\nu}(A_{\mu i}\partial_\nu X^i + P^{ij}(X)A_{\mu i}A_{\nu j}) + \bar{C}^i x^\mu D^j_{\mu i}C_j - \bar{\pi}^i(\partial^\mu A_{\mu i})\Big) \quad [81]$$

Notice that in the noncovariant gauges 2 and 3 the action simplifies, in that the term which arose because of the nonclosed nature of the gauge algebra vanishes.

# Bethe Ansatz

**M T Batchelor**, Australian National University, Canberra, ACT, Australia

## Introduction

The Bethe ansatz is a particular form of wave function introduced in the diagonalization of the Heisenberg spin chain. It underpins the majority of exactly solved models in statistical mechanics and quantum field theory. At the heart of the Bethe ansatz is the way in which multibody interactions factor into two-body interactions. The Bethe ansatz is thus intimately entwined with the theory of integrability.

The way in which the Bethe ansatz works is best understood by working through an explicit hands-on example. The canonical example is the isotropic antiferromagnetic Heisenberg Hamiltonian

$$H = \sum_{i=1}^{L-1} h_{i,i+1} + h_{L,1}, \quad h_{ij} = \tfrac{1}{2}(\boldsymbol{\sigma}_i \cdot \boldsymbol{\sigma}_j + 1) \quad [1]$$

where $\boldsymbol{\sigma} = (\sigma^x, \sigma^y, \sigma^z)$ are Pauli matrices and $L$ is the length of the chain. Periodic boundary conditions are imposed. However, open boundary conditions may also be treated, along with the addition of magnetic bulk and boundary fields. The $z$-components of each of the spins are either up or down. Since the $z$-component of the total spin commutes with the Hamiltonian, the total number $n$ of up spins serves as a good quantum number. A state of the system can therefore be conveniently described in terms of the coordinates of all the up spins. Denote these coordinates by $x_i$, with $1 \leq x_i \leq L$. The quantum number $n$ ensures that the Hamiltonian decomposes into $L+1$ sectors, each of size $L$ choose $n$. The antiferromagnetic ground state occurs in the largest sector.

The normalization of the Hamiltonian [1] is such that its action is that of the permutation operator:

$$\begin{aligned} h|--\rangle &= |--\rangle, \qquad h|++\rangle = |++\rangle \\ h|+-\rangle &= |-+\rangle, \qquad h|-+\rangle = |+-\rangle \end{aligned} \qquad [2]$$

## Diagonalization of Sectors

One can address the diagonalization of the sectors for various cases.

### Case 1: $n=0$

Consider the case with all spins down. The eigenstate is $\Psi = |- \cdots -\rangle$, with $H\Psi = L\Psi$ and, thus, $E = L$ is the trivial solution.

### Case 2: $n=1$

There are $L$ states, with

$$\Psi = \sum_{x=1}^{L} a(x)|\psi(x)\rangle \qquad [3]$$

where $|\psi(x)\rangle$ is the state with an up spin at site $x$. The aim is to find the amplitudes $a(x)$. It is clear that

$$\begin{aligned} H|\psi(x)\rangle = (L-2)|\psi(x)\rangle + |\psi(x-1)\rangle \\ + |\psi(x+1)\rangle \end{aligned} \qquad [4]$$

in the bulk (away from either boundary). Insertion of [3] into $H\Psi = E\Psi$ gives

$$Ea(x) = (L-2)a(x) + a(x-1) + a(x+1) \qquad [5]$$

Substitution of spin waves $a(x) = e^{ikx}$ gives

$$E = L - 2 + 2\cos k \qquad [6]$$

The boundary conditions are such that $a(0) = a(L)$ and $a(L+1) = a(1)$; either gives $e^{ikL} = 1$, from which the $L$ values of $k$ follow.

### Case 3: $n=2$

Here the wave function can be written in terms of the two flipped spins as

$$\Psi = \sum_{x<y} a(x,y)|\psi(x,y)\rangle \qquad [7]$$

It is to be emphasized that one is working in the region with $x < y$. There are two cases to consider: (1) $y > x+1$ and (2) $y = x+1$. Consider the interactions in the bulk. For (1) the action of the Hamiltonian implies

$$\begin{aligned} Ea(x,y) = (L-4)a(x,y) + a(x-1,y) + a(x+1,y) \\ + a(x,y-1) + a(x,y+1) \end{aligned} \qquad [8]$$

and for (2)

$$\begin{aligned} Ea(x,x+1) = (L-2)a(x,x+1) \\ + a(x-1,x+1) + a(x,x+2) \end{aligned} \qquad [9]$$

The compatibility of these two equations requires that

$$2a(x,x+1) = a(x,x) + a(x+1,x+1) \qquad [10]$$

which is known as the "collision" or "meeting" condition.

Some adjustments need to be made for spins which get flipped at the boundaries. Looking at [8] and [9] with $x = 1$ and $x = L$, it is evident that one can take

$$a(y, x+L) = a(x,y) \qquad [11]$$

to restore the original ordering. The terms which arise involve up spins at sites 0 and $L+1$. This illustrates the periodic boundary condition.

We now assume (the Bethe ansatz) that

$$a(x,y) = A_{12}e^{ik_1x}e^{ik_2y} + A_{21}e^{ik_2x}e^{ik_1y} \qquad [12]$$

Substitution of the ansatz [12] into [8] gives

$$E = L - 4 + 2\cos k_1 + 2\cos k_2 \qquad [13]$$

Substitution of [12] into [10] gives

$$\frac{A_{12}}{A_{21}} = -\frac{1 - 2\,e^{ik_1} + e^{i(k_1+k_2)}}{1 - 2\,e^{ik_2} + e^{i(k_1+k_2)}} \qquad [14]$$

The three relations [11], [12], and [14] give the Bethe equations

$$e^{ik_1L} = \frac{A_{12}}{A_{21}} \quad \text{and} \quad e^{ik_2L} = \frac{A_{21}}{A_{12}} \qquad [15]$$

which are to be solved for $k_1$ and $k_2$. Note that $e^{i(k_1+k_2)L} = 1$.

**Case 4:** $n = 3$

The full power of the Bethe ansatz method becomes evident for three particles. Here

$$\Psi = \sum_{x<y<z} a(x,y,z)|\psi(x,y,z)\rangle \qquad [16]$$

There are several cases to consider:

1. $y > x+1$ and $z > y+1$, where

$$Ea(x,y,z) = (L-6)a(x,y,z) + a(x \pm 1, y, z) + a(x, y \pm 1, z) + a(x, y, z \pm 1) \qquad [17]$$

By $a(x \pm 1, y, z)$, we mean $a(x+1,y,z) + a(x-1,y,z)$, etc.

2. $y = x+1$ and $z > y+1$, with

$$Ea(x,x+1,z) = (L-4)a(x,x+1,z) + a(x-1,x+1,z) + a(x,x+2,z) + a(x,x+1,z \pm 1) \qquad [18]$$

3. $y > x+1$ and $z = y+1$, where

$$Ea(x,y,y+1) = (L-4)a(x,y,y+1) + a(x \pm 1, y, y+1) + a(x,y-1,y+1) + a(x,y,y+2) \qquad [19]$$

4. $y = x+1$ and $z = y+1$, for which

$$Ea(x,x+1,x+2) = (L-2)a(x-1,x+1,x+2) + a(x,x+1,x+3) \qquad [20]$$

Again, we must ensure that these equations are compatible. This involves comparison of the last three equations with [17]. The three equations to be satisfied are

$$2a(x,x+1,z) = a(x,x,z) + a(x+1,x+1,z) \qquad [21]$$

$$2a(x,y,y+1) = a(x,y,y) + a(x,y+1,y+1) \qquad [22]$$

$$4a(x,x+1,x+2) = a(x,x,x+2) + a(x,x+1,x+1) + a(x,x+2,x+2) + a(x+1,x+1,x+2) \qquad [23]$$

But note that setting $z = x+2$ in [21] and $y = x+1$ in [22] leads to [23] being automatically satisfied. We are thus left with only two equations [21] and [22]. Note the similarity between these two equations and the meeting condition [10] for the $n = 2$ case.

In this case the Bethe ansatz is

$$a(x,y,z) = A_{123} z_1^x z_2^y z_3^z + A_{132} z_1^x z_3^y z_2^z + A_{213} z_2^x z_1^y z_3^z + A_{231} z_2^x z_3^y z_1^z + A_{321} z_3^x z_2^y z_1^z + A_{312} z_3^x z_1^y z_2^z \qquad [24]$$

in which $z_j = e^{ik_j}$. This is a sum over the 3! permutations of the integers 1, 2, 3. Inserting this ansatz into [17] gives

$$E = L - 6 + 2(\cos k_1 + \cos k_2 + \cos k_3) \qquad [25]$$

To determine the $k_j$, it is convenient to define

$$s_{ij} = 1 - 2z_j + z_i z_j \qquad [26]$$

Substitution of [24] into the meeting conditions [21] and [22] then gives

$$s_{12}A_{123} + s_{21}A_{213} + s_{13}A_{132} + s_{31}A_{312} + s_{23}A_{231} + s_{32}A_{321} = 0 \qquad [27]$$

$$s_{23}A_{123} + s_{32}A_{132} + s_{13}A_{213} + s_{31}A_{231} + s_{21}A_{321} + s_{12}A_{312} = 0 \qquad [28]$$

These equations are assumed to be satisfied in permutation pairs, that is,

$$s_{12}A_{123} + s_{21}A_{213} = 0$$
$$s_{23}A_{123} + s_{32}A_{132} = 0, \text{ etc.} \qquad [29]$$

Up to an overall constant, the relations [27] and [28] are satisfied by

$$A_{123} = s_{21}s_{31}s_{32}, \quad A_{132} = -s_{31}s_{21}s_{23}$$
$$A_{312} = s_{13}s_{23}s_{21}, \quad A_{321} = -s_{23}s_{13}s_{12} \qquad [30]$$
$$A_{231} = s_{32}s_{12}s_{13}, \quad A_{213} = -s_{12}s_{32}s_{31}$$

The boundary condition, $a(y,z,x+L) = a(x,y,z)$, gives

$$(z_1^L A_{321} - A_{132}) z_1^x z_3^y z_2^x + (z_2^L A_{312} - A_{231}) z_2^x z_3^y z_1^x + (z_1^L A_{231} - A_{123}) z_1^x z_2^y z_3^x + (z_3^L A_{213} - A_{321}) z_3^x z_2^y z_1^x + (z_2^L A_{132} - A_{213}) z_2^x z_1^y z_3^x + (z_3^L A_{123} - A_{312}) z_3^x z_1^y z_2^x = 0 \qquad [31]$$

This leads to the equations

$$z_1^L = \frac{A_{123}}{A_{231}} = \frac{A_{132}}{A_{321}} = \frac{s_{21}s_{31}}{s_{12}s_{13}}$$
$$z_2^L = \frac{A_{213}}{A_{132}} = \frac{A_{231}}{A_{312}} = \frac{s_{12}s_{32}}{s_{21}s_{23}} \qquad [32]$$
$$z_3^L = \frac{A_{321}}{A_{213}} = \frac{A_{312}}{A_{123}} = \frac{s_{13}s_{23}}{s_{31}s_{32}}$$

which can be solved for the Bethe roots $k_j$.

### General $n$

The general Bethe ansatz is

$$a(x_1, \ldots, x_n) = \sum_P A_{p_1,\ldots,p_n} z_{p_1}^{x_1} \ldots z_{p_n}^{x_n} \qquad [33]$$

where the sum is over all $n!$ permutations $P = \{p_1, \ldots, p_n\}$ of the integers $1, \ldots, n$. The boundary condition is

$$a(x_2, x_3, \ldots, x_n, x_1 + L) = a(x_1, x_2, \ldots, x_n) \qquad [34]$$

leading to the Bethe equations

$$z_{p_1}^L = \frac{A_{p_1,\ldots,p_n}}{A_{p_2,\ldots,p_n,p_1}} \qquad [35]$$

for all permutations, with

$$A_{p_1,\ldots,p_n} = \epsilon_P \prod_{1 \le i < j \le n} s_{p_j,p_i} \qquad [36]$$

where $\epsilon_P$ is the signature of the permutation. Finally,

$$z_{p_1}^L = (-)^{n-1} \prod_{\ell=2}^{n} \frac{s_{p_\ell,p_1}}{s_{p_1,p_\ell}} \quad \text{or} \quad z_j^L = (-)^{n-1} \prod_{\substack{\ell=1 \\ \neq j}}^{n} \frac{s_{\ell,j}}{s_{j,\ell}} \qquad [37]$$

for $j = 1, \ldots, n$. The eigenvalues are given by

$$E = L + \sum_{j=1}^{n} (2 \cos k_j - 2) \qquad [38]$$

Another form of the Bethe equations is obtained by defining

$$e^{ik_j} = \frac{u_j - (1/2)i}{u_j + (1/2)i} \qquad [39]$$

which gives

$$E = L - \sum_{j=1}^{n} \frac{1}{u_j^2 + 1/4} \qquad [40]$$

with $u_j$ satisfying

$$\left( \frac{u_j - (1/2)i}{u_j + (1/2)i} \right)^L = - \prod_{\ell=1}^{n} \frac{u_j - u_\ell - i}{u_j - u_\ell + i} \qquad [41]$$

for $j = 1, \ldots, n$.

All eigenvalues of the Heisenberg spin chain may be obtained in terms of the Bethe ansatz solution. For example, the distribution of roots $u_j$ for the ground state are real and symmetric about the origin. Excitations may involve complex roots. Although obtained exactly in terms of the Bethe roots, the Bethe ansatz wave function is cumbersome.

We have thus seen how the Bethe ansatz works for the Heisenberg spin chain. The underlying mechanism is the way in which the collision or meeting conditions can be handled in terms of two-body interactions. To see this more clearly, the six permutation pair equations [29] can be written in the general form $A_{abc} = Y_{ab} A_{bac}$ and $A_{abc} = Y_{bc} A_{acb}$, where $Y_{ab} = -s_{ba}/s_{ab}$. Now there are two possible paths to get from $A_{abc}$ to $A_{cba}$, namely

$$\begin{aligned} A_{cba} &= Y_{ab} Y_{ac} Y_{bc} A_{abc} \\ A_{cba} &= Y_{bc} Y_{ac} Y_{ab} A_{abc} \end{aligned} \qquad [42]$$

Both paths must be equivalent, with

$$Y_{ab} Y_{ba} = 1 \quad \text{and} \quad Y_{ab} Y_{ac} Y_{bc} = Y_{bc} Y_{ac} Y_{ab} \qquad [43]$$

The latter is a condition of nondiffraction or equivalently a manifestation of the Yang–Baxter equation.

Historically, the next model to be exactly solved in terms of the Bethe ansatz was the one-dimensional model of $N$ interacting bosons on a line of length $L$ defined by the Hamiltonian

$$H = - \sum_{i=1}^{N} \frac{\partial^2}{\partial x_i^2} + 2c \sum_{1 \le i < j \le N} \delta(x_i - x_j) \qquad [44]$$

where $c$ is a measure of the interaction strength. For this model the Bethe ansatz wave function is of the same form as [33] with the two-body interaction term given by

$$s_{ab} = k_a - k_b + ic \qquad [45]$$

The Bethe equations are given by

$$\exp(ik_j L) = - \prod_{\ell=1}^{N} \frac{k_j - k_\ell + ic}{k_j - k_\ell - ic} \quad \text{for} \quad j = 1, \ldots, N \qquad [46]$$

The energy eigenvalue is

$$E = \sum_{j=1}^{N} k_j^2 \qquad [47]$$

For repulsive ($c > 0$) interactions, one can prove that all Bethe roots are real.

The Bethe ansatz has been applied to a number of other and more general models, both for discrete spins and in the continuum. These include the anisotropic Heisenberg ($XXZ$) spin chain, for which the above working readily generalizes to trigonometric functions. The underlying ansatz [33] remains the same. One key generalization is the nested Bethe ansatz, which arises, for example, in the solution of the general $N$-state permutator model, the Hubbard model, and the Gaudin–Yang model of interacting fermions. For such models the nested Bethe ansatz involves an additional level of work to determine the amplitudes appearing in the

wave function [33] due to higher symmetries. This results in Bethe equations involving different types or colors of roots.

The exactly solved one-dimensional quantum spin chains may also be obtained from their two-dimensional classical counterparts – the vertex models. For example, the six-vertex model shares the same Bethe ansatz wave function and Bethe equations as the *XXZ* spin chain. The more general permutator Hamiltonians are related to multistate vertex models. One may also consider other spin-*S* models.

The discussion in this article has centered on what is known as the coordinate Bethe ansatz. Another formulation is the algebraic Bethe ansatz, which was developed for the systematic treatment of the higher-spin models. In this formulation, operators create the Bethe states by acting on a vacuum. The algebraic Bethe ansatz goes hand-in-hand with the quantum inverse-scattering method. In all of the exactly solved Bethe ansatz models, it is possible to derive quantities like the ground-state energy per site via the root density method, which assumes that the Bethe roots form a uniform distribution in the infinite-size limit. The thermodynamics of the Bethe ansatz solvable models may also be calculated in a systematic fashion.

Despite Bethe's early optimism, the Bethe ansatz has not been extended to higher-dimensional systems.

# BF Theories

**M Blau**, Université de Neuchâtel, Neuchâtel, Switzerland

## Introduction

BF theories are a class of gauge theories with a nontrivial metric-independent classical action. As such these theories are candidate topological field theories akin to the Chern–Simons theory in three dimensions, but in contrast to the Chern–Simons theory these exist and are well defined in arbitrary dimensions.

The name "BF theories" derives from the fact that, roughly (see [1] below and the subsequent discussion for a more precise description), the action of the BF theory takes the form $\int B \wedge F_A$ with $F_A$ the curvature of a connection $A$ and $B$ a Lagrange multiplier. The classical equations of motion imply that $A$ is flat, $F_A = 0$, and thus BF theories are topological gauge theories of flat connections.

Abelian BF theories and their relation to topological invariants (the Ray–Singer torsion) were originally discussed by Schwarz (1978, 1979). In the context of the topological field theory, nonabelian BF theories were introduced in Horowitz (1989) and Blau and Thompson (1989, 1991).

Since then, BF theories have attracted a lot of attention as simple toy-models of (topological) gauge theories, and also because of their relationships with the Chern–Simons theory, the Yang–Mills theory, and gauge-theory formulations of gravity, as well as because of the rather rich and intricate structure of their quantum theories.

The purpose of this article is to provide an overview of these various features of BF theories. The standard reference for the basic classical and quantum properties of BF theories is Birmingham *et al.* (1991).

## Basic Classical Properties of BF Theories

### Nonabelian BF Theories

**The classical action and equations of motion** Typically, the classical action of the BF theory takes the form

$$S_{\mathrm{BF}}(A,B) = \int_M \mathrm{tr}_G\, B \wedge F_A \qquad [1]$$

where $F_A$ is the curvature of a connection $A$ on a principal $G$-bundle $P \to M$ over an $n$-dimensional manifold $M$, $B$ is an ad-equivariant horizontal $(n-2)$-form on $P$, and $\mathrm{tr}_G$ (a trace) denotes an ad-invariant nondegenerate scalar product on the Lie algebra $\mathfrak{g}$ of the Lie group $G$. Generalizations of this are possible, in particular, for $G$ abelian or for $n=3$ and are mentioned below.

We consider $F_A$ and $B$ as forms on $M$ taking values in the bundle of Lie algebras $\mathrm{ad}\, P = P \times_{\mathrm{ad}} \mathfrak{g}$ and refer to such objects as elements of $\Omega^*(M,\mathfrak{g})$. Then $\mathrm{tr}\, B \wedge F_A \in \Omega^n(M,\mathbb{R})$ is a volume form on $M$. In order to simplify the exposition, in the following we will mostly assume that $G$ is compact semisimple and that $M$ is compact without a boundary (even though relaxing any one of these conditions is possible and also of interest in its own right).

Varying the action [1] with respect to $A$ and $B$, one obtains the classical equations of motion

$$F_A = 0, \qquad d_A B = 0 \qquad [2]$$

where

$$d_A B = \mathrm{d}B + [A,B] \qquad [3]$$

is the covariant exterior derivative. In particular, therefore, the equations of motion imply that the connection $A$ is flat.

**Gauge invariance** For any $n$, the action [1] is invariant under $G$ gauge transformations (vertical automorphisms of $P$) acting on $A$ and $B$ as

$$A \to g^{-1}Ag + g^{-1}\mathrm{d}g, \qquad B \to g^{-1}Bg \qquad [4]$$

(the latter is what is meant by the fact that $B$ takes values in ad $P$), because $F_A$ is also ad-equivariant, $F_A \to g^{-1}F_{Ag}$, and $\mathrm{tr}_G$ is ad-invariant. The infinitesimal version of this statement is that the action is invariant under the variations

$$\delta A = d_A\lambda, \qquad \delta B = [B,\lambda] \qquad [5]$$

where $\lambda \in \Omega^0(M,\mathfrak{g})$ can (formally) be thought of as an element of the Lie algebra of the group of gauge transformations.

Gauge-fixing this symmetry can proceed in the usual way (via the Faddeev–Popov or Becchi–Rouet–Stora–Tyupkin procedure), a typical gauge choice being $d_{A_0} \star (A - A_0) = 0$ where $A_0$ is a reference connection, and $\star$ is the Hodge duality operator corresponding to a choice of metric on $M$.

**Local $p$-form symmetries** For $n=2$, the only local symmetries of the BF action are the above $G$ gauge transformations. For $n>2$, however, there are other local symmetries associated with shifts of $B_p \in \Omega^p(M,\mathfrak{g})$ with $p = n-2 > 0$. Indeed, integration by parts using Stokes' theorem and $\partial M = 0$ shows that [1] is invariant under

$$A \to A, \quad B_p \to B_p + d_A\lambda_{p-1}, \quad \lambda_{p-1} \in \Omega^{p-1}(M,\mathfrak{g}) \qquad [6]$$

For $p=1$, $\lambda$ is a 0-form and the invariance follows. For $p>1$, however, the gauge parameter has, in some sense, its own gauge invariance. Namely, under the shift

$$\lambda_{p-1} \to \lambda_{p-1} + d_A\lambda_{p-2} \qquad [7]$$

one has

$$d_A\lambda_{p-1} \to d_A\lambda_{p-1} + [F_A, \lambda_{p-2}] \qquad [8]$$

Thus for $F_A = 0$, the shift [7] has no effect on the local symmetry [6]. Likewise, for $p>2$ the parameter $\lambda_{p-2}$ itself has a similar invariance, etc. Since $F_A=0$ is one of the classical equations of motion, the shift symmetry [6] is what is called an "on-shell reducible symmetry." Gauge-fixing such symmetries is not straightforward, and one generally appeals to the Batalin–Vilkovisky formalism to accomplish this.

**Diffeomorphisms and local symmetries** One manifestation of the general covariance of the BF action [1] is the on-shell equivalence of (infinitesimal) diffeomorphisms and (infinitesimal) local symmetries. Diffeomorphisms are generated by the Lie derivative $L_X$ along a vector field $X$. The action of $L_X$ on differential forms is given by the Cartan formula $L_X = \mathrm{d}i_X + i_X\,\mathrm{d}$, where $i_{(.)}$ is the operation of contraction. The action of the Lie derivative on $A$ and $B$ can be written in gauge covariant form as

$$\begin{aligned} L_X A &= i_X F_A + d_A\lambda(X), \\ L_X B &= i_X\, d_A B + [B,\lambda(X)] + d_A\lambda'(X) \end{aligned} \qquad [9]$$

where $\lambda(X) = i_X A$ and $\lambda'(X) = i_X B$. This shows that on-shell diffeomorphisms are equivalent to field-dependent gauge and $p$-form symmetries of the BF action.

**The classical moduli space** The classical moduli space $\mathcal{C} = \mathcal{C}(P,M,G)$ is the space of solutions to the classical equations of motion modulo the local symmetries of the action. Since the field content

and the nature of the local symmetries of the BF theory depend strongly on the dimension $n$ of $M$, the structure and interpretation of the classical moduli space also depend on $n$.

For $n=2$, by [5] the equation of motion [2] for $B \in \Omega^0(M, \mathfrak{g})$ says that $A$ is invariant under the infinitesimal gauge transformation generated by $B$. Thus if $A$ is "irreducible," there are no nontrivial solutions for $B$ and, away from reducible flat connections, the classical moduli space is just the moduli space of flat connections on $P \to M$ over the surface $M$:

$$\mathcal{C}_{n=2} = \mathcal{M}_{\text{flat}}(P, G) \quad [10]$$

This space may or may not be empty, depending on whether $P$ admits flat connections or not.

For $n=3$, the equation of motion [2] for $B \in \Omega^1(M, \mathfrak{g})$ says that $B$ is a tangent vector to the space of flat connections at the flat connection $A$, in the sense that under the variation $\delta A = B$, one has

$$\delta F_A = d_A B = 0 \quad [11]$$

The local $G$ gauge symmetry and the 1-form symmetry [6] now imply that the moduli space of classical solutions can be identified with the (co-)tangent bundle of the moduli space of flat connections on $P \to M$ over the 3-manifold $M$:

$$\mathcal{C}_{n=3} = T\mathcal{M}_{\text{flat}}(P, G) \quad [12]$$

In higher dimensions there appears to be less geometrical structure associated with BF theories, and all that can be said in general is that the tangent space to $\mathcal{C}_n$ at a solution $(A, B)$ of the equations of motion [2] is the vector space:

$$T_{(A,B)}\mathcal{C}_n = H^1_A(M, \mathfrak{g}) \oplus H^{n-2}_A(M, \mathfrak{g}) \quad [13]$$

where $H^k_A(M, \mathfrak{g})$ are the cohomology groups of the deformation complex

$$d_A : \Omega^*(M, \mathfrak{g}) \to \Omega^{*+1}(M, \mathfrak{g}) \quad [14]$$

associated with the flat connection $A$, $F_A = (d_A)^2 = 0$.

When $M$ is topologically of the form $M = \Sigma \times \mathbb{R}$ (where one can think of $\mathbb{R}$ as time), one has

$$T_{(A,B)}\mathcal{C}_n = H^1_A(\Sigma, \mathfrak{g}) \oplus H^{n-2}_A(\Sigma, \mathfrak{g}) \quad [15]$$

This is naturally a symplectic vector space (necessary for a phase space), the nondegenerate antisymmetric pairing being given by Poincaré duality:

$$\omega([a_1], [b_1]; [a_2], [b_2]) = \int_\Sigma \operatorname{tr}_G(a_1 \wedge b_2 - a_2 \wedge b_1) \quad [16]$$

**Metric independence** Perhaps the most important property of the action [1] is that, in contrast to, for example, the usual Yang–Mills action for nonabelian gauge fields

$$S_{\text{YM}} = \frac{1}{4g^2} \int_M \operatorname{tr}_G F_A \wedge \star F_A \quad [17]$$

it does not require a metric (or the corresponding Hodge duality operator $\star$) for its formulation. This makes it a candidate action for a "topological field theory," this term loosely referring to field theories which, in a suitable sense, do not depend on additional structures imposed on the underlying space(-time) manifold $M$, in this case a Riemannian structure.

To establish that BF theories are "topological quantum field theories," one needs to show that the partition function (and correlation functions) of the quantized BF theory are also metric independent. This is not completely automatic as typically the metric enters in the gauge fixing of the local symmetries of the action which is required to make the quantum theory well defined. The usual lore is that since the metric only enters through the gauge fixing and since the quantum theory should be independent of the choice of gauge, it should also be metric independent. In the case of nonabelian BF theories, the complexity of their local symmetries complicates the analysis somewhat, but it can nevertheless be shown that BF theories indeed define topological field theories also at the quantum level.

### Special Features of Abelian BF Theories

All the features of nonabelian BF theories discussed above are, of course, also valid when $G$ is abelian (with some obvious modifications and simplifications). However, when $G$ is abelian, a more general action than [1] is possible. Indeed, although there is no obvious higher $p$-form analog of nonabelian gauge fields, in the abelian case $G = \mathrm{U}(1)$ or $G = \mathbb{R}$, and the condition $F_A \in \Omega^2(M, \mathbb{R})$ can be relaxed. In particular, one can consider the actions

$$S(n,p) \equiv S(B_p, C_{n-p-1}) = \int_M B_p \wedge \mathrm{d}C_{n-p-1} \quad [18]$$

with $B_p \in \Omega^p(M, \mathbb{R}), C_{n-p-1} \in \Omega^{n-p-1}(M, \mathbb{R})$, and $F_C = \mathrm{d}C$, its $(n-p)$-form field strength. More generally, one can also consider the hybrid action

$$S_A(n,p) = \int_M B_p \wedge d_A C_{n-p-1} \quad [19]$$

where $A$ is a fixed (nondynamical) flat $G$-connection, $d_A^2 = 0$, and $B$ and $C$ take values in the corresponding adjoint bundle. This action can be considered as the linearization of the nonabelian BF action [1] around

the flat connection $A$, and it reduces to the abelian BF action [18] for $\mathfrak{g} = \mathbb{R}$.

The action is invariant under the (reducible) local symmetries

$$\begin{aligned} B_p &\to B_p + d_A \lambda_{p-1} \\ C_{n-p-1} &\to C_{n-p-1} + d_A \lambda'_{n-p-2} \end{aligned} \qquad [20]$$

The space of solutions to the equations of motion $d_A C = d_A B = 0$ modulo gauge symmetries is (cf. [13]) the finite-dimensional vector space

$$\mathcal{C}_{n,p} = H_A^p(M, \mathfrak{g}) \oplus H_A^{n-p-1}(M, \mathfrak{g}) \qquad [21]$$

which is naturally symplectic for $M = \Sigma \times \mathbb{R}$.

## Uses and Applications of Quantum Abelian BF Theories

### Quantization of Abelian BF Theories and the Ray–Singer Torsion

We will now show that the partition function of the abelian BF theory (actually more generally that of the linearized nonabelian BF action [19]) is related to the Ray–Singer torsion of $M$. This requires some preparatory material on Gaussian path integrals, determinants, and gauge fixing that we present first.

In order to simplify the exposition, we assume that there are no harmonic modes, either because they have been gauged away or because the cohomology groups of $d_A$ are trivial, $H_A^k(M, \mathfrak{g}) = 0$, that is, the deformation complex [14] is "acyclic."

**Laplacians, determinants, and the Ray–Singer torsion** Choosing a Riemannian metric $g$ (and Hodge duality operator $\star$) on $M$, the twisted Laplacian on $p$-forms is

$$\Delta_A^{(p)} = (d_A + d_A^\star)^2 = d_A d_A^\star + d_A^\star d_A \qquad [22]$$

where $d_A^\star = \pm \star d_A \star$ is the adjoint of d with respect to the scalar product on $p$-forms defined by $\star$. This is an elliptic operator whose determinant can be defined, for example, by a $\zeta$-function regularization. Denoting the (nonzero) eigenvalues of $\Delta_A^{(p)}$ by $\lambda_k^{(p)}$, its $\zeta$-function is

$$\zeta^{(p)}(s) = \sum_k \left(\lambda_k^{(p)}\right)^{-s} \qquad [23]$$

This converges for Re($s$) sufficiently large and can be analytically continued to a meromorphic function of $s$ analytic at $s = 0$, so that

$$\det \Delta_A^{(p)} := \mathrm{e}^{-\zeta^{(p)\prime}(0)} \qquad [24]$$

is well defined. The Ray–Singer torsion of $(M, \mathfrak{g})$ (with respect to the flat connection $A$) is then defined by

$$T_A(M) = \prod_{p=0}^{n} \left(\det \Delta_A^{(p)}\right)^{(-1)^p p/2} \qquad [25]$$

Even though this definition depends strongly on the metric $g$ on $M$, the Ray–Singer torsion has the remarkable property of being independent of $g$. The Ray–Singer torsion can be shown to be trivial (essentially =1 modulo zero-mode contributions) in even dimensions, but is a nontrivial topological invariant in odd dimensions. Henceforth, we will suppress the dependence on $M$ and denote the $n$-dimensional Ray–Singer torsion by $T_A(n)$.

**Gaussian path integrals and determinants** The path integral for abelian BF theories is modeled on the usual formula for a $\delta$-function

$$\delta^n(x) = \frac{1}{(\sqrt{2\pi})^n} \int_{\mathbb{R}^n} \mathrm{d}^n \pi \, \mathrm{e}^{\mathrm{i}\pi x} \qquad [26]$$

from which one deduces the Gaussian integral formula

$$\begin{aligned} &\frac{1}{(\sqrt{2\pi})^n} \int_{\mathbb{R}^n \times \mathbb{R}^n} \mathrm{d}^n \pi \, \mathrm{d}^n x \, \mathrm{e}^{\mathrm{i}\pi D x + \mathrm{i}K x + \mathrm{i}\pi J} \\ &= \int_{\mathbb{R}^n} \mathrm{d}^n x \delta^n(Dx + J) \, \mathrm{e}^{\mathrm{i}Kx} \\ &= \frac{1}{\det D} \, \mathrm{e}^{-\mathrm{i}K.D^{-1}J} \end{aligned} \qquad [27]$$

Here, we have assumed that the operator (matrix) $D$ is invertible. The model that one uses in the path integral is that

$$\int \mathrm{d}[\phi] \, \mathrm{d}[\chi] \, \mathrm{e}^{\mathrm{i} \int_M \phi \star D \chi} = (\det D)^{\mp 1} \qquad [28]$$

where $\phi$ is a set of fields and the $\chi$ are a set of dual fields with $D$ again a nondegenerate operator. The inverse determinant arises for Grassmann even fields (as in [27]), while it is the determinant that appears for Grassmann odd fields.

**Gauge fixing – the Faddeev–Popov trick** If the action [19], $S_A(n, p) = \int B_p d_A C_{n-p-1}$, were nondegenerate, its partition function could be defined directly by [28]. However, because of gauge invariance of the action, the kinetic term is degenerate and one needs to eliminate the gauge freedom to obtain an (at least formally) well-defined expression for the partition function. Concretely, this degeneracy can be seen by

recalling that, when there are no harmonic forms (as we have assumed), there is a unique orthogonal Hodge decomposition of a $p$-form $B_p \in \Omega^p(M, \mathfrak{g})$ into a sum of a $d_A$-exact and a $d_A$-coexact form:

$$B_p = d_A \lambda_{p-1} + d_A^\star \tau_{p+1} \qquad [29]$$

(and likewise for $C$). Evidently, the exact (longitudinal) parts $d_A\lambda$ of $B$ and $C$ do not appear in the action, and these are precisely the gauge-dependent parts of $B$ and $C$ under the gauge transformation [20]. Gauge fixing amounts to imposing a condition $\mathcal{F}(B_p) = 0$ on $B_p$ that determines the longitudinal part uniquely in terms of the transversal part $d_A^\star \tau$. A natural condition is

$$d_A \lambda_{p-1} = 0 \Leftrightarrow \mathcal{F}(B_p) = d_A^\star B_p = 0 \qquad [30]$$

A gauge-fixing condition independent of the partition function results from inserting “1” in the form of

$$1 = \int_{\mathcal{G}} \mathrm{d}[g] \delta(\mathcal{F}(B^g)) \Delta_{\mathcal{F}}(B) \qquad [31]$$

into the functional integral (the Faddeev–Popov trick), where $\mathcal{G}$ is the gauge group. This defines the Faddeev–Popov determinant $\Delta_{\mathcal{F}}$, and the functional properties of the delta functional imply that $\Delta_{\mathcal{F}}$ is the determinant of the operator that one obtains upon gauge variation of $\mathcal{F}(B)$.

In the general case of reducible gauge symmetries, the nature of the gauge group is complicated and requires some more thought. In the irreducible case, however, that is, for $p = 1$, the Lie algebra of the gauge group can be identified with $\Omega^0(M, \mathfrak{g})$, and $\Delta_{\mathcal{F}}$ is the determinant of the operator:

$$\frac{\delta \mathcal{F}}{\delta B} d_A : \Omega^0(M, \mathfrak{g}) \to \Omega^0(M, \mathfrak{g}) \qquad [32]$$

For [30], this is simply the Laplacian on 0-forms, and thus

$$\Delta_{\mathcal{F}} = \det \Delta_A^{(0)} \qquad [33]$$

**The partition function** Following the finite-dimensional model, both the $\delta$-function implementing the gauge-fixing condition and the Faddeev–Popov determinant can be lifted into the exponential, the former by a Lagrange multiplier $\pi$ [26], a Grassmann even 0-form, and the latter by a pair of Grassmann odd 0-forms $c$ and $\bar{c}$ [28], the ghost and antighost fields, respectively. The sum of the classical action and these gauge-fixing and ghost terms defines the (BRST-invariant) “quantum action” $S_A^q(n, p)$, and the partition function is

$$Z_A(n, p) = \int \mathrm{d}[\phi] \mathrm{e}^{\mathrm{i} S_A^q(n,p)(\phi)} \qquad [34]$$

where $\phi$ denotes collectively all the fields. Concretely, when $n = 2$ and $p = 0$ (or, equivalently, $p = 1$), the quantum action is

$$S_A^q(2, 0) = \int B_0 d_A C_1 + \pi d_A \star C_1 + \bar{c} \star \Delta_A^{(0)} c \qquad [35]$$

Likewise, for $n = 3$ and $p = 1$ (the only other case when the gauge symmetry is indeed irreducible), both $B_1$ and $C_1$ require separate gauge fixing, and the quantum action is

$$S_A^q(3, 1) = \int B_1 d_A C_1 + \pi d_A \star C_1 + \bar{c} \star \Delta_A^{(0)} c + \pi' d_A \star B_1 + \bar{c}' \star \Delta_A^{(0)} c' \qquad [36]$$

Formally, therefore, the two-dimensional partition function is

$$Z_A(2, 0) = \frac{\det \Delta^{(0)}}{\det D_A} \qquad [37]$$

where $D_A$ is the operator:

$$D_A = \begin{pmatrix} \star d_A \\ \star d_A \star \end{pmatrix} : \Omega^1(M, \mathfrak{g}) \to \Omega^0(M, \mathfrak{g}) \oplus \Omega^0(M, \mathfrak{g}) \qquad [38]$$

One can define the determinant of this operator as the square root of the determinant of the operator $D_A^\star D_A = \Delta_A^{(1)}$, and therefore the partition function

$$Z_A(2, 0) = \det \Delta^{(0)} (\det \Delta^{(1)})^{-1/2} = T_A(2) \qquad [39]$$

is equal to the two-dimensional Ray–Singer torsion [25]. In this case, it is easy to see directly that the even-dimensional Ray–Singer torsion is trivial, as one could have equally well defined the determinant of $D_A$ as the square root of the operator $D_A D_A^\star = \Delta_A^{(0)} \oplus \Delta_A^{(0)}$, which implies $Z_A(2, 0) = 1$.

In three dimensions, the two pairs of ghosts each contribute a $\det \Delta_A^{(0)}$, and thus

$$Z_A(3, 1) = \frac{(\det \Delta^{(0)})^2}{\det D_A} \qquad [40]$$

where

$$D_A = \begin{pmatrix} \star d_A & d_A \\ d_A \star & 0 \end{pmatrix} : \Omega^0(M, \mathfrak{g}) \oplus \Omega^1(M, \mathfrak{g}) \to \Omega^0(M, \mathfrak{g}) \oplus \Omega^1(M, \mathfrak{g}) \qquad [41]$$

is the operator acting on the fields $(B_1, C_1, \pi, \pi')$. As before, this operator can be diagonalized by squaring it, $D_A^* D_A = \Delta^{(0)} \oplus \Delta^{(1)}$, and thus

$$Z_A(3, 1) = (\det \Delta_A^{(0)})^{3/2} (\det \Delta_A^{(1)})^{-1/2} = T_A(3)^{-1} \qquad [42]$$

is again related to the (this time genuinely nontrivial) Ray–Singer torsion.

In spite of the complications caused by reducible gauge symmetries, it can be shown that all of the above generalizes to arbitrary $n$ and $p$, with the result that (for $n$ odd)

$$Z_A(n,p) = T_A(n)^{(-1)^p} \qquad [43]$$

confirming the topological nature of BF theories.

In the nonabelian case, the situation is significantly more complicated because of the complexity of the classical moduli space, the (higher cohomology) zero modes, and the on-shell reducibility of the gauge symmetries. Nevertheless, ignoring all the zero modes except those of $A$, that is, except the moduli $m$ of flat connections $A(m)$, the result is similar to that in the abelian case, in that the partition function reduces to an integral over the moduli space of flat connections, with measure determined by the Ray–Singer torsion $T_{A(m)}$.

#### Linking Numbers as Observables of Abelian BF Theories

With the exception of $p=0$, there are no interesting "local" observables (gauge-invariant functionals of the fields $C$ and $B$) in the abelian BF theory, since the gauge-invariant field strengths d$C$ and d$B$ vanish by the equations of motion. (For $p=0$, $B$ is a gauge-invariant 0-form and hence $B(x)$ is a good local observable.) However, as in the Chern–Simons and Yang–Mills theories, certain (weakly) nonlocal observables such as Wilson loops are also of interest. In the case at hand (eqn [18]), we have abelian Wilson surface operators

$$W_S[B] = \int_S B, \qquad W_{S'}[C] = \int_{S'} C \qquad [44]$$

associated with $p$- and $(n-p-1)$-dimensional submanifolds $S$ and $S'$ of $M$, respectively. These operators are gauge invariant, that is, invariant under the local symmetries [20] provided that $\partial S = \partial S' = 0$, so that $S$ and $S'$ represent homology cycles of $M$.

For $M = \mathbb{R}^n$, correlation functions of these operators are related to the topological linking number of $S$ and $S'$. We choose $S = \partial\Sigma$ and $S' = \partial\Sigma'$ to be disjoint compact-oriented boundaries of oriented submanifolds $\Sigma$ and $\Sigma'$ of $\mathbb{R}^n$. We also introduce de Rham currents $\Delta_\Sigma$ and $\Delta_S$ (essentially distributional differential forms with $\delta$-function support on $\Sigma$ or $S$, respectively), characterized by the properties

$$\begin{aligned} \int_S \omega_p &= \int_M \Delta_S \wedge \omega_p \\ \int_\Sigma \omega_{p+1} &= \int_M \Delta_\Sigma \wedge \omega_{p+1} \end{aligned} \qquad [45]$$

for all $\omega_k \in \Omega^k(M, \mathbb{R})$ (and likewise for $S'$ and $\Sigma'$).

Since the dimension of $\Sigma$ is equal to the codimension of $S' = \partial\Sigma'$, $\Sigma$ and $S'$ will generically intersect transversally at isolated points, and we define the "linking number" of $S$ and $S'$ to be the intersection number of $\Sigma$ and $S'$, expressed in terms of de Rham currents as

$$L(S,S') = \int_\Sigma \Delta_{S'} = \int_M \Delta_\Sigma \Delta_{S'} \qquad [46]$$

In terms of de Rham currents, the Wilson surface operators can be written as $W_S[B] = \int_M \Delta_S \wedge B$, etc. Thus, the generating functional for correlation functions of Wilson surface operators

$$\langle e^{i\beta W_S[B]} e^{i\alpha W_{S'}[C]} \rangle = \int D[C]D[B] e^{i\int_M (B\,dC + \alpha\Delta_{S'}C + \beta\Delta_S B)} \qquad [47]$$

is simply a Gaussian path integral. Using the defining properties of de Rham currents, this can be formally evaluated (using [27]) to give

$$\langle e^{i\beta W_S[B]} e^{i\alpha W_{S'}[C]} \rangle = e^{\pm i\alpha\beta L(S,S')} \qquad [48]$$

As expected, correlation functions of these topological field theories encode topological information.

## Uses and Applications of Classical Nonabelian BF Theories

Low-dimensional BF theories are closely related to other theories of interest, for example, the Yang–Mills theory, the Chern–Simons theory, and gravity. Here, we briefly review some of these relationships. In order to avoid the complexities of quantum nonabelian BF theories, we focus on their classical features. Brief suggestions for further reading are provided at the end of each subsection.

#### Relation with Yang–Mills Theory

In any dimension, the nonabelian BF action can be regarded as the zero-coupling limit $g^2 \to 0$ of the Yang–Mills theory since the Yang–Mills action [17] can be written in first-order form as

$$\frac{1}{4g^2}\int_M \mathrm{tr}_G\, F_A \wedge \star F_A \equiv \int_M \mathrm{tr}_G[iB_{n-2} \wedge F_A + g^2 B_{n-2} \wedge \star B_{n-2}] \qquad [49]$$

However, whereas for $n \geq 3$ the $B^2$-term breaks the $p$-form gauge invariance of the BF action (and thus liberates the physical Yang–Mills degrees of freedom), this limit is nonsingular in two dimensions where this $p$-form symmetry is absent and, indeed, both theories have zero physical degrees of freedom.

A nonsingular BF-like zero coupling limit of the Yang–Mills theory for $n \geq 3$ can be obtained by introducing an auxiliary (Stückelberg) field $\eta \in \Omega^{n-3}(M, \mathfrak{g})$ which restores the $p$-form gauge invariance. The resulting BF Yang–Mills action is

$$S_{\mathrm{BFYM}} = \int_M \mathrm{tr}_G \Big[ \mathrm{i}B_{n-2} \wedge F_A + g^2 \left( B_{n-2} - \frac{1}{\sqrt{2}g} d_A \eta \right) \wedge * \left( B_{n-2} - \frac{1}{\sqrt{2}g} d_A \eta \right) \Big] \quad [50]$$

This action is not only invariant under ordinary $G$ gauge transformations, but also under the $p$-form gauge symmetry $B \to B + d_A \lambda$ [6] provided that $\eta$ transforms as $\eta \to \eta + \sqrt{2}g\lambda$. Thus, this shift can be used to set $\eta$ to zero, upon which one recovers the first-order form of the Yang–Mills action. Moreover, in the zero-coupling limit all that survives is a standard (and nontopological) minimal coupling of $\eta$ to the BF action:

$$\lim_{g^2 \to 0} S_{\mathrm{BFYM}} = \int_M \mathrm{tr}_G \left[ \mathrm{i}B_{n-2} \wedge F_A + \tfrac{1}{2} d_A \eta \wedge * d_A \eta \right] \quad [51]$$

accounting for the correct number of degrees of freedom of the Yang–Mills theory (the $(n-3)$-form $\eta$ being absent for $n=2$).

Two-dimensional quantum BF and Yang–Mills theories have a variety of interesting topological properties. An account of some of them can be found in Blau and Thompson (1994) and Witten (1991). For a detailed discussion of the gauge symmetries and gauge fixing of the BFYM action, see Cattaneo *et al.* (1998).

### Chern–Simons Theory, Gravity, and (Deformed) BF Theory

The Chern–Simons theory is a three-dimensional gauge theory. The Chern–Simons action for an $H$-connection $C$, $H$ the gauge group, is

$$S_{\mathrm{CS}}(C) = \int_M \mathrm{tr}_H \left( C \wedge \mathrm{d}C + \tfrac{2}{3} C \wedge C \wedge C \right) \quad [52]$$

It is invariant under the infinitesimal gauge transformations $\delta C = d_C \lambda$, $\lambda \in \Omega^0(M, \mathfrak{h})$, and the gauge-invariant equation of motion is the flatness condition $F_C = 0$. Now let $H = TG$ be the tangent bundle group $TG \sim G \times_s \mathfrak{g}$. This is a semidirect product group with $G$ acting on $\mathfrak{g}$ via the adjoint and $\mathfrak{g}$ regarded as an abelian Lie algebra of translations. Thus, in terms of generators $(J_a, P_a)$, where the $J_a$ are generators of $G$, the commutation relations are $[J_a, J_b] = f_{ab}^c J_c$, $[J_a, P_b] = f_{ab}^c P_c$ and $[P_a, P_b] = 0$, and the curvature of the $TG$-connection $C = J_a A^a + P_a B^a$ is

$$F_C = J_a F_A^a + P_a d_A B^a \quad [53]$$

Thus, the equations of motion of the $TG$ Chern–Simons theory are equivalent to the equations of motion [2] of the BF theory with gauge group $G$. This equivalence also holds at the level of the action:

$$\tfrac{1}{2} S_{\mathrm{CS}}(C) = S_{\mathrm{BF}}(A, B) \quad [54]$$

provided that one chooses the nondegenerate invariant scalar product to be

$$\begin{aligned} \mathrm{tr}_{TG}(J_a P_b) &= \mathrm{tr}_G(J_a J_b) \\ \mathrm{tr}_{TG}(J_a J_b) &= \mathrm{tr}_{TG}(P_a P_b) = 0 \end{aligned} \quad [55]$$

For $G = \mathrm{SO}(3)$, $TG$ is the Euclidean group of isometries of $\mathbb{R}^3$ and for $G = \mathrm{SO}(2,1)$, $TG$ is the Poincaré group of isometries of the three-dimensional Minkowski space $\mathbb{R}^{2,1}$. For these gauge groups, the BF action takes the form of the three-dimensional (Euclidean or Lorentzian) Einstein–Hilbert action, with the interpretation of $B = e$ as the dreibein and $A = \omega$ as the spin connection. The equations of motion for $e$ and $\omega$ express the vanishing of the torsion and the Riemann tensor (equivalent to the vanishing of the Ricci tensor for $n=3$), respectively. This Chern–Simons interpretation of three-dimensional gravity extends to gravity with a cosmological constant, with $H$ the appropriate de Sitter or anti-de Sitter isometry group (SO(4), SO(3, 1), or SO(2, 2), depending on the signature and the sign of the cosmological constant). In terms of the BF interpretation, this corresponds to the simple topological deformation

$$S_{\mu\mathrm{BF}}(A, B) = \int_M \mathrm{tr}_G \left( B \wedge F_A + \tfrac{1}{3} \mu B \wedge B \wedge B \right) \quad [56]$$

of the BF action, which has the deformed local symmetries (cf. [5] and [6])

$$\delta A = d_A \lambda + \mu [B, \lambda'], \qquad \delta B = [B, \lambda] + d_A \lambda' \quad [57]$$

A simple way to understand these symmetries is to note that the action can be written as the difference of two Chern–Simons actions:

$$\begin{aligned} &S_{\mathrm{CS}}(A + \sqrt{\mu} B) - S_{\mathrm{CS}}(A - \sqrt{\mu} B) \\ &\quad = 4\sqrt{\mu} S_{\mu\mathrm{BF}}(A, B) \end{aligned} \quad [58]$$

whose evident standard local gauge symmetries $\delta(A \pm \sqrt{\mu} B) = d_{A \pm \sqrt{\mu} B} \lambda^{\pm}$ are equivalent to [57] for $\lambda^{\pm} = \lambda \pm \sqrt{\mu} \lambda'$.

A detailed account of three-dimensional classical and quantum gravity can be found in Carlip (1998).

### Relation with Gravity

Theories of two-dimensional gravity and topological gravity also have a BF formulation (Blau and Thompson 1991, Birmingham *et al.* 1991) which resembles the Chern–Simons BF formulation of three-dimensional gravity described above, the natural gauge group now being SO(2, 1) or SO(3) or one of its contractions.

In the first-order (Palatini) formulation, the Einstein–Hilbert action for four-dimensional gravity can be written as

$$S_{\mathrm{EH}} = \int \mathrm{tr}(e \wedge e \wedge F_\omega) \qquad [59]$$

where $e$ is the vierbein and $\omega$ is the spin connection. This action has the general form of a BF action with a constraint that $B = e \wedge e$ be a simple bi(co-)vector. Thus, four-dimensional general relativity can be regarded as a constrained BF theory. Although this constraint drastically changes the number of physical degrees of freedom (BF theory has zero degrees of freedom, while four-dimensional gravity has two), this is nevertheless a fruitful analogy which also lies at the heart of the spin-foam quantization approach to quantum gravity. This constrained BF description of gravity is also available for higher-dimensional gravity theories.

For further details, and references, see Freidel *et al.* (1999) and the review article (Baez 2000).

### Knot and Generalized Knot Invariants

The known relationship between Wilson loop observables of the Chern–Simons theory with a compact gauge group and knot invariants (Witten 1989), and the interpretation of the three-dimensional BF theory as a Chern–Simons theory with a noncompact gauge group raise the question of the relation of observables of an $n = 3$ BF theory to knot invariants, and suggest the possibility of using an $n \geq 4$ BF theory to define higher-dimensional analogs of knot invariants. It turns out that an appropriate observable of $n = 3$ BF theory for $G = \mathrm{SU}(2)$ is related to the Alexander–Conway polynomial. The analysis of higher-dimensional BF theories requires the full power of the Batalin–Vilkovisky (BV) formalism. BV observables generalizing Wilson loops have been shown to give rise to cohomology classes on the space of imbedded curves.

For a detailed discussion of these issues, see Cattaneo and Rossi (2001) and references therein. A relation between the algebra of generalized Wilson loops and string topology has been investigated in Cattaneo *et al.* (2003).

# Bicrossproduct Hopf Algebras and Noncommutative Spacetime

**S Majid**, Queen Mary, University of London,
London, UK

## Introduction

One of the sources of quantum groups is a bicrossproduct construction coming in the case of Lie groups from considerations of Planck-scale physics in the 1980s. This article describes these objects and their currently known applications. See also the overview of Hopf algebras which provides the algebraic context (*see* Hopf Algebras and $q$-Deformation Quantum Groups).

The construction of quantum groups here is viewed as a microcosm of the problem of quantization in a manner compatible with geometry. Here quantization enters in the noncommutativity of the algebra of observables and "curvature" enters as a quantum nonabelian group structure on phase space. Among the main features of the resulting bicrossproduct models (Majid 1988) are

1. Compatibility takes the form of nonlinear "matched pair equations" generically leading to singular accumulation regions (event horizons or a maximum value of momentum depending on context).
2. The equations are solved in an "equal and opposite" form from local factorization of a larger object.
3. Different classical limits are related by observer–observed symmetry and Hopf algebra duality.
4. Nonabelian Born reciprocity re-emerges and is linked to $T$-duality.

It has also been argued that noncommutative geometry should emerge as an effective theory of the first corrections to geometry coming from any unknown theory of quantum gravity. Concrete models of noncommutative spacetime currently provide the first framework for the experimental verification of such effects. The most basic of these possible effects is curvature in momentum space or "cogravity." We start with this.

## Cogravity

We recall that curvature in space or spacetime means by definition noncommutativity among the covariant derivatives $D_i$. Here the natural momenta are $p_i = -i\hbar D_i$ and the situation is typified by the top line in Figure 1. There are also mixed relations between the $D_i$ and position functions as indicated

| | Position | Momentum |
|---|---|---|
| Gravity | Curved $\Sigma_\mu x_\mu^2 = \frac{1}{\gamma^2}$ | Noncommutative $[p_i, p_j] = i\hbar\gamma\epsilon_{ijk}p_k$ |
| Cogravity | Noncommutative $[x_i, x_j] = 2i\lambda\epsilon_{ijk}x_k$ | Curved $\Sigma_\mu P_\mu^2 = \frac{1}{\lambda^2}$ |
| Quantum mechanics | $[x_i, p_j] = i\hbar\delta_{ij}$ | |

**Figure 1** Noncommutative spacetime means curvature in momentum space. The equations are for illustration.

for flat space in the bottom line, which is quantum mechanics (there is a similar story for quantum mechanics on a curved space). We see however a third and dual possibility – noncommutativity in position space which should be interpreted as curvature in momentum space, that is, the dual of gravity. This is an independent physical effect and comes therefore with its own length scale which we denote $\lambda$. These ideas were made precise in the mid 1990s using the quantum group Fourier transform; see Majid (2000). Here we show what is involved on three illustrative examples.

1. We consider the "spin space" algebra

$$\mathbb{R}^3_\lambda : [x_i, x_j] = i2\lambda\epsilon_{ij}{}^k x_k$$

where ${\epsilon_{12}}^3 = 1$ and where it is convenient to insert a factor 2. This is the enveloping algebra $U(su_2)$, that is, just angular momentum space but now regarded "upside down" as a coordinate algebra (*see* Hopf Algebras and $q$-Deformation Quantum Groups). Then a plane wave is of the form

$$\psi_p = e^{ip\cdot x}, \quad p \in \mathbb{R}^3$$

where we set $\hbar = 1$ for this discussion. The momenta $p_i$ are nothing but local coordinates for the corresponding point $e^{i\lambda p\cdot\sigma} \in SU_2$ where $\lambda\sigma$ is the representation by Pauli matrices. It is really elements of this curved space $SU_2$ where momenta live. Here $\mathbb{R}^3_\lambda = U(su_2)$ has dual $\mathbb{C}[SU_2]$ and Hopf algebra Fourier transform (after suitable completion) takes one between these spaces. Thus, in one direction

$$\mathcal{F}(f) = \int_{SU_2} du f(u) u \approx \int d^3p J(p) f(p)\, e^{ip\cdot x}$$

for $f$ a function on $SU_2$. We use the Haar measure on $SU_2$. The local result on the right has $J$ the Jacobian for the change to the local $p$ coordinates and $f$ is written in terms of these. Note that the coproduct in

$\mathbb{C}[SU_2]$ in terms of the $p^i$ generators is an infinite series given by the Campbell–Baker–Hausdorff series, and not the usual linear one (this is why the measure is not the Lebesgue one). The physical content here is in the plane waves themselves, one can use any other momentum coordinates to parametrize them with the corresponding measure and coproduct. Differential operators on $\mathbb{R}^3_\lambda$ are given by the action of elements of $\mathbb{C}[SU_2]$ and are diagonal on these plane waves,

$$f.\psi_{\boldsymbol{p}} = f(\boldsymbol{p})\psi_{\boldsymbol{p}}$$

which corresponds under Fourier transform simply to pointwise multiplication in $\mathbb{C}[SU_2]$. For example, the function $\lambda^{-2}(\mathrm{tr}-2)$ as a function on $SU_2$ will give a rotationally invariant wave operator which is also invariant under inversion in the group. Its value on plane waves is

$$\frac{1}{\lambda^2}\mathrm{tr}(\mathrm{e}^{\mathrm{i}\lambda \boldsymbol{p}\cdot\sigma}-1) = \frac{2}{\lambda^2}(\cos(\lambda|\boldsymbol{p}|)-1)$$

In the limit $\lambda \to 0$ this gives the usual wave operator on $\mathbb{R}^3$.

It is also possible to put a differential graded algebra (DGA) structure of differential forms on this algebra, the natural one being

$$\mathrm{d}x_i = \lambda\sigma_i, \qquad x_i\theta - \theta x_i = \mathrm{i}\frac{\lambda^2}{\mu}\,\mathrm{d}x_i$$

$$(\mathrm{d}x_i)x_j - x_j\mathrm{d}x_i = \mathrm{i}\lambda\epsilon_{ij}{}^k\mathrm{d}x_k + \mathrm{i}\mu\delta_{ij}\theta$$

where $\theta$ is the $2\times 2$ identity matrix which, together with the Pauli matrices $\sigma_i$, completes the basis of left-invariant 1-forms. The 1-form $\theta$ provides a natural time direction, even though there is no time coordinate, and the new parameter $\mu \neq 0$ appears as the freedom to change its normalization. The partial derivatives $\partial^i$ are defined by

$$\mathrm{d}\psi(x) = (\partial^i\psi)\mathrm{d}x_i + (\partial^0\psi)\theta$$

and act diagonally on plane waves as

$$\partial^i = \frac{\mathrm{i}}{2\lambda}\mathrm{tr}(\sigma_i(\ )) = \mathrm{i}\frac{p^i}{\lambda|\boldsymbol{p}|}\sin(\lambda|\boldsymbol{p}|)$$

while $\partial^0 = \mathrm{i}\mu(\mathrm{tr}-2)/2\lambda^2$ is computed as above.

Note that $\mu$ cannot be taken to be zero due to an anomaly for translation invariance of the DGA. It is in fact a typical feature of noncommutative differential geometry that there is a 1-form $\theta$ generating d by commutator which can be required as an extra cotangent direction with its associated partial derivative an induced Hamiltonian. In the present model we have

$$\partial^0\psi = \mathrm{i}\frac{\mu}{2}\sum_i(\partial^i)^2\psi + O(\lambda^2)$$

which is of the form of Schrödinger's equation with respect to an auxiliary time variable and for a particle with mass $1/\mu$.

The reader may ask what happens to the Euclidean group of translations and rotations in this context. From the above we find that $U_\lambda(\mathrm{poinc}_3) = \mathbb{C}[SU_2] \bowtie U(su_2)$, the semidirect product generated by translations $\partial^i$ and usual rotations. This in turn is the quantum double $D(U(su_2))$ of the classical enveloping algebra, and as such a quantum group with braiding etc. (*see* Hopf Algebras and $q$-Deformation Quantum Groups). This quantum double has been identified as part of an effective theory in $2+1$ quantum gravity in a Euclidean version based on Chern–Simons theory with Lie algebra $\mathrm{poinc}_3$ and the spin space algebra proposed as an effective theory for this. The quotient of $\mathbb{R}^3_\lambda$ by an allowed value of the quadratic Casimir $\boldsymbol{x}^2$ (which then makes it a matrix algebra) is called a "fuzzy sphere" and appears as a "world-volume algebra" in certain string theories and reduced matrix models. The noncommutative differential geometry that we have described is due to Batista and the author.

2. We take the same type of construction to obtain the "bicrossproduct model" spacetime algebra

$$\mathbb{R}^{1,3}_\lambda: \qquad [t, x_i] = \mathrm{i}\lambda x_i, \quad [x_i, x_j] = 0$$

These are the relations of a Lie algebra $b_+$ (say) but again regarded as coordinates on a noncommutative spacetime. Here $\lambda$ is a timescale which can be written as a mass scale $\kappa = 1/\lambda$ instead. We parametrize the plane waves as

$$\psi_{\boldsymbol{p},p^0} = \mathrm{e}^{\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{x}}\mathrm{e}^{\mathrm{i}p^0 t}, \qquad \psi_{\boldsymbol{p},p^0}\psi_{\boldsymbol{p}',p^{0\prime}} = \psi_{\boldsymbol{p}+\mathrm{e}^{-\lambda p^0}\boldsymbol{p}',p^0+p^{0\prime}}$$

which identifies the $p^\mu$ as the coordinates of the nonabelian group $B_+ = \mathbb{R} \rhd\!\!\!< _\lambda \mathbb{R}^3$ with Lie algebra $b_+$. The group law in these coordinates is read off as usual from the product of plane waves, which also gives the coproduct of $\mathbb{C}[B_+]$ on the $p^\mu$. We have parametrized plane waves in this way (rather than the canonical way by the Lie algebra as before) in order to have a more manageable form for this. We do pay a price that in these coordinates group inversion is not simply $-p^\mu$, but

$$(\boldsymbol{p}, p^0)^{-1} = (-\mathrm{e}^{\lambda p^0}\boldsymbol{p}, -p^0)$$

which is also the action of the antipode $S$ on the abstract $p^\mu$ generators.

In particular, the right-invariant Haar measure on $B_+$ in these coordinates is the usual $\mathrm{d}^4 p$ so the

quantum group Fourier transform reduces to the usual one but normal ordered,

$$\mathcal{F}(f) = \int_{\mathbb{R}^4} \mathrm{d}^4 p\, f(p) \mathrm{e}^{\mathrm{i}p\cdot x} \mathrm{e}^{\mathrm{i}p^0 t}$$

(one can also Fourier transform with respect to the left-invariant measure $\mathrm{d}^4 p\, \mathrm{e}^{3\lambda p^0}$ on $B_+$). The inverse is again given in terms of the usual inverse transform if we specify general fields $\psi$ in $\mathbb{R}^{1,3}_\lambda$ by normal ordering of usual functions, which we shall do. As before, the action of elements of $\mathbb{C}[B_+]$ defines differential operators on $\mathbb{R}^{1,3}_\lambda$ and these act diagonally on plane waves.

We also have a natural DGA with

$$(\mathrm{d}x_j)x_\mu = x_\mu \mathrm{d}x_j, \qquad (\mathrm{d}t)x_\mu - x_\mu \mathrm{d}t = \mathrm{i}\lambda \mathrm{d}x_\mu$$

which leads to the partial derivatives

$$\partial^i \psi =: \frac{\partial}{\partial x_i}\psi(x,t) := \mathrm{i}p^i.\psi$$

$$\partial^0 \psi =: \frac{\psi(x, t+\mathrm{i}\lambda) - \psi(x,t)}{\mathrm{i}\lambda} := \frac{\mathrm{i}}{\lambda}(1 - \mathrm{e}^{-\lambda p^0}).\psi$$

for normal-ordered polynomial functions $\psi$ or in terms of the action of the coordinates $p^\mu$ in $\mathbb{C}[B_+]$. These $\partial^\mu$ do respect our implicit $*$-structure (unitarity) on $\mathbb{R}^{1,3}_\lambda$ but in a Hopf algebra sense which is not the usual sense, since the action of the antipode $S$ is not just $-p^\mu$. This can be remedied by using adjusted derivatives $L^{-(1/2)}\partial^\mu$ where

$$L\psi =: \psi(x, t+\mathrm{i}\lambda) := \mathrm{e}^{-\lambda p^0}.\psi$$

In this case the natural 4D Laplacian is $L^{-1}((\partial^0)^2 - \sum_i (\partial^i)^2)$, which acts on plane waves as

$$-\frac{2}{\lambda^2}(\cosh(\lambda p^0) - 1) + \boldsymbol{p}^2 \mathrm{e}^{\lambda p^0}$$

where

$$\boldsymbol{p}^2 = \sum_{i=1}^{3} p_{i^2}$$

This deforms the usual Laplacian in such a way as to remain invariant under the Lorentz group (which now acts nonlinearly on $B_+$ in this model) and under group inversion.

This model may provide the first experimental test for noncommutative spacetime and cogravity. For the analysis of an experiment, we assume the identification of noncommutative waves in the above normal-ordered form with classical ones that a detector might register. In that case one may argue (Amelino-Camelia and Majid 2000) that the dispersion relation for such waves has the classical derivation as $\partial p^0/\partial p^i$ which now computes as propagation speed for a massless particle:

$$\left|\frac{\partial p^0}{\partial \boldsymbol{p}}\right| = \mathrm{e}^{\lambda p^0}$$

in units where 1 is the usual speed of light. So the prediction is that the speed of light depends on energy. What is remarkable is that even if $\lambda \sim 10^{-44}$ s (the Planck timescale), this prediction could in principle be tested, for example using $\gamma$-ray bursts. These are known in some cases to travel cosmological distances before arriving on Earth, and have a spread of energies from 0.1–100 MeV. According to the above, the relative time delay $\Delta_t$ on traveling distance $L$ for frequencies corresponding to $p^0, p^0 + \Delta_{p^0}$ is

$$\Delta_t \sim \lambda \Delta_{p^0} \frac{L}{c} \sim 10^{-44}\mathrm{s} \times 100\,\mathrm{MeV} \times 10^{10}\mathrm{y} \sim 1\,\mathrm{ms}$$

which is in principle observable by statistical analysis of a large number of bursts correlated with distance (determined, e.g., by using the Hubble telescope to lock in on the host galaxy of each burst). Although the above is only one of a class of predictions, it is striking that even Planck-scale effects are now in principle within experimental reach.

We now explain what happens to the full Poincaré symmetry here. The nonlinear action of the Lorentz group on $B_+$ Fourier transforms to an action on the generators of $\mathbb{R}^{1,3}_\lambda$, which combines with the above action of the $p^\mu$ to generate an entire Poincaré quantum group $U(so_{1,3}) \triangleright\!\!\blacktriangleleft \mathbb{C}[B_+]$. We will say more about its "bicrossproduct" structure in a later section. The above wave operator in momentum space is the natural Casimir in these momentum coordinates. A common mistake in the literature for this model is to suppose that the Casimir relation alone amounts to a physical prediction, whereas in fact the momentum coordinates are arbitrary and have meaning only in conjunction with the plane waves that they parametrize. The deformed Poincaré as an algebra alone is actually isomorphic to the undeformed one by a different choice of generators, so by itself has no physical content; one needs rather the noncommutative spacetime as well. Prior work on the relevant deformed Poincaré algebra either did not consider it acting on spacetime or took it acting on classical (commutative) Minkowski spacetime with inconsistent results (there is no such action as a quantum group).

The above model was introduced by Majid and Ruegg (1994) and later tied up with a dual approach of Woronowicz. There is also a previous "$\kappa$-Poincaré" version of the Hopf algebra alone obtained (Lukierski *et al.* 1991) in another context (by contraction of $U_q(so_{2,3})$) but with fundamentally different generators and relations and hence different physical content (e.g., the Lorentz

generators there do not close among themselves but mix with momentum).

3. The usual Heisenberg algebra of quantum mechanics is another possible noncommutative (phase) space; one may also take the same algebra and view it as a noncommutative spacetime, so:

$$\mathbb{R}^{1,3}_\theta: \quad [x_\mu, x_\nu] = \mathrm{i}\theta_{\mu\nu}$$

for any antisymmetric tensor $\theta_{\mu\nu}$. This is not a Hopf algebra but it turns out that this model can also be completely solved by Hopf algebra methods, namely the theory of covariant twists. Twist models also include versions of the noncommutative torus studied by Connes, and related $\theta$-spaces, which are nontrivial at the level of $C^*$-algebras. However, at an algebraic level, all covariant structures are automatically provided by applying the twisting functor $\mathcal{T}$ to the desired classical construction (*see* Hopf Algebras and $q$-Deformation Quantum Groups). This is not usually appreciated in the physics literature on such models, but see Oeckl (2000).

Thus, consider $H = U(\mathbb{R}^{1,3})$ with generators $p^\mu = -\mathrm{i}\partial^\mu$ acting as usual on functions on Minkowski space. It has a cocycle

$$F = \mathrm{e}^{(\mathrm{i}/2)p^\mu \otimes p^\nu \theta_{\mu\nu}}$$

which induces a new product $\bullet$ on functions by $\phi \bullet \psi = \cdot(F^{-1}(\phi \otimes \psi))$. This is just the standard Moyal product, in the present case on $\mathbb{R}^{1,3}$, viewed as a covariant twist using Hopf algebra methods. The Hopf algebra $U(\mathbb{R}^{1,3})$ in principle has a twisted coproduct given by $\Delta_F = F(\Delta(\ ))F^{-1}$ but this does not change as the algebra is commutative.

Next, $H$ also acts covariantly on $\Omega(\mathbb{R}^{1,3})$, the usual algebra of differential forms, and twisting this in the same way gives

$$\psi(x) \bullet \mathrm{d}x_\mu = \psi \mathrm{d}x_\mu = (\mathrm{d}x_\mu)\psi = (\mathrm{d}x_\mu) \bullet \psi$$

unchanged. This is because no terms higher than $p^\mu \otimes p^\nu \theta_{\mu\nu}$ contribute and then $\mathrm{d}(1) = 0$. The associated partial derivatives defined by d are likewise unchanged and act in the usual way as derivations with respect to both the $\bullet$ product and the undeformed product. The result may look different when the same $\psi(x)$ is expressed as a function of the variables with the $\bullet$ product. In other words, the only deformation comes from the Moyal product itself, with the rest being automatic. Moreover, the plane waves themselves are unchanged because $(x \cdot k)^{\bullet n} = (x \cdot k)^n$ due to $\theta$ being antisymmetric. Hence,

$$\psi_k(x) = \mathrm{e}_\bullet^{\mathrm{i}x\cdot k} = \mathrm{e}^{\mathrm{i}x.k}, \qquad p^\mu \psi_k(x) = k^\mu \psi_k(x)$$

where $p^\mu = -\mathrm{i}\partial^\mu$. The wave operator $-\partial_\mu\partial^\mu$ is therefore given by the action of $p_\mu p^\mu$ and has value $k_\mu k^\mu$ as usual on plane waves. On the other hand,

$$\psi_k \bullet \psi_{k'} = \mathrm{e}^{(\mathrm{i}/2)k^\mu k'^\nu \theta_{\mu\nu}} \psi_{k+k'}$$

or in algebraic terms the twist functor $\mathcal{T}$ applied to the Fourier transform implies also a twisted coproduct or coaddition law for the abstract $k^\mu$ generators, now different from the linear one for the covariance momentum operators $p^\mu$. This leads to some of the more interesting features of the model.

One immediately also has a Poincaré quantum group here, $U_\theta(\mathrm{poinc}_{1,3})$, obtained by similarly twisting the classical $U(\mathrm{poinc}_{1,3})$. We just view $F$ as living here rather than in the original $H$. The translation sector is unchanged as before but if $M^{\alpha\beta}$ are the usual Lorentz generators, then

$$\begin{aligned}\Delta_F M^{\alpha\beta} = {}& M^{\alpha\beta} \otimes 1 + 1 \otimes M^{\alpha\beta} \\ & + \tfrac{1}{2}(p^\alpha \otimes \theta^\beta{}_\mu p^\mu - \theta^\beta{}_\mu p^\mu \otimes p^\alpha) \\ & - \tfrac{1}{2}(p^\beta \otimes \theta^\alpha{}_\mu p^\mu - \theta^\alpha{}_\mu p^\mu \otimes p^\beta)\end{aligned}$$

using the metric $\eta_{\mu\nu}$ to raise or lower indices. The antipode is also modified according to the theory in Majid (1995). The relations in the Poincaré algebra are not modified (so, e.g., $p_\mu p^\mu$ will remain central). Any construction originally Poincaré covariant becomes covariant under this twisted one after application of the twisting functor. As with the differentials above, the action on $\mathbb{R}^{1,3}_\theta$ is not actually modified but may appear so when functions are expressed in terms of the $\bullet$ product.

The above model is popular at the time of writing in connection with string theory. Here, an effective description of the endpoints of open strings landing on a fixed 4-brane has been modeled conveniently in terms of the $\bullet$ product above (Seiberg and Witten 1999). It should be borne in mind, however, that this fixed 4-brane lives in some of the higher dimensions of the string spacetime, so this is not necessarily a prediction of noncommutative spacetime $\mathbb{R}^{1,3}$.

In fact, a proposal superficially similar to $\mathbb{R}^{1,3}_\theta$ above was already proposed in Snyder (1947). Here

$$[x^\mu, x^\nu] = \mathrm{i}\lambda^2 M^{\mu\nu}$$

where $\lambda$ is our length scale and the $M^{\mu\nu}$ are now operators with the usual commutation rules for the Lorentz algebra with themselves and with $x^\mu$ and the momenta $p^\mu$. The latter obey

$$[p^\mu, x^\nu] = \mathrm{i}(\eta^{\mu\nu} - \lambda^2 p^\mu p^\nu), \quad [p^\mu, p^\nu] = 0$$

so the entire Poincaré algebra is undeformed but the phase-space relations are deformed. Snyder also constructed the orbital angular momentum realization $M^{\mu\nu}=x^\mu p^\nu - x^\nu p^\mu$. This model is not a proposal for a noncommutative spacetime because the algebra does not even close among the $x^\mu$. Rather it is a proposal for "mixing" of position and Lorentz generators. On the other hand (which was the point of view in Snyder (1947)), in any representation of the Poincaré algebra, the $M^{\mu\nu}$ become operators and in some sense numerical. The rotational sector has discrete eigenvalues as usual, so to this extent the spacetime has been discretized. Although not fitting into the methods in this article, it is also of interest that the relations above were motivated by considering $p^\mu$ as coordinates projected from a 5D flat space to de Sitter space and $x^\mu$ as the 5-component of orbital angular momentum in the flat space.

To conclude this section, let us note that there are further models that we have not included for lack of space. One of them is a much-studied $\mathbb{R}_q^{1,3}$ in which $t$ is central but the $x_i$ enjoy complicated $q$-relations best understood as $q$-deformed Hermitian matrices. One of the motivations in the theory was the result in Majid (1990) that $q$-deformation could be used to regularize infinities in quantum field theory as poles at $q=1$. Another entire class is to use noncommutative geometry and quantum group methods on finite or discrete spaces. Unlike lattice theory where a finite lattice is viewed as approximation, these models are not approximations but exact noncommutative geometries valid even on a few points. The noncommutativity enters into the fact that finite differences are bilocal and hence naturally have different left and right multiplications by functions. Both aspects are mentioned briefly in the overview article (*see* Hopf Algebras and $q$-Deformation Quantum Groups). Also, on the experimental front, another large area that we have not had room to cover is the prediction of modified uncertainty relations both in spacetime and phase space (Kempf *et al.* 1995).

Moreover, for all of the models above, once one has a noncommutative differential calculus one may proceed to gauge theory etc., on noncommutative spacetimes, at least at the level where a connection is a noncommutative (anti-Hermitian) 1-form $\alpha$. Gauge transformations are invertible (unitary) elements $u$ of the noncommutative "coordinate algebra" and the connection and curvature transform as

$$\alpha \to u^{-1}\alpha u + u^{-1}\,\mathrm{d}u$$
$$F(\alpha) = \mathrm{d}\alpha + \alpha\wedge\alpha \to u^{-1}F(\alpha)u$$

The full extent of quantum bundles and gravity (*see* Quantum Group Differentials, Bundles and Gauge Theory) and quantum field theory is not always possible, although both have been done for covariant twist examples (for functorial reasons) and for small finite sets. For the first two models above, for example, it is not clear at the time of writing how to interpret scattering when the addition of momenta is nonabelian.

## Matched Pair Equations

Although we have presented noncommutative spacetime first, the first actual application of quantum group methods to Planck-scale physics was the Planck-scale Hopf algebra obtained by a theory of bicrossproducts. Like the Snyder model, the intention here was to deform phase space itself, but since then bicrossproducts have had many further applications. The main ingredient here is the notion of a pair of groups $(G, M)$, say, acting on each other as we explain now. The mathematics here goes back to the early 1910s in group theory, but also arose in mathematical physics as a toy version of Einstein's equation in the sense of compatibility between quantization and curvature (see the next section).

By definition, $(G, M)$ are a matched pair of groups if there are left and right actions

$$M \overset{\triangleleft}{\longleftarrow} M\times G \overset{\triangleright}{\rightarrow} G$$

of each group on the set of the other, such that

$$s\triangleleft e = s,\quad e\triangleright u = u,\quad s\triangleright e = e,\quad e\triangleleft u = e$$
$$(s\triangleleft u)\triangleleft v = s\triangleleft(uv),\ s\triangleright(t\triangleright u) = (st)\triangleright u$$
$$s\triangleright(uv) = (s\triangleright u)((s\triangleleft u)\triangleright v)$$
$$(st)\triangleleft u = (s\triangleleft(t\triangleright u))(t\triangleleft u)$$

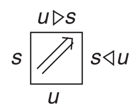
for all $u, v \in G, s, t \in M$. Here $e$ denotes the relevant group unit element. As a first application of such data, one may make a "double cross product group" $G\bowtie M$ with product

$$(u,s).(v,t) = (u(s\triangleright v), (s\triangleleft v)t)$$

and with $G$, $M$ as subgroups. Since it is built on the direct product space, the bigger group factorizes into these subgroups. Conversely, if $X$ is a group factorization such that the product $G\times M\to X$ is bijective, each group acts on the other by actions $\triangleright, \triangleleft$ defined by $su=(s\triangleright u)(s\triangleleft u)$ for $u\in G$ and $s\in M$, where $s$, $u$ are multiplied in $X$ and the product is factorized as something in $G$ and something in $M$. So finite group matched pairs are equivalent to group factorizations. In the Lie group context, the

corresponding system of differential equations is equivalent to a local factorization.

There is a nice graphical representation of the matched pair conditions which relates to "surface integration." Thus, consider squares



labeled by elements of $M$ on the left edge and elements of $G$ on the bottom edge. We can fill in the other two edges by thinking of an edge transformed by the other edge as it goes through the square either horizontally or vertically, the two together is the surface transport $\Rightarrow$ across the square. The matched pair equations have the meaning that a square can be subdivided either vertically or horizontally as shown in Figure 2, where the labeling on vertical edges is to be read from top down. The transport operation here is nothing other than normal ordering in the factorizing group. In the Lie setting, it means that the equations can be solved from infinitesimal solutions (a matched pair of Lie algebras) by a simultaneous double integration over the group (i.e., building up a large box from many small ones). If one considers solving the quantum Yang–Baxter equations on groups, they appear in this notation as an equality of surface transport going two ways around a cube, and the classical Yang–Baxter equations as curvature of the underlying higher-order connection.

Also in this notation there is a bicrossproduct quantum group defined in Figure 3, at least when $M$ is finite. The expressions are considered zero unless the juxtaposed edges have the same group labels. In that case, the product is a semidirect product algebra $\mathbb{C}(M){>\!\!\triangleleft}\mathbb{C}G$ of functions on $M$ by the group algebra of $G$. The coproduct is the adjoint of

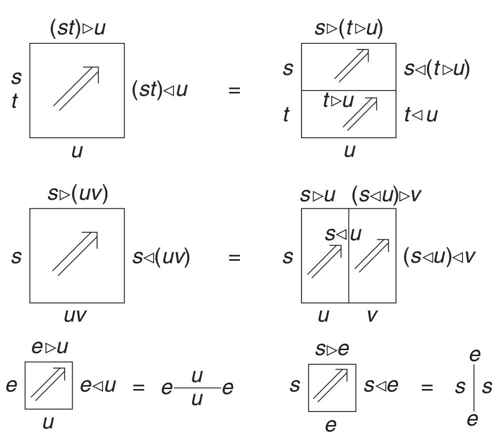


**Figure 2** Matched pair condition as a subdivision property.

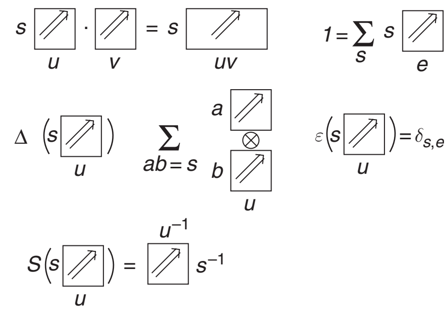

**Figure 3** Bicrossproduct Hopf algebra showing horizontal product and vertical coproduct as an "unproduct."

this, so is a semidirect coalgebra $\mathbb{C}(M){\blacktriangleright\!\!<}\mathbb{C}G$. Hence the two together are denoted $\mathbb{C}(M){\blacktriangleright\!\!\triangleleft}\mathbb{C}G$. The dual needs $G$ finite and has the same form but with vertical and horizontal compositions interchanged, that is, a bicrossproduct $\mathbb{C}M{\triangleright\!\!\blacktriangleleft}\mathbb{C}(G)$. Both Hopf algebras have the above labeled squares as basis.

It is possible to generalize both bicrossproducts and double cross products associated to matched pairs to general Hopf algebras $H_1{\blacktriangleright\!\!\triangleleft}H_2$ and $H_1{\bowtie}H_2$, respectively, where $H_1, H_2$ are Hopf algebras (*see* Majid 1990) and to relate the two in general by dualization of one factor. Another general result (Majid 1995) is that $H_1{\blacktriangleright\!\!\triangleleft}H_2$ acts covariantly on the algebra $H_1^*$ from the right, or $H_1{\triangleright\!\!\blacktriangleleft}H_2$ acts covariantly on $H_2^*$ from the left. A third general result is that bicrossproducts solve the extension problem

$$H_1 \to H \to H_2$$

meaning that such a Hopf algebra $H$ subject to some technical requirements (such as an algebra splitting map $H_2 \to H$) is of the form $H \cong H_1{\blacktriangleright\!\!\triangleleft}H_2$. The theory was also extended to include cocycle bicrossproducts at the end of the 1980s (by the author). The finite group case, however, was first found by Kac and Paljutkin (1966) in the Russian literature and later rediscovered independently in Takeuchi (1981) and in the course of Majid (1988).

## The Planck-Scale Hopf Algebra

We consider a quantum algebra of observables $H$ and ask when it is a Hopf algebra extending some classical position coordinate algebra $\mathbb{C}[M]$ and some possibly noncommutative momentum coordinate algebra $U(\mathfrak{g})$ in the form of a strict extension

$$\mathbb{C}[M] \to H \to U(\mathfrak{g})$$

From the theory above this problem is governed by local solutions of the matched pair equations on $(G, M)$. It requires that $H \cong \mathbb{C}[M]{>\!\!\triangleleft}U(\mathfrak{g})$ as an algebra, that is,

the quantization of a particle moving on orbits in $M$ under some action of $G$ (in an algebraic setting, or one can use von Neumann or $C^*$-algebras etc.). And it requires the classical phase space to be a nonabelian or "curved" group $M \bowtie \mathfrak{g}^*$. This extends to a coproduct on $H$ which becomes the bicrossproduct Hopf algebra $\mathbb{C}[M] \blacktriangleright\!\!\triangleleft U(\mathfrak{g})$. In this way, the problem which was open at the start of the 1980s of finding true examples of Hopf algebras was given a physical interpretation as being equivalent to finding quantum-mechanical systems reconciled with curvature, and the equations that governed this were the matched pair ones (Majid 1988).

We still have to solve these equations. In the Lie case, they mean a pair of cross-coupled first-order equations on $G \times M$. These can be solved locally as a double-holonomy construction in line with the surface transport point of view, but are nonlinear typically with singularities in the noncompact case. The equations are also symmetric under interchange of $G, M$ so Born reciprocity between position and momentum is extended to the quantum system with generally "curved" position and momentum spaces. Moreover, in so far as Einstein's equation $G_{\mu\nu} = 8\pi T_{\mu\nu}$ is also a compatibility between a quantity in position space and a quantity originating (ultimately) in momentum space, the matched pair equations can be viewed as a toy version of these.

Let us note that the reason to look for $H$ a Hopf algebra in the first place, aside from the reasons already given, is for observer–observed symmetry (this was put forward as a postulate for Planck-scale physics). Thus, $H^*$ is also an algebra of observables of some dual system, in our case $U(\mathfrak{m}) \triangleright\!\!\blacktriangleleft \mathbb{C}[G]$ or particles in $G$ moving on orbits under $M$. Thus, Born reciprocity is truly implemented in the quantum/curved system by Hopf algebra duality. Put another way, Hopf algebras are the simplest objects after abelian groups that admit Fourier transform (*see* Hopf Algebras and $q$-Deformation Quantum Groups) and we require this on phase space if Born reciprocity is to be extended to the quantum/curved system.

The Planck-scale Hopf algebra is the simplest example of these ideas (Majid 1988). Here $G = M = \mathbb{R}$ and the matched pair equations can be solved completely. The general solution is

$$\hat{p} = i\hbar(1 - e^{-\gamma x})\frac{\partial}{\partial x}, \qquad \hat{x} = \frac{i}{\hbar}(1 - e^{-\hbar\gamma p})\frac{\partial}{\partial p}$$

for the action of one group with generator $p$ on functions of $x$ in the other group and vice-versa. It has two parameters which we have denoted as $\hbar$ and a background curvature scale $\gamma$, and the corresponding bicrossproduct $\mathbb{C}[p] \triangleright\!\!\blacktriangleleft \mathbb{C}[x]$ is

$$\begin{aligned} &[p, x] = i\hbar(1 - e^{-\gamma x}), \qquad \Delta x = x \otimes 1 + 1 \otimes x \\ &\Delta p = p \otimes e^{-\gamma x} + 1 \otimes p, \quad \epsilon x = \epsilon p = 0 \\ &Sx = -x, \qquad Sp = -pe^{\gamma x} \end{aligned}$$

where we should allow power series or take $e^{\gamma x}$ as an invertible generator.

It is important to note that the matched pair equations here have only this solution and it is necessarily singular at $p = 0$ or $x = 0$. The interpretation in position space is as follows. Consider an infalling particle of mass $m$ with fixed momentum $p = mv_\infty$ (in terms of the velocity at infinity). By definition, $p$ is the free-particle momentum and acts on $\mathbb{R}$ as above. This corresponds to a free-particle Hamiltonian $\hat{p}^2/2m$ and induces

$$\begin{aligned} &\dot{p} = 0 \\ &\dot{x} = \frac{p}{m}(1 - e^{-\gamma x}) = v_\infty\left(1 - \frac{1}{1 + \gamma x + \cdots}\right) \end{aligned}$$

at the classical level. We see that the particle takes an infinite time to reach the origin, which is an accumulation point. This can be compared with the formula in standard radial infalling coordinates

$$\dot{x} = v_\infty\left(1 - \frac{1}{1 + \frac{c^2 x}{2GM}}\right)$$

for distance $x$ from the event horizon of a black hole of mass $M$ (here $G$ is Newton's constant and $c$ the speed of light). So $\gamma \sim c^2/GM$ and for the sake of further discussion we will use this value. With a little more work, one can then see that

$$\begin{array}{l} mM \ll m_{\rm P}^2 \\ \mathbb{C}[x] \blacktriangleright\!\!\triangleleft \mathbb{C}[p] \begin{array}{l} \nearrow \mathbb{C}[x]\,\mathbb{C}[p] \text{usual qu. mech.} \\ \searrow \mathbb{C}(X) \text{usual curved geometry} \end{array} \\ mM \gg m_{\rm P}^2 \end{array}$$

where $m_{\rm P}$ is the Planck mass of the order of $10^{-5}$ g and $X = \mathbb{R} \triangleright\!\!< \mathbb{R}$ is a nonabelian group. In the first limit, the particle motion is not detectably different from usual flat space quantum mechanics outside the Compton wavelength from the origin. In the second limit, the estimate is such that noncommutativity would not show up for length scales much larger than the background curvature scale.

This Hopf algebra is also the simplest way to extend classical position $\mathbb{C}[x]$ and momentum $\mathbb{C}[p]$ in the sense above. In other words, requiring to maintain observer–observed symmetry or Born reciprocity throws up both quantum mechanics (in the form of $\hbar$) and something with the flavor of

gravity (in the form of $\gamma$) and both are required for a nontrivial Hopf algebra. Moreover, the construction necessarily has a self-dual form and indeed the dually paired Hopf algebra is $\mathbb{C}[p]\triangleright\!\!\blacktriangleleft\mathbb{C}[x]$ with new parameters $\hbar' = 1/\hbar$ and $\gamma' = \hbar\gamma$ if we take the standard pairing $x, p$ across the two algebras. Hopf algebra duality realized by the quantum group Fourier transform $\mathcal{F}$ takes one between the two models.

## Bicrossproduct Poincaré Quantum Groups

Another example from the 1980s in the same family as the Planck-scale Hopf algebra is $G = SU_2$ and $M = B_+$, a nonabelian version of $\mathbb{R}^3$ with Lie algebra $b_+$ of the form

$$[x_3, x_i] = \mathrm{i}\lambda x_i, \qquad [x_i, x_j] = 0$$

for $i = 1, 2$. The required solution of the matched pair equations was found in Majid (1990) and has a nonlinear action of rotations on $B_+$. The interpretation of $\mathbb{C}[B_+]\blacktriangleright\!\!\triangleleft U(su_2)$ is of particles moving along orbits which are deformed spheres in $B_+$, and there is a dual model where particles move instead on orbits in $SU_2$ under the action of $b_+$. Moreover, from the general theory of bicrossproducts, we automatically have a covariant action of $\mathbb{C}[B_+]\blacktriangleright\!\!\triangleleft U(su_2)$ on the auxiliary noncommutative space $\mathbb{R}^3_\lambda = U(b_+)$ with relations as above.

The quantum group here was actually obtained as a Hopf–von Neumann algebra but we limit ourselves to the underlying algebraic version. Also, there is of course nothing stopping one considering this Hopf algebra equally well as $U_\lambda(\mathrm{poinc}_3)$, that is, a deformation of the group of motions on $\mathbb{R}^3$, rather than as an algebra of observables. The only difference is to denote the generators of $\mathbb{C}[B_+]$ by the symbols $p^i$, reserving $x_i$ instead for the auxiliary noncommutative space. We lower $i, j, k$ indices using the Euclidean metric. Then the bicrossproduct has the form

$$[p_i, p_j] = 0, \qquad [M_i, M_j] = \mathrm{i}\epsilon_{ij}{}^k M_k$$
$$[M_3, p_j] = \mathrm{i}\epsilon_{3j}{}^k p_k, \qquad [M_i, p_3] = \mathrm{i}\epsilon_{i3}{}^k p_k$$

as usual, for $i, j = 1, 2, 3$, and the modified relations

$$[M_i, p_j] = \frac{\mathrm{i}}{2}\epsilon_{ij}{}^3\left(\frac{1 - \mathrm{e}^{-2\lambda p_3}}{\lambda} - \lambda \boldsymbol{p}^2\right) + \mathrm{i}\lambda\epsilon_i{}^{k3} p_j p_k$$

for $i, j = 1, 2$ and $\boldsymbol{p}^2 = p_1^2 + p_2^2$. The coproducts are

$$\Delta M_i = M_i \otimes \mathrm{e}^{-\lambda p_3} + \lambda M_3 \otimes p_i + 1 \otimes M_i$$
$$\Delta p_i = p_i \otimes \mathrm{e}^{-\lambda p_3} + 1 \otimes p_i$$

for $i = 1, 2$ and the usual additive ones for $p_3, M_3$. There is also an appropriate counit and antipode. The deformed spheres under the nonlinear rotation in Majid (1990) are constant values of the Casimir for the above algebra. This is

$$\frac{2}{\lambda^2}(\cosh(\lambda p_3) - 1) + \boldsymbol{p}^2 \mathrm{e}^{\lambda p_3}$$

which from the group of motions point of view generates the noncommutative Laplacian when acting on $\mathbb{R}^3_\lambda$. The model here is a Euclidean inhomogeneous one.

The four-dimensional (4D) version $U(so_{1,3})\triangleright\!\!\blacktriangleleft\mathbb{C}[B_+]$ of this construction (Majid and Ruegg 1994) is again linked to Planck-scale predictions, this time as a generalized symmetry. In terms of translation generators $p^\mu$, rotations $M_i$ and boosts $N_i$ we have

$$[p^\mu, p^\nu] = 0, \qquad [M_i, M_j] = \mathrm{i}\epsilon_{ij}{}^k M_k$$
$$[N_i, N_j] = -\mathrm{i}\epsilon_{ij}{}^k M_k, \qquad [M_i, N_j] = \mathrm{i}\epsilon_{ij}{}^k N_k$$
$$[p^0, M_i] = 0, \qquad [p^i, M_j] = \mathrm{i}\epsilon^i{}_{jk} p^k, \qquad [p^0, N_i] = -\mathrm{i}p_i$$

as usual, and the modified relations and coproduct

$$[p^i, N_j] = -\frac{\mathrm{i}}{2}\delta^i_j\left(\frac{1 - \mathrm{e}^{-2\lambda p^0}}{\lambda} + \lambda\boldsymbol{p}^2\right) + \mathrm{i}\lambda p^i p_j$$
$$\Delta N_i = N_i \otimes 1 + \mathrm{e}^{-\lambda p^0} \otimes N_i + \lambda\epsilon_{ijk} p^j \otimes M_k$$
$$\Delta p^i = p^i \otimes 1 + \mathrm{e}^{-\lambda p^0} \otimes p^i$$

and the usual additive coproducts on $p^0, M_i$. This time the Lorentz group orbits in $B_+$ are deformed hyperboloids rather than deformed spheres, and the Casimir that controls this has the same form as above but with $-$ in the cosh term, that is, the model is a Lorentzian one. We know from the general theory of bicrossproducts that this Hopf algebra acts on $U(b_+) = \mathbb{R}^{1,3}_\lambda$ the spacetime in the section "Cogravity," and the Casimir induces the wave operator as we have seen there.

Let us look a bit more closely at the deformed hyperboloids. Because neither group here is compact, one expects from the general theory of bicrossproducts to have limiting accumulation regions. This is visible in the contour plot of $p^0$ against $|\boldsymbol{p}|$ in **Figure 4**, where the $p^0 > 0$ mass shells are now cups with almost vertical walls, compressed into the vertical tube

$$|\boldsymbol{p}| < \lambda^{-1}$$

In other words, the 3-momentum is bounded above by the Planck momentum scale (if $\lambda$ is the Planck time). Indeed, the light-cone equation (setting the Casimir to zero) reads $\lambda|\boldsymbol{p}| = 1 - \mathrm{e}^{-\lambda p_3}$ so this is

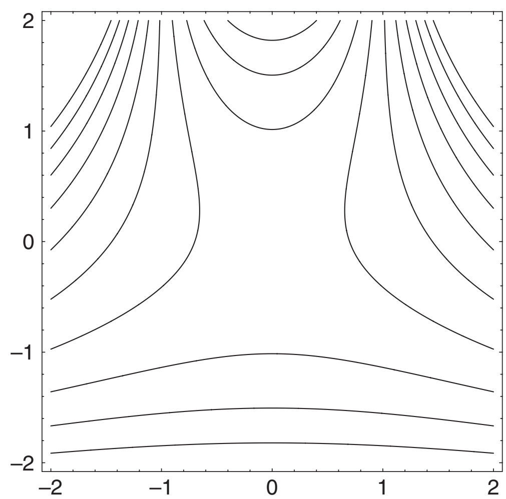

**Figure 4** Deformed mass-shell orbits in the bicrossproduct curved momentum space for $\lambda = 1$.

immediate. Nevertheless, this observation is so striking that the bicrossproduct model has been dubbed "doubly special" and spawned the search for other such models. Such accumulation regions are a main discovery of the noncompact bicrossproduct theory visible already in the Planck-scale Hopf algebra. The model further confirms the role of the matched pair equations as a toy version of Einstein's.

## Poisson–Lie *T*-Duality

We have explained in Section 3 that the matched pair equations are equivalent to a local factorization of Lie groups, with the action and back-reaction created "equally and oppositely" from this. For the two models in the last section, these are $SL_2(\mathbb{C})$ factorizing as $SU_2$ and a 3D $B_+$, and $SO_{2,3}$ locally as $SO_{1,3}$ and a 4D $B_+$. The first of these examples is in fact one of a general family based on the Iwasawa decomposition $G_{\mathbb{C}} = G \bowtie G^*$ where $G$ is a compact Lie group with complexification $G_{\mathbb{C}}$ and $G^*$ a certain solvable group. From this, one may construct a solution $(G, G^*)$ of the matched pair equations and bicrossproduct quantum group

$$\mathbb{C}[G^*] \blacktriangleright\!\!\triangleleft U(\mathfrak{g})$$

associated to all complex simple Lie algebras. This is again part of the bicrossproduct theory from the 1980s. On the other hand, the Lie algebra $\mathfrak{g}^*$ here can be identified with the dual of $\mathfrak{g}$ in which case its Lie algebra corresponds to a Lie coproduct $\delta : \mathfrak{g} \to \mathfrak{g} \otimes \mathfrak{g}$ and makes $(\mathfrak{g}, \delta)$ into a Lie bialgebra in the sense of Drinfeld. This $\delta$ exponentiates to a Poisson bracket on $G$ making it a "Poisson–Lie group" and the quantization of this is provided by the quantum group coordinate algebras $\mathbb{C}_q[G]$ (*see* Hopf Algebras and $q$-Deformation Quantum Groups and Classical $r$-matrices, Lie Bialgebras, and Poisson Lie Groups). The bicrossproduct quantum groups are nevertheless unrelated to the latter even though they spring form related classical data.

As already discussed, one interpretation here is of quantized particles in $G^*$ moving on orbits under $G$ and in vice versa in the dual model. The dual model is equivalent in the sense that the states of one (in the sense of positive-linear functionals) lie in the algebra of observables of the other and we also saw in the Planck-scale example inversion of structure constants reminiscent of $T$-duality in string theory. Motivated in part by this duality Klimcik (1996) along with Severa in the mid 1990s showed that indeed a $\sigma$-model on $G$ could be constructed in such a way that there was a matching dual $\sigma$-model on $G^*$ in some sense equivalent in terms of solutions to the equations of motion. The Lagrangians here have the usual form

$$\mathcal{L} = E_u(u^{-1}\partial_+ u, u^{-1}\partial_- u),$$
$$\hat{\mathcal{L}} = \hat{E}_s(s^{-1}\partial_+ s, s^{-1}\partial_- s)$$

where $u : \mathbb{R}^{1,1} \to G$ and $s : \mathbb{R}^{1,1} \to G^*$ are the dynamical fields, except that the inner products $E, \hat{E}$ are not constant. Rather they are obtained by solving nonlinear differential equations on the groups defined through the structure constants of $\mathfrak{g}, \mathfrak{g}^*$ and the Drinfeld double $D(\mathfrak{g})$. At the time, $T$-duality here was well understood in the case of abelian groups while these Poisson–Lie $T$-duality models provided the first convincing nonabelian models.

This construction was extended by Beggs and Majid (2001) to a general matched pair $(G, M)$, that is, a $\sigma$-model on $G$ dual to one on $M$. The Poisson–Lie case is the special case where the actions are coadjoint actions and the Lie algebra of $G \bowtie M$ is $D(\mathfrak{g})$. The solutions of the equations of motion for the two systems are created "equally and oppositely" from one on the factorizing group. It could be expected that $T$-duality ideas again play a role in Planck-scale physics.

## Other Bicrossproducts

There are also infinite-dimensional factorizations such as the Riemann–Hilbert problem (*see* Riemann–Hilbert Problem) in the theory of integrable systems and hence infinite-dimensional matched pairs and bicrossproducts linked to

them. Here we mention just one partly infinite example of current interest.

Thus, the diffeomorphisms on the line $\mathbb{R}$ may be factorized into transformations of the form $ax + b$ and diffeomorphisms that fix the origin and have unit differential there. After a (logarithmic) change of generators to arrive at an algebraic picture, one has a bicrossproduct

$$H(1) = U(b_+) \triangleright\!\!\blacktriangleleft H_\infty$$

where $b_+$ is now the two-dimensional (2D) Lie algebra with relations $[x, y] = x$ and $H_\infty$ is the algebra of polynomials in generators $\delta_n$ and a certain coalgebra as a model of the coordinate algebra of the group of diffeomorphisms that fix the origin with unit differential. The Hopf algebra $H(1)$ was introduced by Connes and Moscovici (1998) although not actually as a bicrossproduct (but motivated by the bicrossproduct theory) as part of a family $H(n)$ useful in cyclic cohomology computations. It has cross relations and coproduct determined by

$$[\delta_n, x] = \delta_{n+1}, \qquad [\delta_n, y] = n\delta_n,$$
$$\Delta\delta_1 = \delta_1 \otimes 1 + 1 \otimes \delta_1$$
$$\Delta x = x \otimes 1 + 1 \otimes x + \delta_1 \otimes y,$$
$$\Delta y = y \otimes 1 + 1 \otimes y$$

which we see has a semidirect product form where $\delta_n \triangleleft x = \delta_{n+1}, \delta_n \triangleleft y = n\delta_n$. The coalgebra is also a semidirect coproduct by means of a back-reaction of $H_\infty$ in $B_+$ (expressed as a coaction). From the bicrossproduct theory, we also have a dual model

$$\mathbb{C}[B_+] \blacktriangleright\!\!\triangleleft U(\mathrm{diff}_0)$$

where $\mathrm{diff}_0$ is the Lie algebra of the group of diffeomorphisms fixing the origin. As such it could be viewed as in the family of examples in the section "Bicrossproduct Poincaré quantum groups" but now with a 2D $B_+$. We also conclude from the bicrossproduct theory that this acts covariantly on $\mathbb{R}^2_\lambda = U(b_+)$ after introducing the scaling parameter $\lambda$.

Finally, the Hopf algebra $H(1)$ is also part of a family of bicrossproduct Hopf algebras built on rooted trees and related to bookkeeping of overlapping divergences in renormalizable quantum field theories (*see* Hopf Algebra Structure of Renormalizable Quantum Field Theory). While we have not had room to cover all bicrossproduct quantum groups of interest, it would appear that bicrossproducts are indeed intimately tied up with actual quantum physics.

# Bifurcation Theory

**M Haragus**, Université de Franche-Comté, Besançon, France
**G Iooss**, Institut Non Linéaire de Nice, Valbonne, France

## Introduction

Consider the following equation:

$$F(X, \mu) = 0 \qquad [1]$$

where $X$ is the variable, $\mu$ is a parameter, and $X, \mu, F$ belong to appropriate (finite- or infinite-dimensional) spaces. The problem of *bifurcation theory* is to *describe the singularities of the set of solutions*

$$S_\mu = \{X; (X, \mu) \text{ satisfies } F(X, \mu) = 0\}$$

The word "bifurcation" was introduced by H Poincaré (1885) in his study of equilibria of rotating liquid masses.

The simplest example is the study of the real roots $x$ of a quadratic polynomial

$$x^2 + bx + c = 0 \qquad [2]$$

where $\mu$ is represented by the pair of parameters $(b, c) \in \mathbb{R}^2$. As it is well known, real roots are determined by the sign of

$$\Delta \overset{\text{def}}{=} b^2 - 4c$$

For $\Delta < 0$, there is no real solution of [2], while there are two solutions $x_\pm$ in the region $\Delta > 0$, which merge when the distance between the point $(b, c)$ and the parabola $\Delta = 0$ tends towards 0. It is then clear that a *singularity occurs in the structure of the set of solutions of* [2] *at the crossing of the parabola* $\Delta = 0$ or, in other words, a *bifurcation occurs in the parameter space* $(b, c)$ *on the parabola* $\Delta = 0$. A point $(\mu_0, x_0) \in \mathbb{R}^3$ is then called a *bifurcation point* if $\mu_0 = (b, c)$ satisfies $\Delta = 0$, and $x_0 = -b/2$.

In the theory of differential equations, $F(X, \mu)$ often represents a vector field. This study is then concerned with the existence of equilibrium solutions to the differential equation

$$\frac{\mathrm{d}X}{\mathrm{d}t} = F(X, \mu) \qquad [3]$$

and is therefore referred to as *static bifurcation theory*. In addition, *dynamic bifurcation theory* is concerned here with "changes" in the dynamic properties of the solutions of the differential equation as $\mu$ varies. A widely used way to characterize these "changes" is to say that the vector field $F(\cdot, \mu_0)$ is *structurally stable* if the sets of orbits of the differential equation are homeomorphic for $\mu$ close to $\mu_0$, with homeomorphisms which preserve the orientation of the orbits in time $t$. Then a bifurcation occurs at $\mu = \mu_0$ if $F(\cdot, \mu_0)$ is not structurally stable. It turns out that there is a close link between the stability properties of equilibrium solutions of the differential equation and the type of the bifurcation in static theory.

The tools developed in bifurcation theory are extensively used to solve concrete problems arising in physics and natural sciences. These problems may be modeled by ordinary or partial differential equations, integral equations, but also delay equations or iteration maps, and in all these cases the presence of parameters naturally leads to bifurcation phenomena. They can be regarded as problems of the form [1] or [3], in suitable function spaces, and bifurcation theory allows to detect solutions and to describe their qualitative properties. During the last decades, a class of problems in which the use of bifurcation theory led to significant progress is concerned with nonlinear waves in partial differential equations, including hydrodynamic problems, nonlinear water waves, elasticity, but also pattern formation, front propagation, or spiral waves in reaction–diffusion type systems.

## Examples in One and Two Dimensions

The most complete results in bifurcation theory are available in one and two dimensions. The study of static bifurcations in one dimension is concerned with scalar equations

$$f(x, \mu) = 0 \qquad [4]$$

where $x \in \mathbb{R}, \mu \in \mathbb{R}$, and the function $f$ is supposed to be regular enough with respect to $(x, \mu)$. When $f(x_0, \mu_0) = 0$ and the derivative of $f$ with respect to $x$ satisfies $\partial_x f(x_0, \mu_0) \neq 0$, the implicit function theorem gives a unique branch of solutions $x(\mu)$ for $\mu$ close to $\mu_0$, and shows the absence of bifurcation points near $(\mu_0, x_0)$. Bifurcation theory intervenes when

$$\partial_x f(x_0, \mu_0) = 0 \qquad [5]$$

and one cannot apply the implicit function theorem for solving with respect to $x$ near $x_0$. A complete description of the set of solutions near $(x_0, \mu_0)$ can be obtained by looking at the partial derivatives of $f$ with respect to $x$ and $\mu$.

For example, if

$$\partial_\mu f(x_0, \mu_0) \neq 0,$$

it is possible to solve with respect to $\mu$ and obtain a regular solution $\mu(x)$ such that $\mu(x_0) = \mu_0$ and $f(x, \mu(x)) \equiv 0$. In addition, if the second order derivative

$$\partial_x^2 f(x_0, \mu_0) \neq 0$$

the picture of the solution set in the plane $(\mu, x)$, also called *bifurcation diagram*, shows a turning point with a fold opened to the left or to the right depending upon the sign of the product $\partial_\mu f(x_0, \mu_0) \cdot \partial_x^2 f(x_0, \mu_0)$; see **Figure 1**. Notice that here the bifurcation point $(\mu_0, x_0) \in \mathbb{R}^2$ corresponds to the appearance of a pair of solutions of [4] "from nowhere". This is the simplest example of a *one-sided bifurcation* in which the bifurcating solutions exist for either $\mu > \mu_0$ or $\mu < \mu_0$.

A particularly interesting situation arises when the equation possesses a symmetry. For example, assume that in [4] the function $f$ is odd with respect to $x$. This implies that we always have the solution $x = 0$, for any value of the parameter $\mu$. Assume now that $f$ satisfies

$$\partial_x f(0, \mu_0) = 0 \qquad [6]$$

and that

$$\partial_{x\mu}^2 f(0, \mu_0) \neq 0, \qquad \partial_x^3 f(0, \mu_0) \neq 0 \qquad [7]$$

Then the point $(\mu_0, 0)$ is a *pitchfork bifurcation point*, this denomination being related with the bifurcation diagram in the plane $(\mu, x)$; see **Figure 2**. Notice that here, the bifurcation point $(\mu_0, x_0) \in \mathbb{R}^2$ corresponds to the bifurcation from the origin of a pair of solutions exchanged by the symmetry $x \to -x$, in addition to the persistent "trivial" solution $x = 0$ which is invariant under the above symmetry. Such a bifurcation is also referred to as a *symmetry-breaking bifurcation*. Similar bifurcation diagrams are found when the equation [4] has a "known" branch of

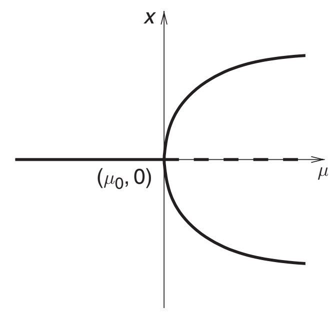

**Figure 2** Supercritical pitchfork bifurcation in the case $\partial_{x\mu}^2 f(0, \mu_0) > 0$ and $\partial_x^3 f(0, \mu_0) < 0$.. The solid (dashed) lines indicate the branch of stable (unstable) solutions in the differential equation.

solutions $x(\mu)$ for $\mu$ close to $\mu_0$. This situation arises often in applications where usually this branch consists of trivial solutions $x(\mu) = 0$. Then at a bifurcation point $(\mu_0, x_0)$ a second branch of solutions appears forming either a one-sided bifurcation, or a two-sided bifurcation; see **Figure 3.**

We can now view $f$ as a vector field in the ordinary differential equation

$$\frac{dx}{dt} = f(x, \mu) \qquad [8]$$

and the study above corresponds to looking for equilibrium solutions of [8]. The stability of such a solution is determined by the sign of the derivative $\partial_x f(x, \mu)$ of $f$ at this equilibrium, and it is closely related to the type of the static bifurcation.

In the case of a *turning point bifurcation*, when $\partial_x^2 f(x_0, \mu_0) \neq 0$, the sign of $\partial_x f(x, \mu)$ is different for the two bifurcating solutions. This means that one solution is attracting (i.e., stable), the other one being repelling (i.e., unstable); see **Figure 1**. In the case of a *pitchfork bifurcation* as above, the stability of the trivial solution $x = 0$ changes when $\mu$ crosses $\mu_0$, and the stability of both bifurcating nonzero solutions is the opposite from the stability of the origin on the side of the bifurcation. The bifurcation

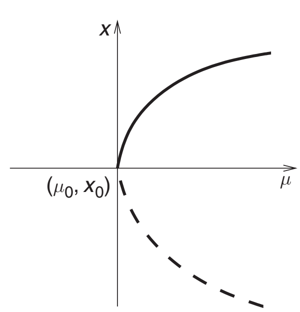

**Figure 1** Turning point bifurcation in the case $\partial_\mu f(x_0, \mu_0) > 0$ and $\partial_x^2 f(x_0, \mu_0) < 0$. The solid (dashed) line indicates the branch of stable (unstable) solutions in the differential equation.

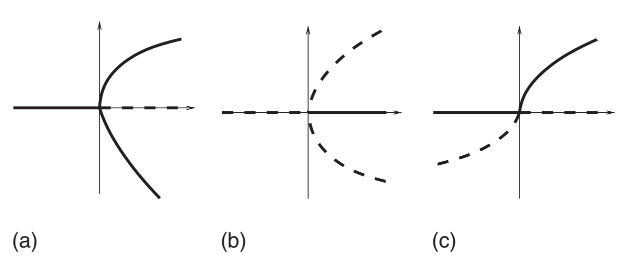

**Figure 3** Typical bifurcation diagrams in the case of a branch of trivial solutions. One-sided bifurcations: (a) supercritical, (b) subcritical; two-sided bifurcation: (c) transcritical. The solid (dashed) lines indicate the branch of stable (unstable) solutions in the differential equation.

is called *supercritical* if the bifurcating solutions lie on the side of the bifurcation point where the basic solution $x=0$ is unstable and *subcritical* otherwise; see Figure 2. The situation is the same in the case of one-sided bifurcations for an equation which has a "known" branch of solutions. In the case of a two-sided bifurcation, there is an *exchange of stability* at the bifurcation point $(\mu_0, x_0)$, solutions on the two branches having opposite stability for $\mu > \mu_0$ and $\mu < \mu_0$, which changes at $(\mu_0, x_0)$. Such a bifurcation is also referred to as *transcritical*; see Figure 3.

Notice that the study of fixed points or periodic points for maps enter in the above frame. Specifically, the period-doubling process occurring in successive bifurcations of one-dimensional maps is a common phenomenon in physics.

The analysis of bifurcations in two dimensions leads to more complicated scenarios. Consider the differential equation [8] in which now $x \in \mathbb{R}^2$ and $f(x,\mu) \in \mathbb{R}^2$, and assume that $f(x_0,\mu_0)=0$. The behavior of solutions near $(x_0,\mu_0)$ is determined by the differential $D_x f(x_0,\mu_0) =: L$ of $f$ with respect to $x$, which can be identified with a $2 \times 2$ matrix. For steady solutions, the implicit function theorem insures the existence of a unique branch of solutions $x(\mu)$ provided $L$ is invertible or, in other words, zero does not belong to the spectrum of $L$. Consequently, the study of bifurcations of steady solutions is concerned with the case when zero belongs to the spectrum of $L$, and can be performed following the strategy described for one dimension, provided that the zero eigenvalue of $L$ is simple. For example, assuming that the second eigenvalue is negative leads in general to a *saddle–node bifurcation*, where an additional dimension is added to the previous picture of a turning point bifurcation, in which one of the two bifurcating steady solutions is a stable node, while the other one is a saddle. If, in addition, there is a symmetry $S$ commuting with $f$, that is, such that $f(Sx,\mu)=Sf(x,\mu)$, and if, for example, $x_0$ is invariant under $S, Sx_0=x_0$, and the eigenvector $\zeta_0$ associated to the zero eigenvalue of $L$ is antisymmetric, $L\zeta_0 = -\zeta_0$, then there is again a *pitchfork bifurcation*. The equation possesses a branch of symmetric steady solutions the stability of which changes when crossing the value $\mu_0$ of the parameter, node on one side and saddle on the other, and a pair of solutions is created in a one-sided bifurcation which are exchanged by the symmetry $S$ and have stability opposite to the one of the symmetric solution, just as in the one-dimensional pitchfork bifurcation above.

A new type of bifurcation that arises for vector fields in two dimensions is the so-called *Hopf bifurcation*. This bifurcation was first understood by Poincaré, and then proved in two dimensions by Andronov (1937) using a Poincaré map, and later in $n$ dimensions by Hopf (1948) by means of a Liapunov–Schmidt-type method. For the differential equation, the absence of the zero eigenvalue in the spectrum of $L$ is not enough to ensure that the vector field $f(\cdot,\mu_0)$ is structurally stable in a neighborhood of $x_0$. This only holds when the spectrum of $L$ does not contain purely imaginary eigenvalues, as asserted by the Hartman–Grobman theorem. We are then left with the case when $L$ has a pair of purely imaginary eigenvalues $\pm i\omega, \omega \in \mathbb{R}^*$. Static bifurcation theory gives that the system has a unique branch of equilibria $(x(\mu),\mu)$ for $\mu$ close to $\mu_0$, and typically their stability changes as $\mu$ crosses $\mu_0$. For the differential equation a *Hopf bifurcation* occurs in which a branch of periodic orbits bifurcates on one side of $\mu_0$, and their stability is opposite to that of the steady solution on this side; see Figure 4. A convenient way to study this bifurcation is through "normal form theory," which is briefly described below.

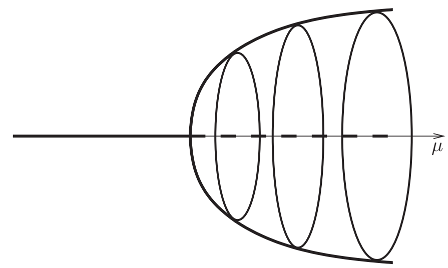

**Figure 4** Supercritical Hopf bifurcation.

## Local Bifurcation Theory

There are two aspects of bifurcation theory, *local* and *global* theory. As this designation suggests, local theory is concerned with (local) properties of the set of solutions in a neighborhood of a "known" solution, while global theory investigates solutions in the entire space.

An important class of tools in *local* bifurcation theory consists of *reduction methods*, among which the *Liapunov–Schmidt reduction* and the *center manifold reduction* are often used to investigate static and dynamic bifurcations, respectively. The basic idea is to replace the bifurcation problem by an equivalent problem in lower dimensions, for example, a one- or a two-dimensional problem as the ones above.

Consider again the equation [1] in which $F: \mathcal{X} \times \mathcal{M} \to \mathcal{Y}$ is sufficiently regular, and $\mathcal{X}, \mathcal{Y}$, and $\mathcal{M}$ are Banach spaces. Assume, without loss of generality,

that $F(0,0)=0$, or, in other words, that one solution is known. The equation can be then written as

$$LX + G(X,\mu) = 0$$

in which $L = D_X F(0,0)$ represents the differential of $F$ with respect to $X$ at (0, 0), and is assumed to have a closed range. The implicit function theorem shows absence of bifurcation if $L$ has a bounded inverse, so that bifurcations are related to the existence of a nontrivial kernel of $L$. The *Liapunov–Schmidt reduction* then goes as follows.

Let $N(L)$ and $R(L)$ denote the kernel and the range of $L$, respectively, and consider continuous projections $P:\mathcal{X}\to N(L)$ and $Q:\mathcal{Y}\to R(L)$. Then there exists a bounded linear operator $B:R(L)\to(\mathrm{id}-P)\mathcal{X}$, the right inverse of $L$, satisfying $LB=\mathrm{id}$ on $R(L)$ and $BL=\mathrm{id}-P$ on $\mathcal{X}$. For $X\in\mathcal{X}$ one may write

$$X = X_0 + X_1, \quad X_0 = PX, X_1 = (\mathrm{id}-P)X$$

and then by projecting with $\mathrm{id}-Q$ and $Q$ the equation becomes

$$(\mathrm{id}-Q)G(X_0+X_1,\mu) = 0$$
$$X_1 + BQG(X_0+X_1,\mu) = 0$$

The implicit function theorem allows to solve the second equation for $X_1=\psi(X_0,\mu)$ in a neighborhood of the origin. Substitution into the first equation leads to the equation in $(\mathrm{id}-Q)\mathcal{Y}$ for $X_0$ in $P\mathcal{X}$,

$$(\mathrm{id}-Q)G(X_0+\psi(X_0,\mu),\mu) = 0$$

also called *bifurcation equation*. This equation completely describes the set of solutions to [1] in a neighborhood of (0, 0), and this problem is then posed in a space of dimension much smaller than the dimension of $\mathcal{X}$.

The basic principle of the Liapunov–Schmidt method has been discovered and used independently by different authors. E Schmidt (1908) used this method for integral equations, while Liapunov used it to study the stability of the zero solution of nonlinear partial differential equations when the linear part has zero eigenvalues (1947), and later in 1960 for the bifurcation problem studied by Poincaré (1885). In working in a Banach space of $t$-periodic functions, the Liapunov–Schmidt method may be used to solve the Hopf bifurcation problem, as did Hopf himself in 1948.

The analog of this reduction procedure for the differential equation [3] is the *center manifold reduction*. Assuming that $F(0,0)=0$, we obtain the differential equation

$$\frac{\mathrm{d}X}{\mathrm{d}t} = LX + G(X,\mu)$$

Since dynamic bifurcations are related to the existence of purely imaginary spectral values of $L$, the kernel of $L$ alone is not enough to describe this situation. One has to consider the spectral space $\mathcal{Y}_c$ of $L$ associated to the purely imaginary spectrum of $L$. A spectral gap is needed between this part of the spectrum and the rest (always true in finite dimensions), so that the spectral projection $P$ onto $\mathcal{Y}_c$ is well defined. One writes

$$X = X_c + X_h, \quad X_c = PX, \ X_h = (\mathrm{id}-P)X$$

and obtains the decomposed system

$$\frac{\mathrm{d}X_c}{\mathrm{d}t} = LX_c + PG(X_c+X_h,\mu)$$
$$\frac{\mathrm{d}X_h}{\mathrm{d}t} = LX_h + (\mathrm{id}-P)G(X_c+X_h,\mu)$$

The reduction procedure works provided the nonhomogeneous linear equation

$$\frac{\mathrm{d}X_h}{\mathrm{d}t} = LX_h + f(t)$$

possesses a unique solution in suitably chosen function spaces with weak exponential growth, such that one can then solve the second equation for $X_h=\Psi(X_c)$ in a neighborhood of the origin in these function spaces. This property is always true in finite dimensions, but it has to be checked in infinite dimensions. Different results showing the solvability of this equation are available in both Banach and Hilbert spaces, relying upon additional conditions on the spectrum of $L$, decaying properties of the resolvent of $L$ on the imaginary axis, and regularity properties of the nonlinearity $G$. The map $\Psi$ is then used to construct a map $\psi:P\mathcal{X}\times\mathcal{M}\to(\mathrm{id}-P)\mathcal{X}$, defined in a neighborhood of the origin, which parametrizes a *local center manifold* invariant under the flow of the equation. The flow on this center manifold is governed by the *reduced equation* in $\mathcal{Y}_c$,

$$\frac{\mathrm{d}X_c}{\mathrm{d}t} = LX_c + PG(X_c+\psi(X_c,\mu),\mu)$$

which completely describes the bifurcation problem.

The first proofs of this result were given in finite dimensions by Pliss (1964) and Kelley (1967). Center manifolds in infinite dimensions have been studied in different settings determined by assumptions on the linear part $L$ and the nonlinear part $G$. One typical assumption in infinite dimensions is that the spectrum of $L$ contains only a finite number of purely imaginary eigenvalues, so that the reduced equation above is a differential equation in a finite-dimensional space.

These reduction methods work for a large class of problems and the advantage of such an approach is that one is left with a bifurcation problem in a lower-dimensional space. The methods involved in

solving this reduced bifurcation problem can be very different from one problem to another, and often make use of some additional structure in the problem, such as a gradient-like structure, Hamiltonian structure, or the presence of symmetries, which are preserved by the reduction procedure.

A powerful tool for the analysis of these reduced differential equations is provided by the *normal form theory*, which goes back to works of Poincaré (1885) and Birkhoff (1927). The idea is to use coordinate transformations to make the expression of the vector field as simple as possible. The transformed vector field is called *normal form*. There is an extensive literature on normal forms for vector fields in many different contexts, in both finite- and infinite-dimensional cases. Typically the classes of normal forms are characterized in terms of the linear part of the differential equation.

For differential equations of the form

$$\frac{\mathrm{d}x}{\mathrm{d}t} = Lx + g(x, \mu) \qquad [9]$$

in which $L$ is a matrix and $g$ a sufficiently regular map such that $g(0,0)=0, D_x g(0,0)=0$, as encountered in bifurcation theory, one possible characterization of normal forms makes use of the adjoint matrix $L^*$. Fixing any order $k \geq 2$, there exist polynomials $\Phi$ and $N$ of degree $k$ in $x$ with coefficients which are regular functions of $\mu$, and $\Phi(0,0)=N(0,0)=0, D_x\Phi(0,0)=D_xN(0,0)=0$, such that by the change of variables

$$x = y + \Phi(y, \mu)$$

the equation [9] is transformed into the normal form

$$\frac{\mathrm{d}y}{\mathrm{d}t} = Ly + N(y, \mu) + o(\|y\|^k) \qquad [10]$$

in which the polynomial $N$ is characterized through

$$N(\mathrm{e}^{tL^*}y, \mu) = \mathrm{e}^{tL^*}N(y, \mu)$$

for all $y, \mu$, and $t$, or, equivalently,

$$D_y N(y, \mu)L^* y = L^* N(y, \mu)$$

for all $y$ and $\mu$. This characterization allows to determine the classes of possible normal forms for a given matrix $L$, and also provides an efficient way to compute the normal form for a given vector field $g$. As for the reduction methods, normal form transformations can be made to preserve the additional structure of the problem, such as Hamiltonian structure or symmetries.

As an example, consider a differential equation of the form [9] with $x \in \mathbb{R}^n$ and $\mu \in \mathbb{R}$, which supports a Hopf bifurcation so that $L$ has simple eigenvalues $\pm\mathrm{i}\omega, \omega > 0$, and no other eigenvalues with zero real part. The center manifold reduction provides a two-dimensional reduced system with linear part having the simple eigenvalues $\pm\mathrm{i}\omega$, for which it is convenient to write the normal form in complex variables

$$\frac{\mathrm{d}A}{\mathrm{d}t} = \mathrm{i}\omega A + AQ\left(|A|^2, \mu\right) + o\left(|A|^{2k+2}\right)$$

for $A(t) \in \mathbb{C}$, where $Q$ is a complex polynomial of degree $k$ in $|A|^2$ with $Q(0,0)=0$, or, equivalently, in polar coordinates $A = r\mathrm{e}^{\mathrm{i}\phi}$,

$$\frac{\mathrm{d}r}{\mathrm{d}t} = rQ_r\left(r^2, \mu\right) + o\left(r^{2k+2}\right)$$

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = \omega + Q_\phi\left(r^2, \mu\right) + o\left(r^{2k+1}\right)$$

$Q_r$ and $Q_\phi$ being the real and imaginary part of $Q$, respectively. The radial equation for $r$ truncated at order $2k+1$ decouples and admits a pitchfork bifurcation. The bifurcating steady solutions of this equation then lead first to periodic solutions for the truncated system, which are then shown to persist for the full equation by a standard perturbation analysis.

A situation that occurs in a large class of problems is when the problem possesses a reversibility symmetry, which often comes from some reflection invariance in the physical space, that is, when the vector field $F(\,\cdot\,, \mu)$ anticommutes with a symmetry operator $S$. One of the simplest examples is the case of a differential equation [9] when the matrix $L$ has a double eigenvalue in 0, no other eigenvalues with zero real part, and a one-dimensional kernel which is invariant by $S$. In this case, the center manifold reduction provides a two-dimensional reduced reversible system, which can be put in the normal form

$$\frac{\mathrm{d}a}{dt} = b$$

$$\frac{\mathrm{d}b}{dt} = \mu - a^2 + o((|a| + |b|)^3)$$

which anticommutes with the symmetry $(a, b) \mapsto (a, -b)$. The above system undergoes a *reversible Takens–Bogdanov bifurcation* and has for $\mu > 0$ a phase portrait as in **Figure 5**. There are two equilibria, one a saddle, the other a center, and a family of periodic orbits with the zero-amplitude limit at the center equilibrium, and the infinite-period limit a homoclinic orbit, originating at the saddle point. In concrete problems the bounded orbits of such a reduced system determine the shape of physically interesting solutions of the full system of equations, such as, for example, in water-wave theory where to homoclinic and periodic orbits correspond solitary and periodic waves, respectively.

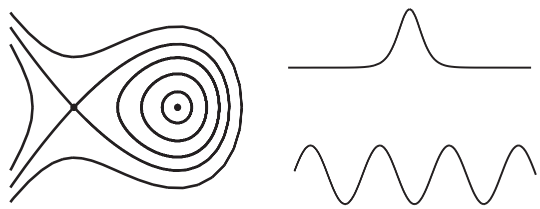

**Figure 5** Phase portrait of the reduced system in a reversible Takens–Bogdanov bifurcation (left) and sketch of the *a*-component of solutions corresponding to homoclinic and periodic orbits (right).

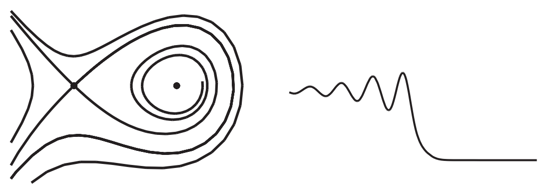

**Figure 6** Phase portrait of the reduced system in absence of reversibility (left) and sketch of the *a*-component of the solution corresponding to the bounded orbit (right).

Notice that in the absence of the reversibility symmetry, the same type of bifurcation may lead to a completely different phase portrait for the reduced system as, for example, the one in Figure 6 in which the homoclinic and the periodic orbits disappear. This situation often occurs in the presence of a small dissipation in nearly reversible systems.

## Global Bifurcation Theory

Most of the existing results in global bifurcation theory concern the static problem [1]. The analysis of *global sets* of solutions often relies upon topological methods, degree theory, but also variational methods, or analytic function theory. Significant progress in understanding global branches of solutions has been made in the 1970s, in particular, for nonlinear eigenvalue problems and the Hopf bifurcation problem (see, e.g., works by Rabinowitz, Crandall, Dancer, and Alexander, Yorke, Ize, respectively).

A now-classical result in the topological theory of global bifurcations is the following theorem by Rabinowitz (1970), which gives a characterization of global sets of solutions for *eigenvalue problems* of the form

$$X = F(X, \mu) = \mu L X + H(X, \mu)$$

$H(X, \mu) = o(\|X\|)$, posed for $(X, \mu) \in \mathcal{X} \times \mathbb{R}, \mathcal{X}$ being a Banach space. In contrast to local theory where the function $F$ is usually $k$-times differentiable (with a suitable $k$), in the global theory a typical assumption is that $F: \mathcal{X} \times \mathbb{R} \to \mathcal{X}$ is *compact*. The equation above possesses a "trivial" branch of solutions $(0, \mu)$ for any $\mu$. The bifurcation result asserts that if for some real parameter value $\mu_0$ zero is an eigenvalue of odd multiplicity of the operator $\mathrm{id} - \mu_0 L$, then the set $S$ of nontrivial solutions $(X, \mu)$ possesses a maximal subcontinuum which contains $(0, \mu_0)$ and meets either infinity in $\mathcal{X} \times \mathbb{R}$ or another trivial solution $(0, \mu_1), \mu_1 \neq \mu_0$. In particular, $(\mu_0, 0)$ is a bifurcation point. A local version of this result is often referred to as Krasnoselski's theorem.

Different versions and extensions of these theorems can be found in the literature, as, for example, in the case of a simple eigenvalue, or if the field $F$ is real-analytic when the set of solutions is path-connected. More recent works address the question of lack of compactness, and a number of results are now available for problems with additional structure (gradient-like or Hamiltonian structure), but also for concrete problems, such as the water-wave problem.

# Bifurcations in Fluid Dynamics

**G Schneider**, Universität Karlsruhe, Karlsruhe, Germany

## Introduction

Almost all classical hydrodynamical stability problems are experiments or gedankenexperiment which have been designed to understand and to extract special phenomena in more complicated situations. Examples are the Taylor–Couette problem, Bénard's problem, Poiseuille flow, or Kolmogorov flow.

The Taylor–Couette problem consists in finding the flow of a viscous incompressible fluid contained in between two coaxial co- or counterrotating cylinders, cf. Figure 1. If the rotational velocity of the inner cylinder is below a certain threshold, the trivial solution, called the Couette flow, is asymptotically stable. At the threshold, this spatially homogenous solution becomes unstable and bifurcates via a pitchfork bifurcation or a Hopf bifurcation into different spatially periodic patterns, that is, depending on the rotational velocity of the outer cylinder the basic patterns are stationary (called the Taylor vortices) or time-periodic. If the rotational velocity of the inner cylinder is increased further, more complicated patterns occur. The bifurcation scenario is well understood from experiments and analytic investigations.

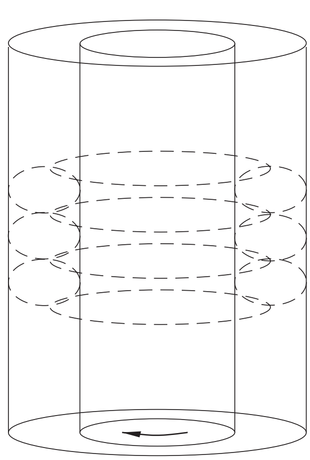

Figure 1 The Taylor–Couette problem with the Taylor vortices.

Bénard's problem consists in finding the flow of a viscous incompressible fluid contained in between two plates, where the lower plate is heated and the upper plate is kept at a constant temperature, cf. Figure 2. If the temperature difference between the two plates is below a certain threshold, the transport of energy from below to above is made by pure conduction. At this threshold, this spatially homogenous solution becomes unstable, convection sets in, and spatially periodic patterns as rolls or hexagons occur. Convection problems play a big role in geophysical applications, that is, in spherical domains, as the earth. The paradigm for an anisotropic pattern-forming system is electroconvection in nematic crystals.

Poiseuille flow consists in finding the flow of a viscous incompressible fluid flowing through a pipe driven by some pressure gradient, cf. Figure 3. In noncircular pipes, the trivial laminar flow becomes unstable at a critical pressure gradient. Experimentally, a direct transition to turbulent flow with large amplitudes is observed, according to the fact that in general at the instability point of the trivial solution a subcritical bifurcation occurs.

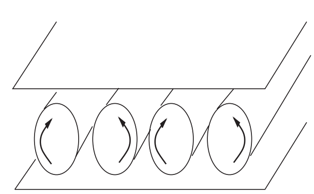

Figure 2 Bénard's problem with rolls.

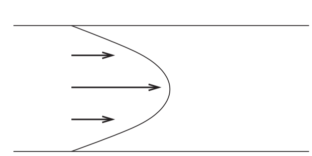

Figure 3 Poiseuille flow with the trivial solution.

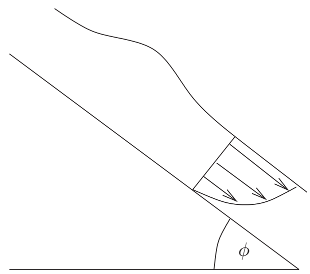

**Figure 4** The inclined-plane problem. The trivial Nusselt solution possesses a flat top surface and a parabolic flow profile.

Kolmogorov flow consists in finding the flow of a viscous incompressible fluid under the action of an external force parallel to the flow direction $x$ and varying periodically in the perpendicular $y$-direction. This gedankenexperiment has been designed by Kolmogorov in 1958 as a simplified model for the Poiseuille flow problem in order to study the nature of turbulence. The trivial solution which is called Kolmogorov flow can become unstable via a long-wave instability along the flow direction.

The inclined-plane problem consists in finding the flow of a viscous liquid running down an inclined plane, cf. Figure 4. The trivial solution, the so-called Nusselt solution, becomes sideband-unstable if the inclination angle $\phi$ is increased. Then the dynamics is dominated by traveling pulse trains, although the individual pulses are unstable due to the long-wave instability of the flat surface. Time series taken from the motion of the individual pulses indicates the occurrence of chaos directly at the onset of instability.

There are other famous hydrodynamical stability problems, with arbitrarily complicated bifurcation scenarios.

## Spectral Analysis of the Trivial Solution

All classical hydrodynamical stability problems are described by the Navier–Stokes equations

$$\begin{aligned} \partial_t U &= \frac{1}{\nu}\Delta U - \nabla p - (U\cdot\nabla)U + f \\ 0 &= \nabla\cdot U \end{aligned} \qquad [1]$$

where $U = U(x,t) \in \mathbb{R}^d$ with $d = 2,3$ is the velocity field, $p = p(x,t) \in \mathbb{R}$ the pressure field, $f$ some external forcing, and $\nu$ the dynamic viscosity. These equations are completed with boundary conditions. In case of Bénard's problem, the Navier–Stokes equations are coupled to a nonlinear heat equation.

By projecting $U$ onto the space of divergence-free vector fields and by taking the trivial solution as new origin all problems from the previous section can be written as evolutionary system

$$\partial_t U = \Lambda U + N(U)$$

where $U = 0$ corresponds to the trivial solution, where $\Lambda$ is a linear and $N(U) = \mathcal{O}(U^2)$ for $U \to 0$ a nonlinear operator. Most of the examples from the previous section are semilinear, that is, from a functional analytic point of view, the nonlinear operator $N$ can be controlled in terms of the linear operator $\Lambda$.

Since the form of the bifurcating pattern is only slightly influenced by far away boundaries, that is, for instance, the upper and lower end of the rotating cylinders in the Taylor–Couette problem, the problems are considered from a theoretical point of view in unbounded domains, $\Omega = \mathbb{R}^d \times \Sigma$, with $\Sigma \subseteq \mathbb{R}^m$ the bounded cross section that is, for instance, that the Taylor–Couette problem is considered with two cylinders of infinite length. Then the eigenfunctions of the linear operator $\Lambda$ are given by Fourier modes, that is,

$$\Lambda(e^{ik\cdot x}\varphi_{k,n}(z)) = \lambda_n(k)e^{ik\cdot x}\varphi_{k,n}(z)$$

with $x \in \mathbb{R}^d, k \in \mathbb{R}^d, k\cdot x = \sum_{j=1}^d k_j x_j, z \in \Sigma, n \in \mathbb{N}$. If an external control parameter is changed, independent of the underlying physical problem, the trivial solution becomes unstable, then the surface $k \mapsto \mathrm{Re}\lambda_1(k)$ intersects the plane $\{\mathrm{Re}\lambda_1(k) = 0\}$. Generically, this happens first at a nonzero wave vector $k_c \neq 0$ (cf. Figure 5).

Examples for such an instability are the Taylor–Couette problem, Bénard's problem, or Poiseuille flow. Very often, due to some conserved quantity in the problem we have $\mathrm{Re}\lambda_1(0) = 0$ for all values of the bifurcation parameter. Then, a so-called sideband instability can occur, cf. Figure 6.

Examples for such an instability are the Kolmogorov flow problem or the inclined plane problem.

According to some symmetries in the problem, for instance, reflection along the cylinders in the Taylor–Couette problem or rotational symmetry in Bénard's problem, the curves in Figure 5 are double or rotational symmetric.

In case of $\Omega$ being spherical symmetric, we have

$$\Lambda(f_l(r)\varphi_{l,n}(z)) = \lambda_l f_l(r)\varphi_{l,n}(z)$$

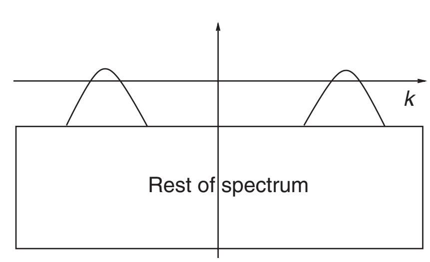

**Figure 5** Real part of the spectrum in case of an instability at a wave number $k_c \neq 0$. Definition of the small bifurcation parameter $\varepsilon$.

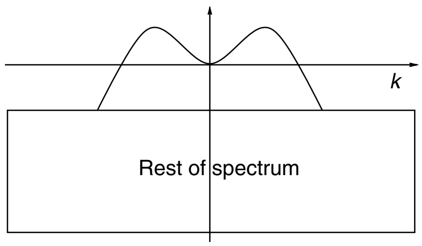

**Figure 6** Real part of the spectrum in case of a sideband instability. Definition of the small bifurcation parameter $\varepsilon$.

with $r \geq 0, z \in S^d, \varphi_{l,n}$ for $l \in \mathbb{N}_0$ and $m = -l, l-1, \ldots, l+1, l$ being a spherical harmonic, that is, if $\lambda_{l_0}$ is the eigenvalue having first positive real part, then by symmetry, simultaneously $2l_0 + 1$ eigenvalues cross the imaginary axis.

## Reduction of the Dimension

In order to understand the occurrence of the spatially periodic Taylor vortices in the Taylor–Couette problem and of the roll solutions and hexagons in Bénard's problem, the problems are considered with periodic boundary conditions along the unbounded directions. Then the instability of the trivial solution occurs when at least one eigenvalue crosses the imaginary axis. Generically, this happens by a simple real eigenvalue or a pair of complex-conjugate eigenvalues crossing the imaginary axis (Figure 7). Center manifold theory and the Lyapunov–Schmidt reduction allow to reduce the *a priori* infinite-dimensional bifurcation problem to a finite-dimensional one.

In case of a real eigenvalue $\lambda_1$ crossing the imaginary axis, the solution $u$ can be written as a sum of the weakly unstable mode and the stable modes, that is, $u = c_1\varphi_1 + u_r$, $(c_1 \in \mathbb{R})$, where $u_r$ lives in the closure of the span of the stable eigenfunctions $\{\varphi_2, \varphi_3, \ldots\}$. For the linearized system all solutions are attracted by the one-dimensional set $E_c = \{u \mid u_r = 0\}$, in which all solutions diverge to infinity.

For the nonlinear system and small bifurcation parameter this attracting structure survives, no longer as a linear space, but as a manifold

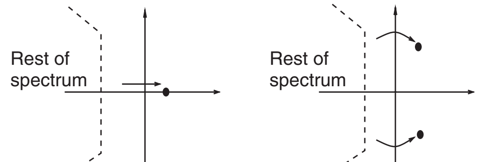

**Figure 7** Generically, a simple real eigenvalue or a pair of complex-conjugate eigenvalues cross the imaginary axis.

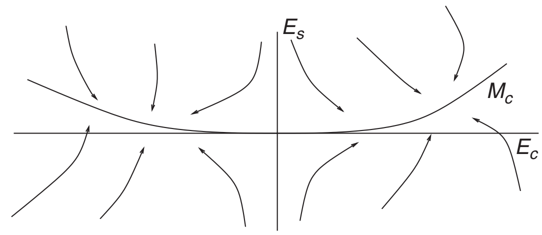

**Figure 8** The center manifold is invariant under the flow, is tangential to the central subspace $E_c$, and attracts nearby solutions with some exponential rate.

$$M_c = \{u = c_1\varphi_1 + h(c_1)| \\ h(c_1) \in \overline{\text{span}\{\varphi_2, \varphi_3, \ldots\}}\}$$

the so-called center manifold which is tangential to $E_c$, that is, $\|h(c_1)\| \leq C\|c_1\|^2$ (Figure 8). The dynamics on $M_c$ is no longer trivial due to the nonlinear terms.

Due to the fact that real problems are considered $\text{Re}\lambda_1(k_c) = 0$ implies $\text{Re}\lambda_1(-k_c) = 0$, that is, in case of $2\pi/k_c$-periodic boundary conditions always two eigenvalues cross the imaginary axis simultaneously. For Bénards's problem in a strip or for the Taylor–Couette problem in case of a bifurcation of fixed points, the reduced system on the center manifold is derived with the ansatz

$$U = \varepsilon A(\varepsilon^2 t)\mathrm{e}^{\mathrm{i}k_c x} + \text{c.c.} + \mathcal{O}(\varepsilon^2)$$

where $0 < \varepsilon \ll 1$ is the small bifurcation parameter, cf. Figure 5. Then due to $\mathrm{e}^{\mathrm{i}k_c x}\mathrm{e}^{\mathrm{i}k_c x}\mathrm{e}^{-\mathrm{i}k_c x} = \mathrm{e}^{\mathrm{i}k_c x}$ the complex-valued amplitude $A$ satisfies the so-called Landau equation

$$\partial_T A = A - \gamma A|A|^2 + \mathcal{O}(\varepsilon^2)$$

where the Landau coefficient $\gamma \in \mathbb{R}$ is obtained by classical perturbation analysis (Figure 9). The reduced system is symmetric under the $S^1$-symmetry

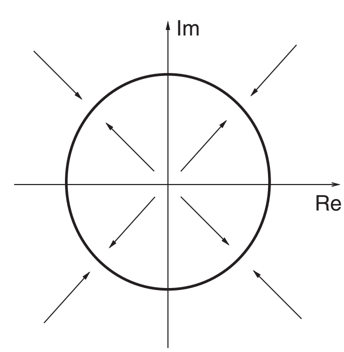

**Figure 9** The dynamics of the Landau equation. Except of the origin which corresponds to the Couette flow, all solutions converge towards the circle of fixed points, which corresponds to the family of Taylor vortices. The translation invariance of the Taylor–Couette problem is reflected by the rotational symmetry of the reduced system.

$A \mapsto Ae^{i\phi}$ with $\phi \in \mathbb{R}$ which corresponds to the translation invariance of the original systems.

This so-called equivariant bifurcation theory has been applied successfully to convection problems in the plane and on the sphere.

The stability of time-periodic flows can be analyzed with Floquet multipliers. Bifurcations from a time-periodic solution can lead to quasiperiodic motion in time. Ruelle and Takens (1971) showed that already the next bifurcation leads to chaotic dynamics. Since this time many classical hydrodynamical stability problems have been analyzed with bifurcation theory up to turbulent flows.

It was observed that center manifold theory can also be applied successfully to elliptic PDE problems posed in spatially unbounded cylindrical domains. A famous example is the construction of capillary-gravity solitary waves for the so-called water-wave problem.

## Modulation Equations

The analysis of the last section is of no use in case of a sideband instability occurring at the wave number $k_c = 0$, as it happens in the inclined-plane problem or in the Kolmogorov flow problem. Moreover, in case of an instability at a wave vector $k_c \neq 0$, based on the above analysis, front solutions cannot be described. In such situations, the method of modulation equations generalizes the role of the finite-dimensional amplitude equations from the last section.

The complex cubic Ginzburg–Landau equation in normal form is given by

$$\partial_T A = (1 + i\alpha)\partial_X^2 A + A - (1 + i\beta)A|A|^2$$

where the coefficients $\alpha, \beta \in \mathbb{R}$ are real, and we have $X \in \mathbb{R}, T \geq 0$, and $A(X,T) \in \mathbb{C}$. The Ginzburg–Landau equation is a universal amplitude equation that describes slowly varying modulations, in space and time, of the amplitude of bifurcating spatially periodic solutions in pattern-forming systems close to the threshold of the first instability. Whenever the instability drawn in Figure 5 occurs, that is, for the Taylor–Couette problem and Bénard's problem in a strip, that is, $d = 1$, it can be derived by a multiple scaling ansatz

$$u(x,t) \sim \varepsilon A(\varepsilon(x - c_g t), \varepsilon^2 t)e^{i(k_c x - \omega_0 t)} + \text{c.c.}$$

For instance, in case of $\alpha = \beta = 0$, the Ginzburg–Landau equation possesses front solutions connecting the stable fixed point $A = 1$ with the unstable fixed point $A = 0$. Such solutions correspond in the Taylor–Couette problem to modulating fronts connecting the stable Taylor vortices with the unstable Couette flow, cf. Figure 10.

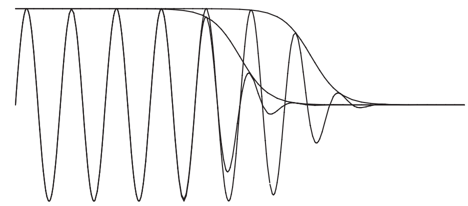

**Figure 10** The front solution of the Ginzburg–Landau equation modulates the underlying pattern in the original system.

The diffusion operator in the Ginzburg–Landau equation reflects the parabolic shape of $\text{Re}\lambda_1$ close to $k = k_c$ in Figure 5. In case of the long-wave instability, as drawn in Figure 6, the second-order differential operator changes in a fourth-order differential operator.

For Kolmogorov flow with $T = \varepsilon^4 t$ and $X = \varepsilon x$ and the amplitude scaled with $\varepsilon$, we obtain that in lowest order $A$ has to satisfy a Cahn–Hilliard equation

$$\partial_T A = -\sqrt{2}\partial_X^2 A - 3\partial_X^4 A + \gamma\partial_X^2(A^3)$$

where $A(X,T) \in \mathbb{R}$ and $\gamma \in \mathbb{R}$ a constant (cf. Figure 6).

The Kuramoto–Shivashinsky (KS)-perturbed KdV equation

$$\partial_T A = -\partial_X^3 u - \partial_X(A^2)/2 - \varepsilon(\partial_x^2 + \partial_x^4)u$$

with $A = A(X,T) \in \mathbb{R}, X \in \mathbb{R}, T \geq 0$, where $0 < \varepsilon \ll 1$ is still a small parameter, can be derived for the inclined problem with $T = \varepsilon^3 t$ and $X = \varepsilon x$ and the amplitude scaled with $\varepsilon^2$.

The theory of modulation equations is nowadays a well-established mathematical tool which allows us to construct special solutions, global existence results for the solutions of pattern-forming systems, or allows to characterize the attractors in such systems. The method is based on approximation results, showing that solutions of the original systems can be approximated by the modulation equation and attractivity results showing that every solution of the original system develops in such a way that it can be described by the modulation equation.

This method can also be applied to secondary bifurcations describing instabilities of spatially periodic wave trains. Then the so-called phase-diffusion equations, conservation laws, Burgers equations, and again the KS equations occur.

However, this method cannot be applied successfully in all situations. There are counterexamples showing that not every formally derived modulation equation describes the original system in a correct way. Moreover, very often according to some symmetries in the original problem no consistent

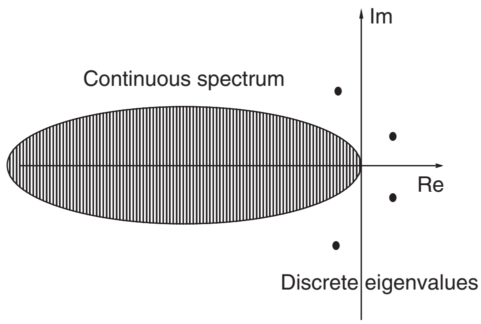

**Figure 11** Spectrum for the flow around an obstacle.

multiple scaling analysis is possible, that is, that the modulation equations still depend on $\varepsilon$.

## Discussion

There is no satisfactory bifurcation analysis for situations where boundary layers play a role. The most simple problem is the flow around some obstacle. The difficulties are according to the fact that due to the unbounded flow region there is always continuous spectrum up to the imaginary axis. From the localized obstacle discrete eigenvalues are created, (cf. Figure 11).

In such a situation, so far there is no mathematical bifurcation theory available.

# Bifurcations of Periodic Orbits

**J-P Françoise**, Université P.-M. Curie, Paris VI, Paris, France

## Introduction

Bifurcation theory of periodic orbits relates to modeling of quite diverse subjects. It appeared classically in the field of celestial mechanics with the contributions of H Poincaré. Van der Pol (1926, 1927, 1928, 1931) observed the frequency-locking phenomenon in electrical circuits. More recently, Malkin's theory (Malkin 1952, 1956, Roseau 1966) was used to justify synchronization of weakly coupled oscillators modeling the electrical activity of the cells of the sinusal node in the heart. This article provides the essential mathematical background necessary for existence of frequency locking. Applications can be found, for instance, in Weakly Coupled Oscillators.

## The Asymptotic Phase of a Stable Periodic Orbit

Let $\Gamma$ be a periodic orbit of a vector field and let $S(\Gamma)$ denote the stable manifold of $\Gamma$ (resp. $U(\Gamma)$ denotes the unstable manifold of $\Gamma$). The following theorem can be found, for instance, in Hartman (1964).

**Theorem** *There exist $\alpha$ and $K$ such that $\mathrm{Re}(\lambda_j) < -\alpha$, $j = 1, \ldots, k$ and $\mathrm{Re}(\lambda_j) > \alpha$, $j = k+1, \ldots,$ and for all $x \in S(\Gamma)$, there is an asymptotic phase $t_0$ such that for all $t \geq 0$*

$$| \phi_t(x) - \gamma(t - t_0) | < K\,\mathrm{e}^{-\alpha(t/T)}$$

*Similarly, for any $x \in U(\Gamma)$, there is a $t_0$ such that $t \leq 0$,*

$$| \phi_t(x) - \gamma(t - t_0) | < K\,\mathrm{e}^{\alpha(t/T)}$$

If the periodic orbit is stable, the local stable manifold coincides with an open neighborhood of $\Gamma$. In such a case, there is a foliation of this open set

whose leaves are the points with a given asymptotic phase. The asymptotic phase can be considered as a coordinate function $\phi$ defined on the neighborhood $S(\Gamma)$.

If we consider now the particular case of a plane system, this function can be completed with the square of the distance function to the orbit into a coordinate system called the "amplitude–phase" system and denoted as $(\rho, \phi)$.

## Frequency Locking and Phase Locking

The term "oscillator" has two meanings. A conservative "oscillator" is a plane vector field which displays an open set of periodic orbits. It is said to be isochronous if all orbits have same period. A dissipative "oscillator" is a planar vector field which displays an attractive limit cycle (attractive periodic orbit).

We consider $N$ dissipative oscillators:

$$\begin{aligned}\frac{dx_i}{dt} &= f(x_i, y_i)\\ \frac{dy_i}{dt} &= g(x_i, y_i)\end{aligned} \qquad [1]$$

where $i = 1, \ldots, m$.

The dynamical system obtained by considering the space of all the variables $(x_i, y_i)$, $i = 1, \ldots, m$, displays an invariant torus full of periodic orbits that we denote by $T^m(0)$.

Assume now that the $N$ oscillators are weakly coupled:

$$\begin{aligned}\frac{dx_i}{dt} &= f(x_i, y_i) + \epsilon F_i(x, y, \epsilon)\\ \frac{dy_i}{dt} &= g(x_i, y_i) + \epsilon G_i(x, y, \epsilon)\end{aligned} \qquad [2]$$

where $\epsilon$ can be considered as small as we wish.

**Definition** The system [2] has a frequency locking if it displays a family of stable periodic orbits $\Gamma_\epsilon$ for all values of $\epsilon$ small enough which tends to (in the sense of Hausdorff's topology) a periodic orbit of [1] contained in the periodic torus $T^m(0)$.

Assume now that [2] has a frequency locking associated with the periodic orbit $\Gamma(t)$. Consider the projections $\Gamma_i(t)$ of $\Gamma(t)$ on the coordinates plane $(x_i, y_i)$, $i = 1, \ldots, m$. Assume that $\epsilon$ is small enough so that the projection belongs to the open set $S_i$ on which are defined the "amplitude–phase" coordinates of the system [1]. We can write the system [2], restricted to the open set $S = \Pi_{i=1}^m S_i$, as

$$\begin{aligned}\frac{d\rho_i}{dt} &= f_i(\rho, \alpha, \epsilon)\\ \frac{d\alpha_i}{dt} &= \mathbf{\Phi}_i(\rho, \alpha, \epsilon), \quad i = 1, \ldots, m\end{aligned} \qquad [3]$$

**Definition** The system [2] has a phase locking if the system induced by [3] on $\Gamma(t)$

$$\frac{d\alpha_i}{dt} = \mathbf{\Phi}_i(0, \alpha, \epsilon) \qquad [4]$$

has an attractive singular point.

As the attractive singular points are structurally stable, this is enough to assume that the system

$$\frac{d\alpha_i}{dt} = \mathbf{\Phi}_i(0, \alpha, 0) \qquad [5]$$

displays an attractive singular point.

## Periodic Orbits of Linear Systems

Consider the linear system

$$\frac{dx}{dt} = P(t) \cdot x + q(t) \qquad [6]$$

where $P$ is a continuous $T$-periodic matrix function and $q$ is a vector $T$-periodic continuous function, $x = (x_1, \ldots, x_n)$. Consider also the two associated homogeneous equations:

$$\frac{dx}{dt} = P(t) \cdot x \qquad [7a]$$

$$\frac{dx}{dt} = -P^*(t) \cdot x \qquad [7b]$$

where $P^*$ denotes the transposed of $P$.

The set of $T$-periodic solutions of [7b] is a vector space. $m$ denotes its dimension. Let $U^j(t)$, $j = 1, \ldots, m$, be a basis of this vector space. This basis is completed by adding $n - m$ solutions $U^j(t)$, $j = m+1, \ldots, n$, to obtain a basis of $R^n$. Let $U(t)$ be the matrix whose columns are these vectors; denote $U_{ij}(t)$ the elements of this matrix.

With the change of variable $x = U^*(0)^{-1}y$, system [6] gets transformed into

$$\frac{dy}{dt} = Q(t)y + r(t) \qquad [8]$$

with $Q(t) = U^*(0)P(t)U^*(0)^{-1}$ and $r(t) = U^*(0)q(t)$.

Matrix $V(t) = U^{-1}(0)U(t)$ is such that

$$\frac{dV}{dt} + Q^*(t)V = 0, \quad V(0) = I$$

and the $k$ first column vectors $V(t)$, denoted as $V^j(t)$, $j = 1, \ldots, m$, are $T$-periodic.

Let $X(t)$ be the fundamental solution defined by

$$\frac{\mathrm{d}X}{\mathrm{d}t} = Q(t) \cdot X, \quad X(0) = I$$

then,

$$X^{-1}(t) = V^*(t)$$

The solution of [8] can be written as

$$y(t) = X(t) \cdot y(0) + X(t) \cdot \int_0^t X^{-1}(u) r(u)\,\mathrm{d}u \qquad [9]$$

This yields that $T$-periodic solutions of [8] have initial data $y(0)$ given by

$$(V^*(T) - I) \cdot y(0) = \int_0^T V^*(s) r(s)\,\mathrm{d}s \qquad [10]$$

Conversely, given a solution $y(0)$ of [10], $T$-periodicity of $P$ and $q$ and uniqueness of solutions of a differential equation imply that $y(0)$ represents the initial data of a $T$-periodic solution of [8]. Hence, the $T$-periodic solutions of [8] are in one-to-one correspondence with the affine space defined by the solutions of [10]. The $m$ first rows of $V^*(T) - I$ are zero and its rank is exactly $n - m$. In the following, assume that the determinant $\Delta$ formed by the $(n - m)$ last rows and last columns of $(V^*(T) - I)$ is not zero.

A necessary and sufficient condition so that [8] displays a $T$-periodic solution is

$$\int_0^T \sum_{j=1}^n V_{jk}(u) r_j(u)\,\mathrm{d}u = 0, \quad k = 1, \ldots, m \qquad [11a]$$

$$\sum_{j=m+1}^n (V_{jk}(T) - \delta_{jk}) y_j(0) = \sum_{j=1}^n \int_0^T V_{jk}(s) r_j(s)\,\mathrm{d}s, \quad m+1 \le s \le n \qquad [11b]$$

This yields the Fredholm alternative, if the $m$ conditions,

$$\sum_{j=1}^n \int_0^T U_{jk}(s) q_j(s)\,\mathrm{d}s = 0, \quad k = 1, \ldots, m \qquad [12]$$

are satisfied, then [6] displays a family $x_\alpha(t)$ of $T$-periodic solutions depending of $m$ parameters $(\alpha_1, \ldots, \alpha_m)$:

$$x_\alpha(t) = \alpha_1 \phi_1(t) + \cdots + \alpha_m \phi_m(t) + \bar{x}(t) \qquad [13]$$

where $\bar{x}(t)$ is a particular $T$-periodic solution and $\phi_j(t)$ denote $T$-periodic independent solutions of [7a]. To be more specific, one can choose $\bar{x}(t)$ to be the unique solution of [6] such that $y(0)_k = 0, k = m+1, \ldots, n$, and $\phi_j(t)$ solutions of [7a], such that $y(0)_k = \delta_{jk}$. With these notations, $x_\alpha(t)$ is such that

$$y(0)_k = \alpha_k, \quad k = 1, \ldots, m$$

and its other initial conditions $y(0)_k = \beta_k$, $k = m + 1, \ldots, n$, are fixed:

$$\beta_k = \beta_k^0$$

## Malkin's Theorem for Quasilinear Systems

Consider now nonlinear systems with the perturbation:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = P(t) \cdot x + q(t) + \epsilon f(x, t, \epsilon) \qquad [14]$$

where $f$ is $C^1$ and $T$-periodic in $t$.

Assume that the solutions $y(t, y(0), \epsilon)$ of [14] exist for all values of $t$, $0 \le t \le T$. The solutions define a differential function of their initial data $y(0)$. This is, for instance, true for perturbations of linear systems if $\epsilon$ is small enough.

Assume that $q$ satisfies la condition [12] and that there is a solution

$$(\alpha_1^0, \ldots, \alpha_m^0)$$

to the equations

$$\psi_k(\alpha) = \sum_{j=1}^n \int_0^T U_{jk}(u) f_j(x_\alpha(u), u, 0)\,\mathrm{d}u = 0, \quad k = 1, \ldots, m \qquad [15a]$$

so that

$$\frac{\partial \psi_k(\alpha)}{\partial \alpha_j}\Big|_{\alpha=\alpha^0}; \quad k = 1, \ldots m,\ j = 1, \ldots, m \qquad [15b]$$

is invertible.

Proceed as in previous section with the coordinate change $x = U^*(0)^{-1} y$. Equation [14] gets transformed into

$$\frac{\mathrm{d}y}{\mathrm{d}t} = Q(t) y + r(t) + \epsilon F(y, t, \epsilon) \qquad [16]$$

with $F = U^*(0) f(U^*(0)^{-1} \cdot y, t, \epsilon)$.

Solutions of [16] are uniquely determined by their initial data. We can understand the parameters $(\alpha, \beta)$ as coordinates on the space of solutions. With this viewpoint, for instance, the set of $T$-periodic solutions of [6] is an affine space of dimension $m$

given by the equations $\beta = \beta^0$ and is parametrized by the coordinates $\alpha$. In this space, we pick up a point (which corresponds to a particular $T$-periodic solution of [6]): $(\alpha = \alpha^0)$. $T$-periodic solutions of [16] are in one-to-one correspondence with the solutions of

$$C_k(\alpha, \beta, \epsilon) = \sum_{j=1}^{n} \int_0^T V_{jk}(s) F_j(y(s, \epsilon, \alpha, \beta), s, \epsilon) \mathrm{d}s = 0, \quad k = 1, \ldots, m \qquad [17a]$$

$$\begin{aligned} C_k(\alpha, \beta, \epsilon) = &\sum_{j=m+1,\ldots,n} (V_{jk}(T) - I)\beta_j \\ &- \sum_{j=1}^{n} \int_0^T V_{jk}(s) r_j(s)\, \mathrm{d}s \\ &- \epsilon \sum_{j=1}^{n} \int_0^T V_{jk}(s) F_j(y(s, \epsilon, \alpha, \beta), s, \epsilon) \mathrm{d}s = 0, \\ &k = m+1, \ldots, n \end{aligned} \qquad [17b]$$

where $\alpha_k, k = 1, \ldots, m$ and $\beta_k = y_k(0)$, $k = m + 1, \ldots, n$ parametrize the solutions $y(t, \epsilon, \alpha, \beta)$ of [14] in this way:

$$y(0) = U^*(0) \cdot x(0), \quad x(0) = \sum_{j=1}^{m} \alpha_j \phi_j(0) + \bar{x}(0) \qquad [18]$$

Consider the determinant of the Jacobian matrix of the mapping

$$(\alpha, \beta) \mapsto C(\alpha, \beta, \epsilon) \qquad [19]$$

for $\alpha = \alpha^0$, $\beta_k = \beta_k^0$, $k = m+1, \ldots, n$, $\epsilon = 0$. This is equal to the product of $\Delta$ and the determinant of

$$\frac{\partial \psi_k(\alpha)}{\partial \alpha_j}\Big|_{\alpha=\alpha^0} \qquad [20]$$

which is nonzero.

The implicit-function theorem shows that the differential equation [14] (and thus [16] as well) has, for $\epsilon$ small enough, a unique $T$-periodic solution which tends to $x_{\alpha^0}$ when $\epsilon$ tends to 0.

## Generalization of Malkin's Theorem

Finally, we consider the most general situation of the perturbation of a general system (not necessarily linear):

$$\frac{\mathrm{d}x}{\mathrm{d}t} = f(x, t) + \epsilon g(x, t, \epsilon) \qquad [21]$$

where we assume that

$$\frac{\mathrm{d}x}{\mathrm{d}t} = f(x, t) \qquad [22]$$

displays an $m$-parameter family $x_\alpha(t)$ of $T$-periodic orbits.

Assume that the solutions $y(t, y(0), \epsilon)$ exist for all $0 \le t \le T$ and define a differentiable mapping of the initial data $y(0)$. This is, for instance, the case if we assume that the nonperturbed equation defines a flow and if $\epsilon$ is small enough.

Assume also that the different solutions $x_\alpha(t)$ are independent in the sense that the mapping

$$\alpha \mapsto x_\alpha(t)$$

is an immersion for any $t$. In other words, the $m$ vectors $\mathrm{d}x_\alpha(t)/\mathrm{d}\alpha_j$ are independent.

We linearize the solution along the family of periodic orbits:

$$x = x_\alpha(t) + \epsilon\xi \qquad [23]$$

Equation [21] gets transformed into

$$\frac{\mathrm{d}\xi}{\mathrm{d}t} = Df_x(x_\alpha(t), t) \cdot \xi + g(x_\alpha(t), t, 0) + \epsilon F(\xi, t, \epsilon) \qquad [24]$$

Set, furthermore,

$$P(t) = Df_x(x_\alpha(t), t), \quad r(t) = g(x_\alpha(t), t, 0)$$

and denote $U(t)$ the fundamental solution of [7b] described earlier.

**Theorem** *Assume that there is a solution*

$$(\alpha_1^0, \ldots, \alpha_m^0)$$

*of the m equations*:

$$\sigma_k(\alpha) = \sum_{j=1}^{n} \int_0^T U_{jk}(u) g_j(x_\alpha(u), u, 0)\, \mathrm{d}u = 0, \quad k = 1, \ldots, m \qquad [25a]$$

*such that*

$$\frac{\partial \sigma_k(\alpha)}{\partial \alpha_j}\Big|_{\alpha=\alpha^0}; \quad k = 1, \ldots m, \ j = 1, \ldots, m \qquad [25b]$$

*is invertible. Then, for all $\epsilon$ sufficiently small*, eqn [21] *has a unique T-periodic solution which tends to $x_{\alpha^0}$ when $\epsilon$ tends to* 0.

We show that under the hypothesis of the theorem, we can apply the results proved in the preceding section. Note that one can prove the theorem for eqn [24] because it reduces to [21] with the change of variables [23].

Note first that the $m$ conditions [25a] imply that the $m$ equations,

$$\frac{d\xi}{dt} = Df_x(x_{\alpha^0}(t), t) \cdot \xi + g(x_{\alpha^0}(t), t, 0)$$

display a family of $T$-periodic solutions which depend on $m$ parameters $\gamma = (\gamma_1, \ldots, \gamma_m)$. From (13), one can write

$$\xi_\gamma(t) = \gamma_1\phi_1(t) + \cdots + \gamma_m\phi_m(t) + \bar{\xi}(t) \qquad [26]$$

where $\bar{\xi}(t)$ is a particular $T$-periodic solution and the $\phi_j(t)$ are independent $T$-periodic solutions of (22a).

**Lemma 1** *A possible choice for the solutions* $\phi_j(t)$ is $\partial x_\alpha(t)/\partial\alpha_j\,|_{\alpha=\alpha^0}$.

We have already assumed that these vectors are independent. They are obviously $T$-periodic solutions to (22a).

In the following, we will assume that all other periodic solutions of (22a) are linear combinations of these.

As a consequence of what was proved in the section on periodic orbits of linear systems, system [24] displays a periodic solution (for $\epsilon$ small enough) if there exists a solution

$$(\gamma_1^0, \ldots, \gamma_m^0)$$

to equations

$$\nu_k(\gamma) = \sum_{j=1}^{n} \int_0^T U_{jk}(s) F_j(\xi_\gamma(s), s, 0)\, ds = 0,$$
$$k = 1, \ldots, m$$

such that

$$\frac{\partial\nu_k(\gamma)}{\partial\gamma_j}\Big|_{\gamma=\gamma^0}; \quad k = 1, \ldots m,\ j = 1, \ldots, m$$

is invertible.

**Lemma 2** *The quantities* $\nu_k(\gamma)$ *depend linearly in* $\gamma$.

**Proof** Observe first that the quantities $F_j(\xi, s, 0)$ depend quadratically of $\xi$:

$$F_j(\xi, s, 0) = \frac{1}{2}\sum_{k,l} \frac{\partial^2 f_j}{\partial z_k \partial z_l}(x_{\alpha^0}(s), s)\xi_k\xi_l + \sum_k \frac{\partial g_j}{\partial z_k}(x_{\alpha^0}(s), s, 0) + \frac{\partial g_j}{\partial\epsilon}(x_{\alpha^0}(s), s, 0) \qquad [27]$$

Then, the solutions $\xi(t)$ depend linearly on $\gamma$. We thus obtain that *a priori* $\nu_p(\gamma)$ are quadratic functions of $\gamma$:

$$\nu_p(\gamma_1, \ldots, \gamma_m) = \frac{1}{2}\sum_{qrkl} \gamma_q\gamma_r \int_0^T U_{jp} \frac{\partial^2 f_j}{\partial z_k \partial z_l} \cdot \frac{\partial z_k}{\partial\gamma_q} \cdot \frac{\partial z_l}{\partial\gamma_r}\, ds + \sum_{qkl} \gamma_q \int_0^T U_{jp} \left[ \frac{1}{2}\frac{\partial^2 f_j}{\partial z_k \partial z_l} \left( \frac{\partial z_k}{\partial\gamma_q} \cdot \bar{\xi}_l + \frac{\partial z_l}{\partial\gamma_q}\bar{\xi}_k \right) + \frac{\partial g_j}{\partial z_k} \cdot \frac{\partial z_k}{\partial\gamma_q} \right] ds + \cdots \qquad [28]$$

where the dots represent quantities independent of $\gamma$. We use then the expression

$$\frac{d}{dt}\left(\frac{\partial^2 z_j}{\partial\gamma_q \partial\partial_r}\right) = \sum_{kl} \frac{\partial^2 f_j}{\partial z_k \partial z_l} \cdot \frac{\partial z_k}{\partial\gamma_q} \cdot \frac{\partial z_l}{\partial\gamma_r} + \sum_k \frac{\partial f_j}{\partial z_k} \frac{\partial^2 z_k}{\partial\gamma_q \partial\partial_r}$$

This allows one to find the homogeneous quadratic part as

$$\sum_{jkl} \int_0^T U_{jp} \frac{\partial^2 f_j}{\partial z_k \partial z_l} \cdot \frac{\partial z_k}{\partial\gamma_q} \cdot \frac{\partial z_l}{\partial\gamma_r}\, ds = \sum_j \int_0^T U_{jp}(s) \frac{d}{ds}\left(\frac{\partial^2 z_j}{\partial\gamma_q \partial\partial_r}\right) ds - \sum_{jk} \int_0^T U_{jp}(s) \frac{\partial f_j}{\partial z_k} \frac{\partial^2 z_k}{\partial\gamma_q \partial\gamma_r}\, ds$$

Integration by parts yields

$$\sum_{jkl} \int_0^T U_{jp} \frac{\partial^2 f_j}{\partial z_k \partial z_l} \cdot \frac{\partial z_k}{\partial\gamma_q} \cdot \frac{\partial z_l}{\partial\gamma_r}\, ds = -\sum_j \int_0^T \left( \frac{dU_{jp}}{ds} + U_{jp}(s)\frac{\partial f_j}{\partial z_k} \right) \frac{\partial^2 z_k}{\partial\gamma_q \partial\gamma_r}\, ds = 0$$

because $U^*$ is solution to [7a]. This shows that [28] is linear in $\gamma$. Suffices to show that the determinant of this system does not vanish to have existence and uniqueness of the solution such that

$$\frac{\partial\nu_1, \ldots, \nu_m}{\partial\gamma_1, \ldots, \gamma_m} \neq 0$$

Consider now the coefficient of the linear part:

$$\sum_{kl} \int_0^T U_{jp} \left[ \frac{\partial^2 f_j}{\partial z_k \partial z_l} \cdot \bar{\xi}_l + \frac{\partial g_j}{\partial z_k} \right] \cdot \frac{\partial z_k}{\partial\gamma_q}\, ds$$

and the coefficient

$$\sigma_p(\alpha) = \sum_{j=1}^{n} \int_0^T U_{jp}(u) g_j(x_\alpha(u), u, 0)\, \mathrm{d}u$$

We can write

$$\frac{\mathrm{d}\sigma_p}{\mathrm{d}\alpha_q} = \int_0^T \left( \frac{\partial U_{jp}}{\partial \alpha_q} \cdot g_j + U_{jp} \frac{\partial g_j}{\partial z_k} \cdot \frac{\partial z_k}{\partial \alpha_q} \right) \mathrm{d}s$$

Note that

$$\frac{\mathrm{d}\bar{\xi}_j}{\mathrm{d}t} = \sum_r \frac{\partial f_j}{\partial z_r} \bar{\xi}_r + g_j(z(t), \alpha^0, 0)$$

and we obtain

$$\frac{\mathrm{d}\sigma_p}{\mathrm{d}\alpha_q} = \int_0^T \left( \frac{\partial U_{jp}}{\partial \alpha_q} \cdot \left( \frac{\mathrm{d}\bar{\xi}_j}{\mathrm{d}s} - \sum_r \frac{\partial f_j}{\partial z_r} \bar{\xi}_r \right) + U_{jp} \frac{\partial g_j}{\partial z_k} \cdot \frac{\partial z_k}{\partial \alpha_q} \right) \mathrm{d}s$$

Integration by parts yields

$$\left. \frac{\mathrm{d}\sigma_p}{\mathrm{d}\alpha_q} \right|_{\alpha=\alpha^0} = -\int_0^T \left( \frac{\mathrm{d}}{\mathrm{d}s} \left( \frac{\partial U_{jp}}{\partial \alpha_q} \right) \cdot \bar{\xi}_j + \sum_r \frac{\partial f_j}{\partial z_r} \bar{\xi}_r \right) + \int_0^T U_{jp} \left( \frac{\partial g_j}{\partial z_k} \cdot \frac{\partial z_k}{\partial \alpha_q} \right) \mathrm{d}s$$

From the equation

$$\frac{\mathrm{d}U_{jp}}{\mathrm{d}t} + \sum_k \frac{\partial f_k}{\partial z_j} U_{kp} = 0$$

we deduce that

$$\frac{\mathrm{d}}{\mathrm{d}t} \left( \frac{\partial U_{jp}}{\partial \alpha_q} \right) = -\sum_k \frac{\partial f_k}{\partial z_j} \frac{\partial U_{jp}}{\partial \alpha_q} + \sum_k \frac{\partial^2 f_k}{\partial z_j \partial z_r} U_{kp} \frac{\partial z_r}{\partial \alpha_q}$$

and thus this shows that

$$\left. \frac{\mathrm{d}\sigma_p}{\mathrm{d}\alpha_q} \right|_{\alpha=\alpha^0} = \sum_{kl} \int_0^T U_{jp} \left[ \frac{\partial^2 f_j}{\partial z_k \partial z_l} \cdot \bar{\xi}_l + \frac{\partial g_j}{\partial z_k} \right] \cdot \frac{\partial z_k}{\partial \gamma_q} \mathrm{d}s$$

This achieves the proof of the theorem. In the special case of Hamiltonian systems, in the case of the peturbations of an isochronous system, the method explained is equivalent to Moser's averaging theory.

The reader is referred to other articles in this encyclopedia for a discussion of other aspects of synchronization, frequency locking, and phase locking.

# Bi-Hamiltonian Methods in Soliton Theory

**M Pedroni**, Università di Bergamo, Dalmine (BG), Italy

## Introduction

At the end of the 1960s, the theory of integrable systems received a great boost by the discovery (made by Gardner, Green, Kruskal, and Miura) of the inverse-scattering method (*see* Integrable Systems: Overview). It allows one to reduce the solution of the (nonlinear) Korteweg–de Vries equation (henceforth simply the KdV equation)

$$u_t = \tfrac{1}{4}(u_{xxx} - 6uu_x) \qquad [1]$$

to the solution of linear equations. After the KdV equation, a lot of other nonlinear partial differential equations, solvable by means of the inverse-scattering method, were found out. A common feature of such equations is the existence of soliton solutions, that is, solutions in the shape of a solitary wave (with additional interaction properties). For this reason they are called "soliton equations."

It was soon observed that the KdV equation can be seen as an infinite-dimensional Hamiltonian system with an infinite sequence of constants of motion in involution; the corresponding (commuting) vector fields are symmetries for the KdV equation, and form the so-called KdV hierarchy. In particular, Zakharov and Faddeev constructed action-angle variables for the KdV equation. These facts pointed out that the KdV equation is an infinite-dimensional analog of a classical integrable Hamiltonian system (Dubrovin *et al.* 2001), whose theory has been developed during the nineteenth century by Liouville, Jacobi, and many others. Moreover, the infinite-dimensional case suggested methods (such as the existence of a Lax pair) which were applied successfully also to finite-dimensional cases such as the Toda lattices and the Calogero systems. More recently, after the discovery by Witten and Kontsevich of remarkable relations between the KdV hierarchy and matrix models of two-dimensional (2D) quantum gravity, there has been a renewed interest in the study of soliton equations in the community of theoretical physicists. We also mention that the classical versions of the extended $\mathcal{W}_n$-algebras of 2D conformal field theory are the (second) Poisson structures of the Gelfand–Dickey hierarchies.

In this article we describe the so-called bi-Hamiltonian formulation of soliton equations. This approach to integrable systems springs from the observation, made by Magri at the end of the 1970s, that the KdV equation can be seen as a Hamiltonian system in two different ways. In the same circle of ideas, there were important works by Adler, Dorfman, Gelfand, Kupershmidt, Wilson, and many others. Thus, the concept of bi-Hamiltonian manifold, which constitutes the geometric setting for the study of bi-Hamiltonian systems, emerged. This notion and its applications to the theory of finite-dimensional integrable systems is discussed in Multi-Hamiltonian Systems.

In the first section of this article, we discuss the Hamiltonian form of soliton equations and, more generally, we present an important class of infinite-dimensional Poisson (also called Hamiltonian) structures, namely those of hydrodynamic type. Then we show how to use the bi-Hamiltonian properties of the KdV equation in order to construct its conserved quantities. We also recall that the KdV equation can be seen as an Euler equation on the dual of the Virasoro algebra. In the third section, we deal with other examples of integrable evolution equations admitting a bi-Hamiltonian representation, that is, the Boussinesq and the Camassa–Holm equations, and we consider the bi-Hamiltonian structures of hydrodynamic type.

## Hamiltonian Methods in Soliton Theory

The most famous example of soliton equation is the KdV equation [1], where $u$ is usually a periodic or rapidly decreasing real function. The choice of the coefficients in the equation has no special meaning, since they can be changed arbitrarily by rescaling $x$, $t$, and $u$. Right after the discovery of the inverse-scattering method for solving the Cauchy problem for the KdV equation, it was realized that this equation can be seen as an infinite-dimensional Hamiltonian system. Indeed, from a geometrical point of view, eqn [1] defines a vector field $X(u)=(1/4)(u_{xxx}-6uu_x)$ on $\mathcal{M}$, the infinite-dimensional vector space of $C^\infty$ functions from the unit circle $S^1$ to $\mathbb{R}$. (For the sake of simplicity, we consider only the periodic case; the integrals in this article are therefore understood to be taken on $S^1$.) The vector field $X$ associated with the KdV equation is Hamiltonian, that is, it can be factorized as

$$X(u) = [-2\partial_x]\left[\tfrac{1}{8}(-u_{xx}+3u^2)\right]$$

where $\mathrm{d}H=(1/8)(-u_{xx}+3u^2)$ is the differential of the functional

$$H(u)=\frac{1}{8}\int\left(u^3+\frac{1}{2}u_x^2\right)\mathrm{d}x$$

that is, the variational derivative $\delta h/\delta u$ of the density $h=(1/8)(u^3+(1/2)u_x^2)$, and $P=-2\partial_x$ is a Poisson (or Hamiltonian) operator. This means that the corresponding composition law

$$\{F,G\}=\int \mathrm{d}F\,P(\mathrm{d}G)\,\mathrm{d}x=-2\int \mathrm{d}F\,(\mathrm{d}G)_x\,\mathrm{d}x \qquad [2]$$

between functionals of $u$ has the usual properties of the Poisson bracket, that is, it is $\mathbb{R}$-bilinear and skew-symmetric, and it fulfills the Leibniz rule and the Jacobi identity. In other words, $(\mathcal{M},P)$ is an infinite-dimensional Poisson manifold. Using the Poisson bracket [2], eqn [1] can be written as

$$u_t=\{u,H\} \qquad [3]$$

corresponding to the usual Hamilton equation in $\mathbb{R}^{2n}$

$$\dot{z}^i=\{z^i,H\},\quad i=1,\ldots,2n \qquad [4]$$

up to the replacement of $z$ with $u$, and of the discrete index $i$ with the continuous index $x$. More precisely, in the expression $u_t=\{u,H\}$ the symbol $u$ should be replaced by $u^x$ (in analogy with $z^i$), the functional assigning to the generic function $v\in\mathcal{M}$ its value at a fixed point $x$, that is, $u^x: v\mapsto v(x)$. In

these notations, the Poisson bracket [2] takes the form

$$\{u^x, u^y\} = -2\delta'(x-y)$$

where the $\delta$-function is as usual defined as

$$\int f(y)\delta(x-y)\,\mathrm{d}x = f(x)$$

so that its derivatives are given by

$$\int f(y)\delta^{(k)}(x-y)\,\mathrm{d}x = f^{(k)}(x)$$

Another important example is given by the Boussinesq equation

$$u_{tt} = \tfrac{1}{3}\left(-u_{xxxx} + 4u_x^2 + 4uu_{xx}\right) \qquad [5]$$

describing, like KdV, shallow water (soliton) waves in a nonlinear approximation. It can be obtained by the first-order (in time) system

$$u^1{}_t = \tfrac{2}{3}u^2u_x^2 + u_{xx}^1 - \tfrac{2}{3}u_{xxx}^2, \quad u^2{}_t = 2u_x^1 - u_{xx}^2 \qquad [6]$$

by taking the derivative of its second equation with respect to $t$, plugging the result in the first one, and setting $u = u^2$. The system [6] is Hamiltonian, since it can be written as

$$u^1{}_t = \left(\frac{\delta h}{\delta u^2}\right)_x, \qquad u^2{}_t = \left(\frac{\delta h}{\delta u^1}\right)_x$$

with $h = (u^1)^2 + (1/9)(u^2)^3 - u^1u_x^2 + (1/3)(u_x^2)^2$, and

$$\begin{pmatrix} 0 & \partial_x \\ \partial_x & 0 \end{pmatrix} \qquad [7]$$

is easily seen to be a Poisson operator. Thus, the Poisson manifold associated with the Boussinesq equation is the space of periodic $C^\infty$ functions with values in $\mathbb{R}^2$. More generally, one can consider the space $\mathcal{M}^n$ of $C^\infty$ functions from the unit circle $S^1$ to $\mathbb{R}^n$. If $P^{ij}$, for $i, j = 1, \ldots, n$, are the entries of a constant skew-symmetric matrix and $u^{i,x}$ assigns to the generic function $v \in \mathcal{M}^n$ the value of its $i$th components at a fixed point $x$, then

$$\{u^{i,x}, u^{j,y}\} = P^{ij}\delta(x-y)$$

defines a Poisson bracket on $\mathcal{M}^n$. One can also let the $P^{ij}$ depend on the $u^k$ in such a way that they form the components of a Poisson tensor on $\mathbb{R}^n$. If $H = \int h\,\mathrm{d}x$ is a functional on $\mathcal{M}^n$ with density $h$, the associated Hamiltonian vector field gives rise to the following system of partial differential equations:

$$u_t^i = \sum_{j=1}^n P^{ij}\frac{\delta h}{\delta u^j}, \quad i = 1, \ldots, n$$

In particular, if $n = 2N$ and

$$[P^{ij}] = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}$$

then we have the Hamiltonian formulation of the field equations,

$$q_t^i = \frac{\delta h}{\delta p^i}, \qquad p_t^i = -\frac{\delta h}{\delta q^i}, \quad i = 1, \ldots, N$$

Another important example of Poisson bracket on $\mathcal{M}^n$ is given by

$$\{u^{i,x}, u^{j,y}\} = g^{ij}\delta'(x-y) \qquad [8]$$

where $g^{ij}$ are the entries of a constant symmetric matrix. In this case, the Hamiltonian vector field associated with $H = \int h\,\mathrm{d}x$ is given by

$$u_t^i = \sum_{j=1}^n g^{ij}\partial_x\left(\frac{\delta h}{\delta u^j}\right), \quad i = 1, \ldots, n \qquad [9]$$

Notice that this vector field is zero if $H = \int u^k\,\mathrm{d}x$, with $k = 1, \ldots, n$. This amounts to saying that such an $H$ is a Casimir function of the Poisson bracket [8], that is, that $\{H, F\} = 0$ for all functionals $F$. A simple example of this class (with $n = 2$) is given by the Poisson structure of the Boussinesq equation, corresponding to the choice $g^{11} = g^{22} = 0$ and $g^{12} = g^{21} = 1$. Suppose now that the matrix with entries $g^{ij}$ is invertible. Then they can be interpreted as the contravariant components of a flat pseudo-Riemannian metric in $\mathbb{R}^n$. A change of coordinates $(u^1, \ldots, u^n) \mapsto (\bar{u}^1, \ldots, \bar{u}^n)$ in $\mathbb{R}^n$ transforms the Poisson bracket [9] in

$$\{\bar{u}^{i,x}, \bar{u}^{j,y}\} = g^{ij}(\bar{u})\delta'(x-y) + \Gamma_k^{ij}(\bar{u})\bar{u}_x^k\delta(x-y) \qquad [10]$$

where $g^{ij}(\bar{u})$ are the components of the metric in the new coordinates and the $\Gamma_k^{ij}$ are the contravariant Christoffel symbols related to the usual Christoffel symbols by

$$\Gamma_k^{ij} = -g^{il}\Gamma_{lk}^j \qquad [11]$$

Conversely, the expression [10] gives a Poisson bracket if the metric defined by $g^{ij}$ is flat and its Christoffel symbols are related to the $\Gamma_k^{ij}$ by [11]. These are the Poisson structures of hydrodynamic type introduced by Dubrovin and Novikov. We will consider them again later.

## Bi-Hamiltonian Formulation of the KdV Equation

The KdV equation [1] has a lot of remarkable properties, such as the Lax representation and the existence of a $\tau$-function. In this section, we recall a geometrical feature of KdV, namely, the fact that it

has a second Hamiltonian structure, and we show that the integrability of KdV can be seen as a natural consequence of its double Hamiltonian representation. We have already seen that the KdV vector field $X(u) = (1/4)(u_{xxx} - 6uu_x)$ can be written as

$$X(u) = P_0\, \mathrm{d}H_2$$

where $P_0 = -2\partial_x$ and

$$H_2 = \frac{1}{8}\int \left(u^3 + \frac{1}{2}u_x^2\right) \mathrm{d}x$$

But $X$ admits another Hamiltonian representation:

$$X(u) = P_1\, \mathrm{d}H_1$$

where $P_1 = -(1/2)\partial_{xxx} + 2u\partial_x + u_x$ and

$$H_1 = -\frac{1}{4}\int u^2\, \mathrm{d}x$$

The important point is that $P_1$ is also a Poisson operator. Moreover, it is compatible with $P_0$, that is, any linear combination of $P_0$ and $P_1$ is still a Poisson operator. Thus, the KdV equation is a bi-Hamiltonian system, that is, it can be seen in two different (but compatible) ways as a Hamiltonian system. Next, we will show how this property can be used to construct an infinite sequence of conserved quantities for the KdV equation, which are in involution with respect to the Poisson brackets $\{\cdot\,,\cdot\}_0$ and $\{\cdot\,,\cdot\}_1$ associated with $P_0$ and $P_1$. In particular, the phase space $\mathcal{M}$ of KdV is a bi-Hamiltonian manifold, that is, it has two different (but compatible) Poisson structures. Let us rename $X_1 = X$ the KdV vector field. Since $X = P_0\, \mathrm{d}H_2 = P_1\, \mathrm{d}H_1$, one is naturally led to consider the vector fields

$$X_0 = P_0\, \mathrm{d}H_1, \quad X_2 = P_1\, \mathrm{d}H_2$$

Explicitly, $X_0(u) = u_x$ and $X_2(u) = (1/16)(u_{xxxxx} - 10uu_{xxx} - 20u_xu_{xx} + 30u^2u_x)$. One can check that these vector fields are also bi-Hamiltonian. Indeed, $X_0(u) = P_1\, \mathrm{d}H_0$, with $H_0 = \int u\, \mathrm{d}x$, and

$$X_2 = P_0\, \mathrm{d}H_3 \quad \text{with}$$
$$H_3 = -\frac{1}{64}\int \left(u_{xx}^2 + 5uu_x^2 + \frac{5}{2}u^4\right) \mathrm{d}x$$

The functional $H_0$ is a Casimir of $P_0$, that is, $P_0\, \mathrm{d}H_0 = 0$, so that the iteration ends on this side, but it can be continued indefinitely from the other side, as shown below. For the time being, let us take for granted that there exists an infinite sequence $\{H_k\}_{k\geq 0}$ of functionals such that $P_1\, \mathrm{d}H_k = P_0\, \mathrm{d}H_{k+1}$; in other words,

$$\{\cdot, H_k\}_1 = \{\cdot, H_{k+1}\}_0 \qquad [12]$$

Such relations are often called Lenard–Magri relations. Then the functionals $H_k$ are in involution with respect to both Poisson brackets. Indeed, for $k > j$, one has

$$\{H_j, H_k\}_0 = \{H_j, H_{k-1}\}_1 = \{H_{j+1}, H_{k-1}\}_0$$
$$= \cdots = \{H_k, H_j\}_0$$

so that $\{H_j, H_k\}_0 = 0$ for all $j, k \geq 0$, and therefore $\{H_j, H_k\}_1 = 0$ for all $j, k \geq 0$. Hence, these functionals are constants of motion (in involution) for the KdV equation. The Hamiltonian vector fields associated with them are symmetries for the KdV equation; the corresponding evolution equations are called higher-order KdV equations. The set of such equations is the well-known KdV hierarchy. We remark that the existence of a sequence of functionals $\{H_k\}_{k\geq 0}$, fulfilling the Lenard–Magri relations [12] and starting from a Casimir of $P_0$, is equivalent to the existence of a Casimir function $H(\lambda) = \sum_{k\geq 0} H_k\lambda^{-k}$ for the Poisson pencil $P_\lambda = P_1 - \lambda P_0$, where $\lambda$ is a real parameter. A straightforward way (due essentially to Miura, Gardner, and Kruskal) to determine such a Casimir function is to consider the (generalized) Miura map $h \mapsto u = h_x + h^2 - \lambda$. As shown by Kupershmidt and Wilson, it transforms the Poisson structure $(1/2)\partial_x$ (in the variable $h$) into the Poisson pencil $P_\lambda = -(1/2)\partial_{xxx} + 2(u + \lambda)\partial_x + u_x$. Given $u$, the Riccati equation

$$h_x + h^2 = u + \lambda \qquad [13]$$

admits a unique solution with the asymptotic expansion $h = z + \sum_{k\geq 1} h_k z^{-k}$, where $z^2 = \lambda$. Moreover, the coefficients $h_k$ are differential polynomials in $u$ (i.e., polynomials in $u$ and its $x$-derivatives) that can be computed by recurrence. Thus, the generalized Miura map can be seen as an invertible transformation. Since the functional $h \mapsto \int h\, \mathrm{d}x$ is a Casimir of the Poisson structure $(1/2)\partial_x$, it follows that if $h(u)$ is the solution of the Riccati equation [13], then $u \mapsto \int h(u)\, \mathrm{d}x$ is a Casimir of the Poisson pencil $P_\lambda$. More precisely, one has to introduce the functional $H(\lambda) = z\int h(u)\, \mathrm{d}x$, that turns out to be a Laurent series in $\lambda$, because the even coefficients of $h(u)$ are $x$-derivatives. This is the Casimir function we were looking for. Explicitly, one finds that the first terms of $h(u)$ are

$$h_1 = \tfrac{1}{2}u, \qquad h_2 = -\tfrac{1}{4}u_x, \qquad h_3 = \tfrac{1}{8}(u_{xx} - u^2)$$
$$h_4 = -\tfrac{1}{16}(u_{xxx} - 4uu_x)$$
$$h_5 = \tfrac{1}{32}(u_{xxxx} - 6uu_{xx} - 5u_x^2 + 2u^3)$$

Obviously, $h_1$ is the density of a Casimir function of $P_0$, while $h_3$ and $h_5$ are (one-half of) the densities of the

two Hamiltonians $H_1$ and $H_2$ of the KdV equation. We conclude this section showing that, as observed by Khesin and Ovsienko (Arnol'd and Khesin 1998), the bi-Hamiltonian structures of KdV have a clear Lie-algebraic origin. Indeed, the second Hamiltonian structure is the Lie–Poisson structure on the dual of the Virasoro algebra, while the first one can be obtained by "freezing" the second one at a suitable point. Let $\mathcal{X}(S^1)$ be the Lie algebra of vector fields on $S^1$. The Virasoro algebra is the vector space $\mathfrak{g}=\mathcal{X}(S^1)\oplus\mathbb{R}$ endowed with the Lie-algebra structure

$$\left[\left(f(x)\frac{\partial}{\partial x},a\right),\left(g(x)\frac{\partial}{\partial x},b\right)\right] = \left((f'(x)g(x)-g'(x)f(x))\frac{\partial}{\partial x},\ \int f'(x)g''(x)\,dx\right) \quad [14]$$

It is called a central extension of $\mathcal{X}(S^1)$ since it is obtained by considering the usual commutator between vector fields (up to a sign) and by adding a copy of $\mathbb{R}$, which turns out to be the center of the Virasoro algebra. Equation [14] gives rise indeed to a Lie-algebra structure because the expression $\int f'(x)g''(x)\,dx$ defines a 2-cocycle of $\mathcal{X}(S^1)$. The dual space $\mathfrak{g}^*$ of $\mathfrak{g}$ can be considered as the space of the pairs $(u\,dx\otimes\,dx,c)$, where $u\in C^\infty(S^1)$ and $c\in\mathbb{R}$. The pairing is obviously given by

$$\left\langle (u\,dx\otimes\,dx,c),\left(f\frac{\partial}{\partial x},a\right)\right\rangle \int u(x)f(x)\,dx+ac$$

The Lie–Poisson structure on the dual $\mathfrak{g}^*$ of a Lie algebra $\mathfrak{g}$ is defined as

$$\{F,G\}(X)=\langle X,[dF(X),dG(X)]\rangle \quad [15]$$

where $F,G\in C^\infty(\mathfrak{g})^*$ and their differentials at $X\in\mathfrak{g}^*$ are seen as elements of $\mathfrak{g}$. When $\mathfrak{g}$ is the Virasoro algebra and $F(u,c)=\int f(u,c)\,dx$, $G(u,c)=\int g(u,c)\,dx$ are two functionals on $\mathfrak{g}^*$ whose densities $f$ and $g$ are differential polynomials in $u$, one has

$$\begin{aligned}\{F,G\}(u,c) &= \left\langle (u\,dx\otimes\,dx,c),\left(\left(\frac{\delta f}{\delta u}\right)'\left(\frac{\delta g}{\delta u}\right) - \left(\frac{\delta g}{\delta u}\right)'\left(\frac{\delta f}{\delta u}\right)\right)\frac{\partial}{\partial x},\int\left(\frac{\delta f}{\delta u}\right)'\left(\frac{\delta g}{\delta u}\right)''dx\right\rangle \\ &= \int u\left(\left(\frac{\delta f}{\delta u}\right)'\left(\frac{\delta g}{\delta u}\right)-\left(\frac{\delta g}{\delta u}\right)'\left(\frac{\delta f}{\delta u}\right)\right)dx \\ &\quad + \int c\left(\frac{\delta f}{\delta u}\right)'\left(\frac{\delta g}{\delta u}\right)''dx\end{aligned} \quad [16]$$

This is (up to rescaling) the second Poisson bracket of KdV. The KdV equation is therefore an Euler equation, that is, it can be obtained from the Euler equations for the rigid body by replacing the Lie algebra of the rotation group with the Virasoro algebra. To be more precise, the Hamiltonian vector field associated with $H_1(u,c)=-(1/2)(\int u^2\,dx+c)$ is

$$u_t+3uu_x+cu_{xxx}=0,\quad c_t=0$$

If $c\neq 0$, this is (up to rescaling) the KdV equation [1]. For $c=0$, we have the Burgers equation (also called dispersionless KdV equation), to be discussed again later on. The first Poisson bracket for the KdV hierarchy can be obtained by "freezing" the Lie–Poisson bracket at the point $((1/2)dx\otimes dx,0)$ of the dual of the Virasoro algebra. This means that instead of [16] one has to consider

$$\begin{aligned}\{F,G\}_0(u,c) &= \left\langle\left(\frac{1}{2}dx\otimes dx,0\right),\left(\left(\frac{\delta f}{\delta u}\right)'\left(\frac{\delta g}{\delta u}\right) - \left(\frac{\delta g}{\delta u}\right)'\left(\frac{\delta f}{\delta u}\right)\right)\frac{\partial}{\partial x},\int\left(\frac{\delta f}{\delta u}\right)'\left(\frac{\delta g}{\delta u}\right)''dx\right\rangle \\ &= \frac{1}{2}\int\left(\left(\frac{\delta f}{\delta u}\right)'\left(\frac{\delta g}{\delta u}\right)-\left(\frac{\delta g}{\delta u}\right)'\left(\frac{\delta f}{\delta u}\right)\right)dx\end{aligned} \quad [17]$$

The corresponding Hamiltonian is $H_2=(1/2)\int(-u^3+cu_x^2)\,dx$. From this (Lie algebraic) point of view, the compatibility between the two Poisson brackets follows from the fact that the pencil $\{\cdot,\cdot\}_\lambda=\{\cdot,\cdot\}-\lambda\{\cdot,\cdot\}_0$ is obtained from the Lie–Poisson bracket $\{\cdot,\cdot\}$ by applying the translation

$$(u\,dx\otimes\,dx,c)\mapsto\left(\left(u+\frac{\lambda}{2}\right)dx\otimes\,dx,c\right)$$

## Other Examples

In the previous section, we have presented the bi-Hamiltonian structure of the KdV equation and some of its properties. Now we give two more examples of equations – the Boussinesq equation and the Camassa–Holm equation – admitting a bi-Hamiltonian formulation. We have seen in an earlier section that the system [6] associated with the Boussinesq equation [5] is Hamiltonian with respect to the Poisson structure [7] and the Hamiltonian

$$H_1(u^1,u^2)=\int\left((u^1)^2+\tfrac{1}{9}(u^2)^3-u^1u_x^2+\tfrac{1}{3}(u_x^2)^2\right)dx$$

A more complicated Poisson structure for this system is

$$P = \begin{pmatrix} A & -3\partial_x^4 + 3u^2\partial_x^2 + 9u^1\partial_x + 3u_x^1 \\ B & -6\partial_x^3 + 6u^2\partial_x + 3u_x^2 \end{pmatrix} \quad [18]$$

with

$$A = 2\partial_x^5 - 4u^2\partial_x^3 - 6u_x^2\partial_x^2 + (2(u^2)^2 + 6u_x^1 - 6u_{xx}^2)\partial_x + (3u_{xx}^1 - 2u_{xxx}^2 + 2u^2u_x^2)$$

and

$$B = 3\partial_x^4 - 3u^2\partial_x^2 + (9u^1 - 6u_x^2)\partial_x + (6u_x^1 - 3u_{xx}^2)$$

It can be obtained by means of the Drinfeld–Sokolov reduction (or also by means of a bi-Hamiltonian reduction) from the Lie–Poisson structure (modified with the cocycle $\partial_x$) on the space of $C^\infty$ maps from $S^1$ to the Lie algebra of $3 \times 3$ traceless matrices. This is the reason why it is a Poisson structure, compatible with [7]. The system [6] can be written as

$$\begin{pmatrix} u_t^1 \\ u_t^2 \end{pmatrix} = P\begin{pmatrix} (\delta h_2/\delta u^1) \\ (\delta h_2/\delta u^2) \end{pmatrix}$$

where $h_2 = (1/3)u_1$ is the density of a Casimir of the Poisson structure [7]. Thus, the Boussinesq equation is a bi-Hamiltonian system and can be shown to possess, like KdV, an infinite sequence of conserved quantities and symmetries, forming the Boussinesq hierarchy. The KdV and the Boussinesq hierarchy are indeed particular examples of Gelfand–Dickey hierarchies (Dickey 2003). They are hierarchies of systems of $n$ equations with $n$ unknown functions and they are related, via the Drinfeld–Sokolov approach, to the Lie algebra $\mathfrak{sl}(n+1)$. As shown by Adler, Dickey, and Gelfand, these hierarchies have a bi-Hamiltonian formulation. Also the generalized KdV equations, associated by Drinfeld and Sokolov with an arbitrary affine Kac–Moody Lie algebra, are bi-Hamiltonian (or are obtained as suitable reductions of bi-Hamiltonian systems). Let us consider now the (dispersionless) Camassa–Holm equation

$$u_t - u_{txx} = -3uu_x + 2u_xu_{xx} + uu_{xxx} \quad [19]$$

which also describes shallow water waves, and possesses remarkable solutions called peakons, since they represent traveling waves with discontinuous first derivative. In order to supply this equation with a (bi-)Hamiltonian structure, one has to perform the change of variable $m = u - u_{xx}$, whose inverse, in the space of period-1 functions, turns out to be given by

$$u(x) = \int_0^x m(y)\,\sinh(y-x)\,dy + \frac{1}{2\,\sinh(1/2)}\int_0^1 m(y)\cosh\left(y - x - \frac{1}{2}\right)dy$$

The Camassa–Holm equation is then bi-Hamiltonian with respect to the Poisson pair

$$P_1 = \partial_{xxx} - \partial_x, \qquad P_2 = 2m\partial_x + m_x$$

Indeed, it can be written as $m_t = P_1\,dH_2 = P_1\,dH_2$, where

$$H_1 = -\frac{1}{2}\int (u^2 + u_x^2)\,dx$$
$$H_2 = \frac{1}{2}\int (u^3 + uu_x^2)\,dx$$

Notice that the Poisson pair of the Camassa–Holm equation can be obtained from that of KdV by moving the cocycle $\partial_{xxx}$ from the second Poisson structure to the first one. Indeed,

$$P_{(a,b,c)} = a\partial_{xxx} + b\partial_x + c(2m\partial_x + m_x) \qquad a,b,c \in \mathbb{R} \quad [20]$$

is a family of pairwise compatible Poisson operators. Moreover, we mention that Misiołek has shown that also the Camassa–Holm equation is an Euler equation on the dual of the Virasoro algebra. We conclude this article with a brief discussion concerning the so-called bi-Hamiltonian structures of hydrodynamic type. They play a relevant role in the theory of Frobenius manifolds, that, in turn, have deep relations with many important topics in contemporary mathematics and physics, such as Gromov–Witten invariants and isomonodromic deformations. As we have seen in the earlier section, a Poisson structure of hydrodynamic type is given, on the space of $C^\infty$ maps from $S^1$ to (an open set of) $\mathbb{R}^n$, by

$$\{u^{i,x}, u^{j,y}\} = g^{ij}(u)\delta'(x-y) + \Gamma_k^{ij}(u)u_x^k\delta(x-y) \quad [21]$$

where $g^{ij}(u)$ are the contravariant components of a (pseudo-)Riemannian flat metric and the $\Gamma_k^{ij}$ are the (contravariant) Christoffel symbols of the metric. If two Poisson structures of hydrodynamic type are given, it can be shown that they are compatible if and only if the two corresponding metrics form a flat pencil. This means that their linear combinations (with constant coefficients) are still flat (pseudo-)Riemannian metrics, and that the contravariant Christoffel symbols of the linear combinations are the linear combinations of the contravariant Christoffel symbols of the

two metrics. The simplest example is given by the bi-Hamiltonian formulation of the Burgers (or dispersionless KdV) equation,

$$u_t + 3uu_x = 0$$

that we have already encountered. We know that this equation is Hamiltonian with respect to the (Lie–)Poisson operator $2u\partial_x + u_x$, with Hamiltonian function $H_1 = -(1/2)\int u^2\,dx$, and with respect to the Poisson operator $\partial_x$, with Hamiltonian function $H_2 = -(1/2)\int u^3\,\mathrm{d}x$. This also means that the bi-Hamiltonian structure of the Burgers equation comes from the family [20]. The first Hamiltonian structure corresponds to the standard metric on $\mathbb{R}$, that is, $\mathrm{d}u \otimes \mathrm{d}u$, whereas the second one is given by the metric $(2u)^{-1}\,\mathrm{d}u \otimes \mathrm{d}u$.

# Billiards in Bounded Convex Domains

**S Tabachnikov**, Pennsylvania State University, University Park, PA, USA

## Billiard Flow and Billiard Ball Map

The billiard system describes the motion of a free particle inside a domain with elastic reflection off the boundary. More precisely, a billiard table is a Riemannian manifold $M$ with a piecewise smooth boundary, for example, a domain in the plane. The point moves along a geodesic line with a constant speed until it hits the boundary. At a smooth boundary point, the billiard ball reflects so that the tangential component of its velocity remains the same, while the normal component changes its sign. This means that both energy and momentum are conserved. In dimension 2, this collision is described by a well-known law of geometrical optics: the angle of incidence equals the angle of reflection. Thus, the theory of billiards has much in common with geometrical optics. If the billiard ball hits a corner, its further motion is not defined.

The billiard reflection law satisfies a variational principle. Let $A$ and $B$ be fixed points in the billiard table and let $AXB$ be a billiard trajectory from $A$ to $B$ with reflection at a boundary point $X$. Then, the position of a variable point $X$ extremizes the length $AXB$. This is the Fermat principle of geometrical optics.

In this article, we discuss billiards in bounded convex domains with smooth boundary, also called Birkhoff billiards. A related article treats billiards in polygons (*see* Polygonal Billiards).

The billiard flow is defined as a continuous-time dynamical system. The time-$t$ billiard transformation acts on unit tangent vectors to $M$ which constitute the phase space of the billiard flow, and the manifold $M$ is its configuration space. Thus, the billiard flow is the geodesic flow on a manifold with boundary.

It is useful to reduce the dimensions by one and to replace continuous time by discrete one, that is, to replace the billiard flow by a mapping, called the billiard ball map and denoted by $T$. The phase space of the billiard ball map consists of unit tangent vectors $(x, v)$ with the foot point $x$ on the boundary of $M$ and the inward direction $v$. A vector $(x, v)$ moves along the geodesic through $x$ in the direction of $v$ to the next point of its intersection $x_1$ with the boundary $\partial M$, and then $v$ reflects in $\partial M$ to the new

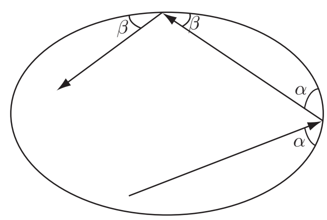

**Figure 1** Billiard ball map.

inward vector $v_1$. Then, one has: $T(x, v) = (x_1, v_1)$. For a convex $M$, the map $T$ is continuous. If $M$ is $n$-dimensional, then the dimension of the phase space of the billiard ball map is $2n - 2$.

Equivalently, and more in the spirit of geometrical optics, one considers $\mathcal{L}$, the space of oriented geodesics (rays of light) that intersect the billiard table. This space of lines is in one-to-one correspondence with the phase space of the billiard ball map: to an inward unit vector $(x, v)$ there corresponds the oriented line through $x$ in the direction $v$ (Figure 1).

The space of rays $\mathcal{L}$ carries a canonical symplectic structure, that is, a closed nondegenerate differential 2-form. In the Euclidean case, this symplectic structure $\omega$ is defined as follows. Given an oriented line $\ell$ in $\boldsymbol{R}^n$, let $q$ be the unit vector along $\ell$ and $p$ be the vector obtained by dropping the perpendicular from the origin to $\ell$. Then, $\omega = \mathrm{d}p \wedge \mathrm{d}q = \sum \mathrm{d}p_i \wedge \mathrm{d}q_i$. This construction identifies $\mathcal{L}$ with the cotangent bundle of the unit sphere: $q$ is a unit vector and $p$ is a (co)tangent vector at $q$, and $\omega$ identifies with the canonical symplectic structure of $T^*S^{n-1}$. In the general case of a Riemannian manifold $M$, the symplectic structure on the space of oriented geodesics is obtained from that on $T^*M$ by symplectic reduction.

One has an important result: the billiard ball map preserves the symplectic structure $T^*(\omega) = \omega$. As a consequence, $T$ is also measure preserving. In the planar case, one has the following explicit formula for this measure. Let $t$ be an arc length parameter along the boundary of the billiard table and let $\alpha \in [0, \pi]$ be the angle made by the unit vector with this boundary. Then, $(\alpha, t)$ are coordinates in the phase space, identified with the cylinder, and the invariant measure is $\sin\alpha \, \mathrm{d}\alpha \, \mathrm{d}t$.

As a consequence, the total area of the phase space equals $2L$ where $L$ is the perimeter length of the boundary of the billiard table, and the mean free path equals $\pi A/L$, where $A$ is the area of the billiard table. In the general $n$-dimensional case, the mean free path equals

$$\frac{\mathrm{vol}(S^{n-1})}{\mathrm{vol}(B^{n-1})} \frac{\mathrm{vol}(M)}{\mathrm{vol}(\partial M)}$$

where $S^{n-1}$ and $B^{n-1}$ are the unit sphere and the unit disk in Euclidean spaces.

## Existence and Nonexistence of Caustics

Given a plane billiard table, a caustic is a curve inside the table such that if a segment of a billiard trajectory is tangent to this curve then so is each reflected segment. Caustics correspond to invariant circles of the billiard ball map (i.e., invariant curves that go around the phase cylinder): such an invariant circle is a one-parameter family of oriented lines, and the respective caustic is their envelop. An envelop may have cusp-like singularities but if the boundary of the billiard table is a smooth curve with positive curvature then a caustic, sufficiently close to the boundary, is smooth and convex.

One can recover the table from a caustic by the following string construction. Let $\gamma$ be a caustic. Wrap a closed nonstretchable string around $\gamma$, pull it tight at a point and move this point around $\gamma$ to obtain a new curve $\Gamma$. Then, $\gamma$ is a caustic for the billiard inside $\Gamma$. Note that this construction has one parameter, the length of the string.

The following useful "mirror equation" relates various quantities depicted in Figure 2:

$$\frac{1}{a} + \frac{1}{b} = \frac{2k}{\sin\alpha}$$

where $k$ is the curvature of the boundary at the impact point.

Do caustics exist for every convex billiard table? This is important to know, in particular, because the existence of a caustic implies that the billiard ball map is not ergodic. The answer is given by a theorem of Lazutkin: *if the boundary of the billiard table is sufficiently smooth and its curvature never vanishes, then there exists a collection of smooth caustics in the vicinity of the billiard curve whose union has a positive area.* Originally this theorem asked for 553 continuous derivatives; later this was reduced to six. This result uses the techniques of the KAM (Kolmogorov–Arnol'd–Moser) theory. The

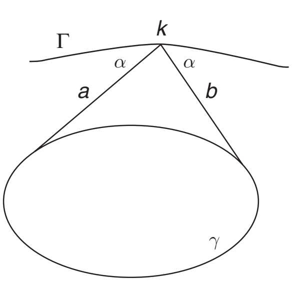

**Figure 2** String construction and mirror equation.

crucial fact is that, in appropriate coordinates, the billiard ball map is approximated, near the boundary of the phase cylinder, by the integrable map $(x, y) \mapsto (x + y, y)$.

On the other hand, by a theorem of Mather, if the curvature of a convex smooth billiard curve vanishes at some point, then this billiard ball map has no invariant circles. This result belongs to the well-developed theory of area-preserving twist maps of the cylinder, of which the billiard ball map is an example.

## Integrable Billiards

Let a plane billiard table be an ellipse with foci $F_1$ and $F_2$. It is known since antiquity that a billiard ball shot from $F_1$ reflects to $F_2$. A generalization of this optical property of the ellipse is the following theorem: *a billiard trajectory inside an ellipse forever remains tangent to a fixed confocal conic*. More precisely, if a segment of a billiard trajectory does not intersect the segment $F_1F_2$, then all the segments of this trajectory do not intersect $F_1F_2$ and are all tangent to the same ellipse with foci $F_1$ and $F_2$; and if a segment of a trajectory intersects $F_1F_2$, then all the segments of this trajectory intersect $F_1F_2$ and are all tangent to the same hyperbola with foci $F_1$ and $F_2$.

It follows that confocal ellipses are the caustics of the billiard inside an ellipse. In particular, a neighborhood of the boundary of such a billiard table is foliated by caustics. A long-standing conjecture, attributed to Birkhoff, asserts that if a neighborhood of a strictly convex smooth boundary of a billiard table is foliated by caustics, then this table is an ellipse. This conjecture remains open. The best result in this direction is a theorem of Bialy: *if almost every phase point of the billiard ball map in a strictly convex billiard table belongs to an invariant circle, then the billiard table is a disk*.

The multidimensional analogs of the optical properties of an ellipse are as follows. Consider an ellipsoid $M$ in $\boldsymbol{R}^n$ given by the equation

$$\frac{x_1^2}{a_1^2} + \frac{x_2^2}{a_2^2} + \cdots + \frac{x_n^2}{a_n^2} = 1 \qquad [1]$$

and define the confocal family of quadrics $M_\lambda$ by the equation

$$\frac{x_1^2}{a_1^2 + \lambda} + \frac{x_2^2}{a_2^2 + \lambda} + \cdots + \frac{x_n^2}{a_n^2 + \lambda} = 1$$

where $\lambda$ is a real parameter. The topological type of $M_\lambda$ changes as $\lambda$ passes the values $-a_i^2$.

One has the following theorem: *a billiard trajectory inside $M$ remains tangent to fixed $(n-1)$ confocal quadrics*. A similar and closely related result holds for the geodesic curves on $M$: the tangent lines to a fixed geodesic on $M$ are tangent to $(n-2)$ other fixed quadrics, confocal with $M$. For a triaxial ellipsoid, this theorem goes back to Jacobi.

Explicit formulas for the integrals of the billiard in an $n$-dimensional ellipsoid [1] are as follows. Let $(x, v)$ be a phase point, a unit inward tangent vector whose foot point $x$ lies on the boundary. The following functions are invariant under the billiard ball map:

$$F_i(x, v) = v_i^2 + \sum_{j \neq i} \frac{(v_i x_j - v_j x_i)^2}{a_j^2 - a_i^2}, \quad i = 1, \ldots, n$$

these functions are not independent: $F_1 + \cdots + F_n = 1$.

In fact, the integrals $F_i$ Poisson-commute (with respect to the Poisson bracket associated with the symplectic structure in the phase space of the billiard ball map that was described above). According to the Arnol'd–Liouville theorem, this complete integrability of the billiard inside an ellipsoid implies that the phase space is foliated by invariant tori and, in appropriate coordinates, the map on each torus is a parallel translation.

Similar results on complete integrability hold for billiards inside quadrics in spaces of constant positive or negative curvature. The former is the intersection of a quadratic cone with the unit sphere, and the latter with the unit pseudosphere.

## Periodic Orbits

Periodic billiard trajectories inside a planar billiard table correspond to inscribed polygons of extremal perimeter length. When counting periodic trajectories, one does not distinguish between polygons obtained from each other by cyclic permutation or reversing the order of the vertices. In other words, one counts the orbits of the dihedral group $D_n$ acting on $n$-periodic billiard polygons.

An additional topological characteristic of a periodic billiard trajectory is the rotation number defined as follows. Assume that the boundary $\gamma$ of a billiard table is parametrized by the unit circle and consider a polygon $(x_1, x_2, \ldots, x_n)$ inscribed in $\gamma$. For all $i$, one has $x_{i+1} = x_i + t_i$ with $t_i \in (0, 1)$. Since the polygon is closed, $t_1 + \cdots + t_n \in \boldsymbol{Z}$. This integer, that takes values from 1 to $n-1$, is called the rotation number of the polygon and denoted by $\rho$. Changing the orientation of a polygon replaces the

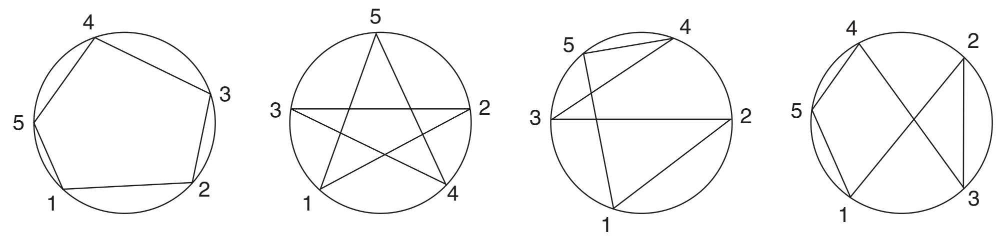

**Figure 3** Rotation numbers of periodic trajectories.

rotation number $\rho$ by $n - \rho$. The leftmost 5-periodic trajectory in Figure 3 has $\rho = 1$ and the other three $\rho = 2$.

The following theorem is due to Birkhoff: *for every* $n \geq 2$ *and* $\rho \leq \lfloor (n-1)/2 \rfloor$, *coprime with* $n$, *there exist two geometrically distinct* $n$*-periodic billiard trajectories with the rotation number* $\rho$. For example, there are at least two 2-periodic billiard trajectories inside every smooth oval: one is the diameter, the longest chord, and another one is of minimax type, similar to the minor axis of an ellipse.

In higher dimensions, lower bounds on the number of periodic billiard trajectories inside strictly convex domains with smooth boundaries were obtained only recently by Farber and the present author. Here is one of the results: for a generic billiard table in $\boldsymbol{R}^m$, the number of $n$-periodic trajectories is not less than $(n-1)(m-1)$. The proof consists in using the Morse theory to estimate below the number of critical points of the perimeter length function on the space of inscribed $n$-gons and its quotient space by the dihedral group $D_n$, and the main difficulty is in describing the topology of these spaces.

Returning to convex smooth planar billiards, the following conjecture remains open for a long time: the set of $n$-periodic points of the billiard ball map has zero measure. This is easy for $n = 2$; for $n = 3$ this is a theorem by M Rychlik. The motivation for this question comes from spectral geometry. In particular, according to a theorem of Ivrii, the above conjecture implies the Weyl conjecture on the second term for the spectral asymptotics of the Laplacian in a bounded domain with the Dirichlet or Neumann boundary conditions.

## Length Spectrum

The set of lengths of the closed trajectories in a convex billiard $M$ is called the length spectrum of $M$. There is a remarkable relation between the length spectrum and the spectrum of the Laplace operator in $M$ with the Dirichlet boundary condition: $\Delta f = \lambda f$, $f|_{\partial M} = 0$. From the physical point of view, the eigenvalues $\lambda$ are the eigenfrequencies of the membrane $M$ with a fixed boundary. Roughly speaking, one can recover the length spectrum from that of the Laplacian. More precisely, the following theorem of K Anderson and R Melrose holds:

$$\sum_{\lambda_i \in \text{spec } \Delta} \cos\left(t\sqrt{-\lambda_i}\right)$$

*is a well-defined generalized function (distribution) of* $t$, *smooth away from the length spectrum*. That is, if $l > 0$ belongs to the singular support of this distribution, then there exists either a closed billiard trajectory of length $l$, or a closed geodesic of length $l$ in the boundary of the billiard table.

This relation between the Laplacian and the length spectrum is due to the fact that geometric optics is not a very accurate description of light. In wave optics, light is considered as electromagnetic waves, and geometric optics gives a realistic approximation only when the wave length is small. This small-wave approximation is based on the assumption that the waves are locally almost harmonic, while their amplitudes change slowly from point to point. The substitution of such a function into the corresponding PDEs gives, in the first approximation, the equations of wave fronts, that is, of geometric optics.

Here is another spectral result concerning a smooth strictly convex plane domain, due to S Marvizi and R Melrose. Let $L_n$ be the supremum and $l_n$ the infimum of the perimeters of simple billiard $n$-gons. Then,

$$\lim_{n \to \infty} n^k (L_n - l_n) = 0$$

for any positive $k$. Furthermore, $L_n$ has an asymptotic expansion, as $n \to \infty$,

$$L_n \sim l + \sum_{i=1}^{\infty} \frac{c_i}{n^{2i}}$$

where $l$ is the length of the boundary of billiard table and $c_i$ are constants, depending on the curvature of the boundary.

# Black Hole Mechanics

**A Ashtekar**, Pennsylvania State University, University Park, PA, USA

## Introduction

Over the last 30 years, black holes have been shown to have a number of surprising properties. These discoveries have revealed unforeseen relations between the otherwise distinct areas of general relativity, quantum physics, and statistical mechanics. This interplay, in turn, led to a number of deep puzzles at the very foundations of physics. Some have been resolved while others continue to baffle physicists. The starting point of these fascinating developments was the discovery of laws of black hole mechanics by Bardeen, Bekenstein, Carter, and Hawking. They dictate the behavior of black holes in equilibrium, under small perturbations away from equilibrium, and in fully dynamical situations. While they are consequences of classical general relativity alone, they have a close similarity with the laws of thermodynamics. The origin of this seemingly strange coincidence lies in quantum physics. For further discussion, *see* Asymptotic Structure and Conformal Infinity; Loop Quantum Gravity; Quantum Geometry and Its Applications; Quantum Field Theory in Curved Spacetime; Stationary Black Holes.

The focus of this article is just on black hole mechanics. The discussion is divided into three parts. In the first, we will introduce the notions of event horizons and black hole regions and discuss properties of globally stationary black holes. In the second, we will consider black holes which are themselves in equilibrium but in surroundings which may be time dependent. Finally, in the third part, we summarize what is known in the fully dynamical situations. For simplicity, all manifolds and fields are assumed to be smooth and, unless otherwise stated, spacetime is assumed to be four dimensional, with a metric of signature $-, +, +, +$, and the cosmological constant is assumed to be zero. An arrow under a spacetime index denotes the pullback of that index to the horizon.

## Global Equilibrium

To capture the intuitive notion that black hole is a region from which signals cannot escape to the asymptotic part of spacetime, one needs a precise definition of future infinity. The standard strategy is to use Penrose's conformal boundary $\mathcal{J}^+$. A black hole region $\mathcal{B}$ of a spacetime $(\mathbb{M}, g_{ab})$ is defined as $\mathcal{B} = \mathbb{M} \setminus I^-(\mathcal{J}^+)$, where $I^-$ denotes "chronological past." The boundary $\partial\mathcal{B}$ of the black hole region is called the "event horizon" and denoted by $\mathcal{E}$. Thus, $\mathcal{E}$ is the boundary of the past of $\mathcal{J}^+$. It therefore follows that $\mathcal{E}$ is a null 3-surface, ruled by future inextendible null geodesics without caustics. If the spacetime is globally hyperbolic, an "instant of time" is represented by a Cauchy surface $M$. The intersection of $\mathcal{B}$ with $M$ may have several disjoint components, each representing a black hole at that instant of time. If $M'$ is a Cauchy surface to the future of $M$, the number of disjoint components of $M' \cup \mathcal{B}$ in the causal future of $M \cup \mathcal{B}$ must be less than or equal to those of $M \cup \mathcal{B}$

(see Hawking and Ellis (1973)). Thus, black holes can merge but can not bifurcate. (By a time reversal, i.e., by replacing $\mathcal{J}^+$ with $\mathcal{J}^-$ and $I^-$ with $I^+$, one can define a white hole region $\mathcal{W}$. However, here we will focus only on black holes.)

A spacetime $(\mathbb{M}, g_{ab})$ is said to be stationary (i.e., time independent) if $g_{ab}$ admits a Killing field $t^a$ that represents an asymptotic time translation. By convention, $t^a$ is assumed to be unit at infinity. $(\mathbb{M}, g_{ab})$ is said to be axisymmetric if $g_{ab}$ admits a Killing field $\phi^a$ generating an SO(2) isometry. By convention $\phi^a$ is normalized such that the affine length of its integral curves is $2\pi$. Stationary spacetimes with nontrivial $\mathbb{M}\setminus I^-(\mathcal{J}^+)$ represent black holes which are in global equilibrium. In the Einstein–Maxwell theory in four dimensions, there exists a unique three-parameter family of stationary black hole solutions, generally parametrized by mass $m$, angular momentum $J$, and electric charge $Q$. This is the celebrated Kerr–Newman family. Therefore, in general relativity a great deal of work on black holes has focused on these solutions and perturbations thereof. The Kerr–Newman family is axisymmetric and furthermore, its metric has the property that the 2-flats spanned by the Killing fields $t^a$ and $\phi^a$ are orthogonal to a family of 2-surfaces. This property is called "$t$–$\phi$ orthogonality." These features of Kerr–Newman space-times are widely used in black hole physics. Note however that uniqueness fails in higher dimensions, and also in the presence of nonabelian gauge fields or rings of perfect fluids around black holes in four dimensions. In mathematical physics, there is significant literature on the new stationary black hole solutions in Einstein–Yang–Mills–Higgs theories. These are called "hairy black holes." Research on stationary black hole solutions with rings received a boost by a recent discovery that these black holes can violate the Kerr inequality $J \leq Gm^2$ between angular momentum $J$ and mass $m$.

A null 3-manifold $\mathcal{K}$ in $\mathbb{M}$ is said to be a "Killing horizon" if $g_{ab}$ admits a Killing field $K^a$ which is everywhere normal to $\mathcal{K}$. On a Killing horizon, one can show that the acceleration of $K^a$ is proportional to $K^a$ itself:

$$K^a \nabla_a K^b = \kappa K^b \qquad [1]$$

The proportionality function $\kappa$ is called "surface gravity." We will show in the next section that if a mild energy condition holds on $\mathcal{K}$, then $\kappa$ must be constant. Note that if we rescale $K^a$ via $K^a \to cK^a$, where $c$ is a constant, surface gravity also rescales as $\kappa \to c\kappa$.

In the Kerr–Newman family, the event horizon is a Killing horizon. More generally, if an axisymmetric, stationary black hole spacetime $(\mathbb{M}, g_{ab})$ satisfies the $t$–$\phi$ orthogonality property, its event horizon $\mathcal{E}$ is a Killing horizon. (Although one can envisage stationary black holes in which these additional symmetry conditions are not met, this possibility has been ignored in black hole mechanics on stationary spacetimes. Quasilocal horizons, discussed below, do not require any spacetime symmetries.) In these cases, the normalization freedom in $K^a$ is fixed by requiring that $K^a$ have the form

$$K^a = t^a + \Omega \phi^a \qquad [2]$$

on the horizon, where $\Omega$ is a constant, called the "angular velocity of the horizon." The resulting $\kappa$ is called the surface gravity of the black hole. It is remarkable that $\kappa$ is constant for all such black holes, even when their horizon is highly distorted (i.e., far from being spherically symmetric) either due to rotation or due to external matter fields. This is analogous to the fact that the temperature of a thermodynamical system in equilibrium is constant, independently of the details of the system. In analogy with thermodynamics, constancy of $\kappa$ is referred to as the "zeroth law of black hole mechanics."

Next, let us consider an infinitesimal perturbation $\delta$ within the three-parameter Kerr–Newman family. A simple calculation shows that the changes in the Arnowitt–Deser–Misner (ADM) mass $m$, angular momentum $J$, and the total charge $Q$ of the spacetime and in the area $a$ of the horizon are constrained via

$$\delta m = \frac{\kappa}{8\pi G}\,\delta a + \Omega\,\delta J + \Phi \delta Q \qquad [3]$$

where the coefficients $\kappa, \Omega, \Phi$ are black hole parameters, $\Phi = A_a K^a$ being the electrostatic potential at the horizon. The last two terms, $\Omega\delta J$ and $\Phi\delta Q$, have the interpretation of "work" required to spin the black hole up by an amount $\delta J$ or to increase its charge by $\delta Q$. Therefore, [3] has a striking resemblance to the first law, $\delta E = T\delta S + \delta W$, of thermodynamics if (as the zeroth law suggests) $\kappa$ is made proportional to the temperature $T$, and the horizon area $a$ to the entropy $S$. Therefore, [3] and its generalizations discussed below are referred to as the "first law of black hole mechanics."

In Kerr–Newman spacetimes, the only contribution to the stress–energy tensor comes from the Maxwell field. Bardeen *et al.* (1973) consider stationary black holes with matter such as perfect fluids in the exterior region and stationary perturbations $\delta$ thereof. Using Einstein's equations, they show that the form [3] of the first law does not change; the only modification is addition of certain matter terms on the right-hand side which can be

interpreted as the work $\delta W$ done on the total system. A generalization in another direction was made by Iyer and Wald (1994) using Noether currents. They allow nonstationary perturbations and, more importantly, drop the restriction to general relativity. Instead, they consider a wide class of diffeomorphism-invariant Lagrangian densities $L(g_{ab}, R_{abcd}, \nabla_a R_{bcde}, \ldots, \Phi^{\cdot\cdot}{}_{..}, \nabla_a \Phi^{\cdot\cdot}{}_{..}, \ldots)$ which depend on the metric $g_{ab}$, matter fields $\Phi^{\cdot\cdot}{}_{..}$, and a finite number of derivatives of the Riemann tensor and matter fields. Finally, they restrict themselves to $\kappa \neq 0$. In this case, on the maximal analytic extension of the spacetime, the Killing field $K^a$ vanishes on a 2-sphere $S_o$ called the bifurcate horizon. Then, [3] is generalized to

$$\delta m = \frac{\kappa}{2\pi} \delta S_{\text{hor}} + \delta W \qquad [4]$$

Here $\delta W$ again represents "work terms" and $S_{\text{hor}}$ is given by

$$S_{\text{hor}} = -2\pi \oint_{S_o} \frac{\delta L}{\delta R_{abcd}} n_{ab} n_{cd} \qquad [5]$$

where $n_{ab}$ is the binormal to $S_o$ (with $n_{ab}n^{ab} = -2$), and the functional derivative inside the integral is evaluated by formally viewing the Riemann tensor as a field independent of the metric. For the Einstein–Hilbert action, this yields $S_{\text{hor}} = a/4G$ and one recovers [3].

These results are striking. However, the underlying assumptions have certain unsatisfactory aspects. First, although the laws are meant to refer just to black holes, one assumes that the entire spacetime is stationary. In thermodynamics, by contrast, one only assumes that the system under consideration is in equilibrium, not the whole universe. Second, in the first law, quantities $a, \Omega, \Phi$ are evaluated at the horizon while $M$, $J$ are evaluated at infinity and include contributions from possible matter fields outside the black hole. A more satisfactory law of black hole mechanics would involve attributes of the black hole alone. Finally, the notion of the event horizon is extremely global and teleological since it explicitly refers to $\mathcal{J}^+$. An event horizon may well be developing in the very room you are sitting today in anticipation of a gravitational collapse in the center of our galaxy which may occur a billion years hence. This feature makes it impossible to generalize the first law to fully dynamical situations and relate the change in the event horizon area to the flux of energy and angular momentum falling across it. Indeed, one can construct explicit examples of dynamical black holes in which an event horizon $\mathcal{E}$ forms and grows in the flat part of a spacetime where nothing happens physically. These considerations call for a replacement of $\mathcal{E}$ by a quasilocal horizon which leads to a first law involving only horizon attributes, and which can grow only in response to the influx of energy. Such horizons are discussed in the next two sections.

## Local Equilibrium

The key idea here is drop the requirement that spacetime should admit a stationary Killing field and ask only that the intrinsic horizon geometry be time independent. Consider a null 3-surface $\Delta$ in a spacetime $(\mathbb{M}, g_{ab})$ with a future-pointing normal field $\ell^a$. The pullback $q_{ab} := g_{\underleftarrow{ab}}$ of the spacetime metric to $\Delta$ is the intrinsic, degenerate "metric" of $\Delta$ with signature 0, +, +. The first condition is that it be "time independent," that is, $\mathcal{L}_\ell q_{ab} = 0$ on $\Delta$. Then by restriction, the spacetime derivative operator $\nabla$ induces a natural derivative operator $D$ on $\Delta$. While $D$ is compatible with $q_{ab}$, that is, $D_a q_{bc} = 0$, it is not uniquely determined by this property because $q_{ab}$ is degenerate. Thus, $D$ has extra information, not contained in $q_{ab}$. The pair $(q_{ab}, D)$ is said to determine the intrinsic geometry of the null surface $\Delta$. This notion leads to a natural definition of a horizon in local equilibrium. Let $\Delta$ be a null, three-dimensional submanifold of $(\mathbb{M}, g_{ab})$ with topology $\mathbb{S} \times \mathbb{R}$, where $\mathbb{S}$ is compact and without boundary.

**Definition 1** $\Delta$ is said to be "isolated horizon" if it admits a null normal $\ell^a$ such that:

(i) $\mathcal{L}_\ell \, q_{ab} = 0$ and $[\mathcal{L}_\ell, D] = 0$ on $\Delta$ and
(ii) $-T^a{}_b \ell^b$ is a future pointing causal vector on $\Delta$.

On can show that, generically, this null normal field $\ell^a$ is unique up to rescalings by positive constants.

Both conditions are local to $\Delta$. In particular, $(\mathbb{M}, g_{ab})$ is not required to be asymptotically flat and there is no longer any teleological feature. Since $\Delta$ is null and $\mathcal{L}_\ell q_{ab} = 0$, the area of any of its cross sections is the same, denoted by $a_\Delta$. As one would expect, one can show that there is no flux of gravitational radiation or matter across $\Delta$. This captures the idea that the black hole itself is in equilibrium. Condition (ii) is a rather weak "energy condition" which is satisfied by all matter fields normally considered in classical general relativity. The nontrivial condition is (i). It extracts from the notion of a Killing horizon just a "tiny part" that refers only to the intrinsic geometry of $\Delta$. As a result, every Killing horizon $\mathcal{K}$ is, in particular, an isolated horizon. However, a spacetime with an isolated horizon $\Delta$ can admit gravitational radiation and dynamical matter fields away from $\Delta$. In fact, as a family of Robinson–Trautman spacetimes illustrates,

gravitational radiation could even be present arbitrarily close to $\Delta$. Because of these possibilities, there are many nontrivial examples and the transition from event horizons of stationary spacetimes to isolated horizons represents a significant generalization of black hole mechanics. (In fact, the derivation of the zeroth and the first law requires slightly weaker assumptions, encoded in the notion of a "weakly isolated horizon" (Ashtekar *et al.* 2000, 2001).)

An immediate consequence of the requirement $\mathcal{L}_\ell q_{ab} = 0$ is that there exists a 1-form $\omega_a$ on $\Delta$ such that $D_a \ell^b = \omega_a \ell^b$. Following the definition of $\kappa$ on a Killing horizon, the surface gravity $\kappa_{(\ell)}$ of $(\Delta, \ell)$ is defined as $\kappa_{(\ell)} = \omega_a \ell^a$. Again, under $\ell^a \to c\ell^a$, we have $\kappa_{(c\ell)} = c\kappa_\ell$. Together with Einstein's equations, the two conditions of Definition 1 imply $\mathcal{L}_\ell \omega_a = 0$ and $\ell^a D_{[a}\omega_{b]} = 0$. The Cartan identity relating the Lie and exterior derivative now yields

$$D_a(\omega_b \ell^b) \equiv D_a \kappa_{(\ell)} = 0 \qquad [6]$$

Thus, surface gravity is constant on every isolated horizon. This is the zeroth law, extended to horizons representing local equilibrium. In the presence of an electromagnetic field, Definition 1 and the field equations imply $\mathcal{L}_\ell \underline{F_{ab}} = 0$ and $\ell^a \underline{F_{ab}} = 0$. The first of these equations implies that one can always choose a gauge in which $\mathcal{L}_\ell \underline{A_a} = 0$. By Cartan identity it then follows that the electrostatic potential $\Phi_{(\ell)} := A_a \ell^a$ is constant on the horizon. This is the Maxwell analog of the zeroth law.

In this setting, the first law is derived using a Hamiltonian framework (Ashtekar *et al.* 2000, 2001). For concreteness, let us assume that we are in the asymptotically flat situation and the only gauge field present is electromagnetic. One begins by restricting oneself to horizon geometries such that $\Delta$ admits a rotational vector field $\varphi^a$ satisfying $\mathcal{L}_\varphi q_{ab} = 0$. (In fact for black hole mechanics, it suffices to assume only that $\mathcal{L}_\varphi \epsilon_{ab} = 0$, where $\epsilon_{ab}$ is the intrinsic area 2-form on $\Delta$. The same is true on dynamical horizons discussed in the next section.) One then constructs a phase space $\boldsymbol{\Gamma}$ of gravitational and matter fields such that (1) $\mathbb{M}$ admits an internal boundary $\Delta$ which is an isolated horizon; and (2) all fields satisfy asymptotically flat boundary conditions at infinity. Note that the horizon geometry is allowed to vary from one phase-space point to another; the pair $(q_{ab}, D)$ induced on $\Delta$ by the spacetime metric only has to satisfy Definition 1 and the condition $\mathcal{L}_\varphi q_{ab} = 0$.

Let us begin with angular momentum. Fix a vector field $\phi^a$ on $\mathbb{M}$ which coincides with the fixed $\varphi^a$ on $\Delta$ and is an asymptotic rotational symmetry at infinity. (Note that $\phi^a$ is not restricted in any way in the bulk.) Lie derivatives of gravitational and matter fields along $\phi^a$ define a vector field $X(\phi)$ on $\boldsymbol{\Gamma}$. One shows that it is an infinitesimal canonical transformation, that is, satisfies $\mathcal{L}_{X(\phi)}\boldsymbol{\Omega} = 0$, where $\boldsymbol{\Omega}$ is the symplectic structure on $\boldsymbol{\Gamma}$. The Hamiltonian $H(\phi)$ generating this canonical transformation is given by

$$\begin{aligned} H(\phi) &= J_\Delta^{(\phi)} - J_\infty^{(\phi)} \\ J_\Delta^{(\phi)} &= -\frac{1}{8\pi G}\oint_{\mathbb{S}} (\omega_a \phi^a)\epsilon - \frac{1}{4\pi}\oint_{\mathbb{S}} (A_a \phi^a)^\star F \end{aligned} \qquad [7]$$

where $J_\infty^{(\phi)}$ is the ADM angular momentum at infinity, $\mathbb{S}$ is any cross section of $\Delta$, and $\epsilon$ the area element thereon. The term $J_\Delta^{(\phi)}$ is independent of the choice of $\mathbb{S}$ made in its evaluation and interpreted as the "horizon angular momentum." It has numerous properties that support this interpretation. In particular, it yields the standard angular momentum expression in Kerr–Newman spacetimes.

To define horizon energy, one has to introduce a "time-translation" vector field $t^a$. At infinity, $t^a$ must tend to a unit time translation. On $\Delta$, it must be a symmetry of $q_{ab}$. Since $\ell^a$ and $\varphi^a$ are both horizon symmetries, $t^a = c\ell^a + \Omega\varphi^a$ on $\Delta$, for some constants $c$ and $\Omega$. However, unlike $\phi^a$, the restriction of $t^a$ to $\Delta$ cannot be fixed once and for all but must be allowed to vary from one phase-space point to another. In particular, on physical grounds, one expects $\Omega$ to be zero at a phase-space point representing a nonrotating black hole but nonzero at a point representing a rotating black hole. This freedom in the boundary value of $t^a$ introduces a qualitatively new element. The vector field $X(t)$ on $\boldsymbol{\Gamma}$ defined by the Lie derivatives of gravitational and matter fields does not, in general, satisfy $\mathcal{L}_{X(t)}\boldsymbol{\Omega} = 0$; it need not be an infinitesimal canonical transformation. The necessary and sufficient condition is that $(\kappa_{(c\ell)}/8\pi G)\delta a_\Delta + \Omega\delta J_\Delta + \Phi_{(c\ell)}\delta Q_\Delta$ be an exact variation. That is, $X(t)$ generates a Hamiltonian flow if and only if there exists a function $E_\Delta^{(t)}$ on $\boldsymbol{\Gamma}$ such that

$$\delta E_\Delta^{(t)} = \frac{\kappa_{(c\ell)}}{8\pi G}\delta a_\Delta + \Omega\delta J_\Delta + \Phi_{(c\ell)}\delta Q_\Delta \qquad [8]$$

This is precisely the first law. Thus, the framework provides a deeper insight into the origin of the first law: it is the necessary and sufficient condition for the evolution generated by $t^a$ to be Hamiltonian. Equation [8] is a genuine restriction on the choice of phase-space functions $c$ and $\Omega$, that is, of restrictions to $\Delta$ of evolution fields $t^a$. It is easy to verify that $\mathbb{M}$ admits many such vector fields. Given one, the Hamiltonian $H(t)$ generating the time evolution along $t^a$ takes the form

$$H(t) = E_\infty^{(t)} - E_\Delta^{(t)} \qquad [9]$$

re-enforcing the interpretation of $E_{\Delta}^{(t)}$ as the horizon energy.

In general, there is a multitude of first laws, one for each vector field $t^a$, the evolution along which preserves the symplectic structure. In the Einstein–Maxwell theory, given any phase-space point, one can choose a canonical boundary value $t_o^a$ exploiting the uniqueness theorem. $E_{\Delta}^{(t_o)}$ is then called the horizon mass and denoted simply by $m_{\Delta}$. In the Kerr–Newman family, $\boldsymbol{H}(t_o)$ vanishes and $m_{\Delta}$ coincides with the ADM mass $m_{\infty}$. Similarly, if $\phi^a$ is chosen to be a global rotational Killing field, $J_{\Delta}^{(\phi)}$ equals $J_{\infty}^{(\phi)}$. However, in more general spacetimes where there is matter field or gravitational radiation outside $\Delta$, these equalities do not hold; $m_{\Delta}$ and $J_{\Delta}$ represent quantities associated with the horizon alone while the ADM quantities represent the total mass and angular momentum in the spacetime, including contributions from matter fields and gravitational radiation in the exterior region. In the first law [8], only the contributions associated with the horizon appear.

When the uniqueness theorem fails, as, for example, in the Einstein–Yang–Mills–Higgs theory, first laws continue to hold but the horizon mass $m_{\Delta}$ becomes ambiguous. Interestingly, these ambiguities can be exploited to relate properties of hairy black holes with those of the corresponding solitons. (For a summary, see Ashtekar and Krishnan (2004).)

## Dynamical Situations

A natural question now is whether there is an analog of the second law of thermodynamics. Using event horizons, Hawking showed that the answer is in the affirmative (see Hawking and Ellis (1973)). Let $(\mathbb{M}, g_{ab})$ admit an event horizon $\mathcal{E}$. Denote by $\ell^a$ a geodesic null normal to $\mathcal{E}$. Its expansion is defined as $\theta_{(\ell)} := q^{ab}\nabla_a \ell_b$, where $q^{ab}$ is any inverse of the degenerate intrinsic metric $q_{ab}$ on $\mathcal{E}$, and determines the rate of change of the area element of $\mathcal{E}$ along $\ell^a$. Assuming that the null energy condition and Einstein's equations hold, the Raychaudhuri equation immediately implies that if $\theta_{(\ell)}$ were to become negative somewhere it would become infinite within a finite affine parameter. Hawking showed that, if there is a globally hyperbolic region containing $I^-(\mathcal{J}^+) \cup \mathcal{E}$ – that is, if there are no naked singularities – this can not happen, whence $\theta(\ell) \geq 0$ on $\mathcal{E}$. Hence, if a cross section $S_2$ of $\mathcal{E}$ is to the future of a cross section $S_1$, we must have $a_{S_2} \geq a_{S_1}$. Thus, in any (i.e., not necessarily infinitesimal) dynamical process, the change $\Delta a$ in the horizon area is always non-negative. This result is known as the "second law of black hole mechanics." As in the first law, the analog of entropy is the horizon area.

It is tempting to ask if there is a local physical process directly responsible for the growth of area. For event horizons, the answer is in the negative since they can grow in a flat portion of spacetime. However, one can introduce quasilocal horizons also in the dynamical situations and obtain the desired result (Ashtekar and Krishnan 2003). These constructions are strongly motivated by earlier ideas introduced by Hayward (1994).

**Definition 2** A three-dimensional spacelike submanifold $\mathcal{H}$ of $(\mathbb{M}, g_{ab})$ is said to be a "dynamical horizon" if it admits a foliation by compact 2-manifolds $\mathbb{S}$ (without boundary) such that:

(i) the expansion $\theta_{(\ell)}$ of one (future directed) null normal field $\ell^a$ to $\mathbb{S}$ vanishes and the expansion of the other (future directed) null normal field, $n^a$ is negative; and
(ii) $-T^a{}_b \ell^b$ is a future pointing causal vector on $\mathcal{H}$.

One can show that this foliation of $\mathcal{H}$ is unique and that $\mathbb{S}$ is either a 2-sphere or, under degenerate and physically over-restrictive conditions, a 2-torus. Each leaf $\mathbb{S}$ is a marginally trapped surface and referred to as a "cut" of $\mathcal{H}$. Unlike event horizons $\mathcal{E}$, dynamical horizons $\mathcal{H}$ are locally defined and do not display any teleological feature. In particular, they cannot lie in a flat portion of spacetime. Dynamical horizons commonly arise in numerical simulations of evolving black holes as world tubes of apparent horizons. As the black hole settles down, $\mathcal{H}$ asymptotes to an isolated horizon $\Delta$, which tightly hugs the asymptotic future portion of the event horizon. However, during the dynamical phase, $\mathcal{H}$ typically lies well inside $\mathcal{E}$.

The two conditions in Definition 2 immediately imply that the area of cuts of $\mathcal{H}$ increases monotonically along the "outward direction" defined by the projection of $\ell^a$ on $\mathcal{H}$. Furthermore, this change turns out to be directly related to the flux of energy falling across $\mathcal{H}$. Let $R$ denote the "radius function" on $\mathcal{H}$ so that the area of any cut $\mathbb{S}$ is given by $a_{\mathbb{S}} = 4\pi R^2$. Let $N$ denote the norm of $\partial_a R$ and $\Delta\mathcal{H}$, the portion of $\mathcal{H}$ bounded by two cross sections $\mathbb{S}_1$ and $\mathbb{S}_2$. The appropriate energy turns out to be associated with the vector field $N\ell^a$, where $\ell^a$ is normalized such that its projection on $\mathcal{H}$ is the unit normal $\hat{r}^a$ to the cuts $\mathbb{S}$. In the generic and physically interesting case when $\mathbb{S}$ is a 2-sphere, the Gauss and the Codazzi (i.e., constraint) equations imply

$$\frac{1}{2G}(R_2 - R_1) = \int_{\Delta\mathcal{H}} T_{ab} N \ell^a \hat{r}^b \, \mathrm{d}^3V + \frac{1}{16\pi G} \times \int_{\Delta\mathcal{H}} N\left(\sigma_{ab}\sigma^{ab} + 2\zeta_a\zeta^a\right) \mathrm{d}^3V \qquad [10]$$

Here $\hat{r}^a$ is the unit normal to $\mathcal{H}$, $\sigma^{ab}$ the shear of $\ell^a$ (i.e., the tracefree part of $q^{am}q^{bm}\nabla_m\ell_n$), and $\zeta^a = q^{ab}\hat{r}^c\nabla_c\ell_b$, where $q^{ab}$ is the projector onto the tangent space of the cuts $\mathbb{S}$. The first integral on the right-hand side can be directly interpreted as the flux across $\Delta\mathcal{H}$ of matter–energy (relative to the vector field $N\ell^a$). The second term is purely geometric and is interpreted as the flux of energy carried by gravitational waves across $\Delta\mathcal{H}$. It has several properties which support this interpretation. Thus, not only does the second law of black hole mechanics hold for a dynamical horizon $\mathcal{H}$, but the "cause" of the increase in the area can be directly traced to physical processes happening near $\mathcal{H}$.

Another natural question is whether the first law [8] can be generalized to fully dynamical situations, where $\delta$ is replaced by a finite transition. Again, the answer is in the affirmative. We will outline the idea for the case when there are no gauge fields on $\mathcal{H}$. As with isolated horizons, to have a well-defined notion of angular momentum, let us suppose that the intrinsic 3-metric on $\mathcal{H}$ admits a rotational Killing field $\varphi$. Then, the angular momentum associated with any cut $\mathbb{S}$ is given by

$$J_{\mathbb{S}}^{(\varphi)} = -\frac{1}{8\pi G}\oint_{\mathbb{S}} K_{ab}\varphi^a\hat{r}^b\, \mathrm{d}^2V \equiv \frac{1}{8\pi G}\oint_{\mathbb{S}} j^{(\varphi)}\, \mathrm{d}^2V \qquad [11]$$

where $K_{ab}$ is the extrinsic curvature of $\mathcal{H}$ in $(\mathbb{M}, g_{ab})$ and $j^{(\varphi)}$ is interpreted as "the angular momentum density." Now, in the Kerr family, the mass, surface gravity, and the angular velocity can be unambiguously expressed as well-defined functions $\bar{m}(a,J)$, $\bar{\kappa}(a,J)$, and $\bar{\Omega}(a,J)$ of the horizon area $a$ and angular momentum $J$. The idea is to use these expressions to associate mass, surface gravity, and angular velocity with each cut of $\mathcal{H}$. Then, a surprising result is that the difference between the horizon masses associated with cuts $\mathbb{S}_1$ and $\mathbb{S}_2$ can be expressed as the integral of a locally defined flux across the portion $\Delta\mathcal{H}$ of $\mathcal{H}$ bounded by $\mathcal{H}_1$ and $\mathcal{H}_2$:

$$\bar{m}_2 - \bar{m}_1 = \frac{1}{8\pi G}\int_{\Delta\mathcal{H}} \bar{\kappa}\, \mathrm{d}a + \frac{1}{8\pi G}\left\{ \oint_{\mathbb{S}_2} \bar{\Omega} j^{\varphi}\, \mathrm{d}^2V - \oint_{\mathbb{S}_1} \bar{\Omega} j^{\varphi}\, \mathrm{d}^2V - \int_{\bar{\Omega}_1}^{\bar{\Omega}_2} \mathrm{d}\bar{\Omega} \oint_{\mathbb{S}} j^{\varphi}\, \mathrm{d}^2V \right\} \qquad [12]$$

If the cuts $\mathbb{S}_2$ and $\mathbb{S}_1$ are only infinitesimally separated, this expression reduces precisely to the standard first law involving infinitesimal variations. Therefore, [12] is an integral generalization of the first law.

Let us conclude with a general perspective. On the whole, in the passage from event horizons in stationary spacetimes to isolated horizons and then to dynamical horizons, one considers increasingly more realistic situations. In all the three cases, the analysis has been extended to allow the presence of a cosmological constant $\Lambda$. (The only significant change is that the topology of cuts $\mathbb{S}$ of dynamical horizons is restricted to be $\mathbb{S}^2$ if $\Lambda > 0$ and is completely unrestricted if $\Lambda < 0$.) In the first two frameworks, results have also been extended to higher dimensions. Since the notions of isolated and dynamical horizons make no reference to infinity, these frameworks can be used also in spatially compact spacetimes. The notion of an event horizon, by contrast, does not naturally extend to these spacetimes. On the other hand, the generalization [4] of the first law [3] is applicable to event horizons of stationary spacetimes in a wide class of theories while so far the isolated and dynamical horizon frameworks are tied to general relativity (coupled to matter satisfying rather weak energy conditions). From a mathematical physics perspective, extension to more general theories is an important open problem.

# Boltzmann Equation (Classical and Quantum)

**M Pulvirenti**, Università di Roma “La Sapienza,” Rome, Italy

## Introduction

Ludwig Boltzmann (1872) established an evolution equation to describe the behavior of a rarefied gas, starting from the mathematical model of elastic balls and using mechanical and statistical considerations. The importance of this equation is twofold. First, it provides a reduced description (as well as the hydrodynamical equations) of the microscopic world. Second, it is also an important tool for the applications, especially for dilute fluids when the hydrodynamical equations fail to hold.

The starting point of the Boltzmann analysis is to abandon the study of the gas in terms of the detailed motion of molecules which constitute it because of their large number. Instead, it is better to investigate a function $f(x, v)$, which is the probability density of a given particle, where $x$ and $v$ denote its position and velocity. Actually, $f(x, v)\mathrm{d}x\,\mathrm{d}v$ is often confused with the fraction of molecules falling in the cell of the phase space of size $\mathrm{d}x\,\mathrm{d}v$ around $x$, $v$. The two concepts are not exactly the same, but they are asymptotically equivalent (when the number of particles is diverging) if a law of large numbers holds.

The Boltzmann equation is the following:

$$(\partial_t + v \cdot \nabla_x) f = Q(f, f) \qquad [1]$$

where $Q$, the collision operator, is defined by eqn [2]:

$$Q(f, f) = \int_{\mathbb{R}^3} \mathrm{d}v_1 \int_{S^2_+} \mathrm{d}n (v - v_1) \cdot n \times [f(x, v') f(x, v'_1) - f(x, v) f(x, v_1)] \qquad [2]$$

and

$$\begin{aligned} v' &= v - n[n \cdot (v - v_1)] \\ v'_1 &= v_1 + n[n \cdot (v - v_1)] \end{aligned} \qquad [3]$$

Moreover, $n$ (the impact parameter) is a unitary vector and $S^2_+ = \{n | n \cdot (v - v_1) \geq 0\}$.

Note that $v', v'_1$ are the outgoing velocities after a collision of two elastic balls with incoming velocities $v$ and $v_1$ and centers $x$ and $x + rn$, $r$ being the diameter of the spheres. Obviously, the collision takes place if $n \cdot (v - v_1) \geq 0$. Equations [3] are a consequence of the conservation of total energy, momentum, and angular momentum. Note also that $r$ does not enter in eqn [1] as a parameter.

As fundamental features of eqn [1], we have the conservation in time of the following five quantities

$$\int \mathrm{d}x \int \mathrm{d}v\, f(x, v; t) v^\alpha \qquad [4]$$

with $\alpha = 0, 1, 2$, expressing conservation of the probability, momentum, and energy.

From now on we shall set $\int = \int_{\mathbb{R}^3}$ for notational simplicity.

Moreover, Boltzmann introduced the (kinetic) entropy defined as

$$H(f) = \int \mathrm{d}x \int \mathrm{d}v\, f \, \log f(x, v) \qquad [5]$$

and proved the famous $H$-theorem asserting the decreasing of $H(f(t))$ along the solutions to eqn [1].

Finally, in the case of bounded domains or homogeneous solutions ($f = f(v; t)$ is independent of $x$), the distribution defined for some $\beta > 0, \rho > 0$, and $u \in \mathbb{R}^3$ by

$$M(x, v) = \frac{\rho}{(2\pi/\beta)^{3/2}} \mathrm{e}^{-(\beta/2)|v-u|^2} \qquad [6]$$

called Maxwellian distribution, is stationary for the evolution given by eqn [1]. In addition, $M$ minimizes $H$ among all distributions with given total mass $\rho$, given mean velocity $u$, and mean energy. The parameter $\beta$ is interpreted as the inverse temperature.

In conclusion, Boltzmann was able to introduce not only an evolutionary equation with the remarkable properties expressing mass, momentum, and energy conservation, but also the trend to the thermal equilibrium. In other words, he tried to conciliate the Newton’s laws with the second principle of thermodynamics.

## The Boltzmann Heuristic Argument

Thus, we want to find an evolution equation for the quantity $f(x, v; t)$. The molecular system we are considering consists of $N$ identical particles of diameter $r$ in the whole space $\mathbb{R}^3$. We denote by $x_1, v_1, \ldots, x_N, v_N$ a state of the system, where $x_i$ and $v_i$ indicate the position and the velocity of the particle $i$. The particles cannot overlap (i.e., the centers of two particles cannot be at a distance smaller than the particle diameter $r$).

The particles are moving freely up to the first instance of contact, that is, the first time when two particles (say particles $i$ and $j$) arrive at a distance $r$. Then the pair interacts when an elastic collision occurs. This means that they change instantaneously

their velocities, according to the conservation of the energy and linear and angular momentum. More precisely, the velocities after a collision with incoming velocities $v$ and $v_1$ are those given by formula [3]. After the first collision, the system evolves by iterating the procedure. Here we neglect triple collisions because they are unlikely. The evolution equation for a tagged particle is then of the form

$$(\partial_t + v \cdot \nabla_x)f = \text{Coll} \qquad [7]$$

where Coll denotes the variation of $f$ due to the collisions.

We have

$$\text{Coll} = G - L \qquad [8]$$

where $L$ and $G$ (the loss and gain terms, respectively) are the negative and positive contributions to the variation of $f$ due to the collisions. More precisely, $L\,\mathrm{d}x\,\mathrm{d}v\,\mathrm{d}t$ is the probability of the test particle to disappear from the cell $\mathrm{d}x\,\mathrm{d}v$ of the phase space because of a collision in the time interval $(t, t + \mathrm{d}t)$ and $G\mathrm{d}x\,\mathrm{d}v\,\mathrm{d}t$ is the probability to appear in the same time interval for the same reason. Let us consider the sphere of center $x$ with radius $r$ and a point $x + rn$ over the surface, where $n$ denotes the generic unit vector. Consider also the cylinder with base area $\mathrm{d}S = r^2\,\mathrm{d}n$ and height $|V|\mathrm{d}t$ along the direction of $V = v_2 - v$.

Then a given particle (say particle 2) with velocity $v_2$ can contribute to $L$ because it can collide with the test particle in the time $\mathrm{d}t$, provided it is localized in the cylinder and if $V \cdot n \le 0$. Therefore, the contribution to $L$ due to the particle 2 is the probability of finding such a particle in the cylinder (conditioned to the presence of the first particle in $x$). This quantity is $f_2(x, v, x + nr, v_2)\,|\,(v_2 - v) \cdot n|r^2\,\mathrm{d}n\,\mathrm{d}v_2\,\mathrm{d}t$, where $f_2$ is the joint distribution of two particles. Integrating in $\mathrm{d}n$ and $\mathrm{d}v_2$, we obtain that the total contribution to $L$ due to any predetermined particle is

$$r^2 \int \mathrm{d}v_2 \int_{S^2_-} \mathrm{d}n\, f_2(x, v, x + nr, v_2)|(v_2 - v) \cdot n| \qquad [9]$$

where $S^2_-$ is the unit hemisphere $(v_2 - v) \cdot n < 0$. Finally, we obtain the total contribution multiplying by the total number of particles:

$$L = (N-1)r^2 \int \mathrm{d}v_2 \times \int_{S_-} \mathrm{d}n\, f_2(x, v, x + nr, v_2)|(v_2 - v) \cdot n| \qquad [10]$$

The gain term can be derived analogously by considering that we are looking at particles which have velocities $v$ and $v_2$ after the collisions so that we have to integrate over the hemisphere $S^2_+ = \{(v_2 - v) \cdot n > 0\}$:

$$G = (N-1)r^2 \int \mathrm{d}v_2 \times \int_{S_+} \mathrm{d}n\, f_2(x, v, x + nr, v_2)|(v_2 - v) \cdot n| \qquad [11]$$

Summing $G$ and $-L$, we get

$$\text{Coll} = (N-1)r^2 \int \mathrm{d}v_2 \times \int \mathrm{d}n\, f_2(x, v, x + nr, v_2)(v_2 - v) \cdot n \qquad [12]$$

which, however, is not a very useful expression because the time derivative of $f$ is expressed in terms of another object, namely $f_2$. An evolution equation for $f_2$ will imply $f_3$, the joint distribution of three particles, and so on, up to we include the total particle number $N$. Here the basic main assumption of Boltzmann enters, namely that two given particles are uncorrelated if the gas is rarefied, namely

$$f(x, v, x_2, v_2) = f(x, v)f(x_2, v_2) \qquad [13]$$

Condition [13], referred to as the propagation of chaos, seems contradictory at first sight: if two particles collide, correlations are created. Even though we could assume eqn [13] at some time, if the test particle collides with particle 2, such an equation cannot be satisfied anymore after the collision.

Before discussing the propagation of chaos hypothesis, we first analyze the size of the collision operator. We remark that, in practical situations for a rarefied gas, the combination $Nr^3 \approx 10^{-4}\,\mathrm{cm}^3$ (i.e., the volume occupied by the particles) is very small, while $Nr^2 = O(1)$. This implies that $G = O(1)$. Therefore, since we are dealing with a very large number of particles, we are tempted to perform the limit $N \to \infty$ and $r \to 0$ in such a way that $r^2 = O(N^{-1})$. As a consequence, the probability that two tagged particles collide (which is of the order of the surface of a ball, i.e., $O(r^2)$) is negligible. However, the probability that a given particle performs a collision with any one of the remaining $N - 1$ particles (which is $O(Nr^2) = O(1)$) is not negligible. Therefore, condition [13] is referring to two preselected particles (say particles 1 and 2), so that it is not unreasonable to conceive that it holds in the limiting situation in which we are working.

However, we cannot insert [13] in [12] because this latter equation refers to instants before and after the collision and, if we know that a collision took place, we certainly cannot invoke eqn [13]. Hence, it is more convenient to assume eqn [13] in the loss term and work over the gain term to keep advantage

of the factorization property which will be assumed only before the collision.

Coming back to eqn [11] for the outgoing pair velocities $v, v_2$ (satisfying the condition $(v_2 - v) \cdot n > 0$), we make use of the continuity property

$$f_2(x, v, x + nr, v_2) = f_2(x, v', x + nr, v'_2) \quad [14]$$

where the pair $v', v'_2$ is pre-collisional. On $f_2$ expressed before the collision, we can reasonably apply condition [13] and obtain

$$G - L = (N-1)r^2 \int dv_2 \int_{S^2_+} dn (v - v_2) \cdot n \times [f(x, v') f(x - nr, v'_2) - f(x, v) f(x + nr, v_2)] \quad [15]$$

after a change $n \to -n$ in the gain term, using the notation $S^2_+$ for the hemisphere $\{n| = (v_2 - v) \cdot n \geq 0\}$. This transforms the pair $v', v'_2$ from a pre-collisional to a post-collisional pair.

Finally, in the limit $N \to \infty$, $r \to 0$, $Nr^2 = \lambda^{-1}$, we find

$$(\partial_t + v \cdot \nabla_x) f = \lambda^{-1} \int dv_2 \int_{S_+} dn (v - v_2) \cdot n \times [f(x, v') f(x, v'_2) - f(x, v) f(x, v_2)] \quad [16]$$

The parameter $\lambda$, called mean free path, represents, roughly speaking, the typical length a particle can cover without undergoing any collision. In eqns [1] and [2], we just chose $\lambda = 1$.

Equation [16] (or, equivalently, eqns [1] and [2]) is the Boltzmann equation for hard spheres. Such an equation has a statistical nature, and it is not equivalent to the Hamiltonian dynamics from which it has been derived. Indeed, the $H$-theorem shows that such an equation is not reversible in time as expected of any law of mechanics.

This concludes the heuristic preliminary analysis of the Boltzmann equation. We certainly know that the above arguments are delicate and require a more rigorous and deeper analysis. If we want the Boltzmann equation not to be a phenomenological model, derived by *ad hoc* assumptions and justified only by its practical relevance, but rather that it is a consequence of a mechanical model, we must derive it rigorously. In particular, the propagation of chaos should be not a hypothesis but the statement of a theorem.

## Beyond the Hard Spheres

The heuristic arguments we have developed so far can be extended to different potentials than that of the hard-sphere systems. If the particles interact via a two-body interaction $V = V(r)$, the resulting Boltzmann equation is eqn [1], with

$$Q(f, f) = \int dv_1 \int_{S^2_+} dn\, B(v - v_1; n) [f' f'_1 - f f_1] \quad [17]$$

where we are using the usual shorthand notation:

$$f' = f(x, v'), \quad f'_1 = f(x, v'_1), \quad f = f(x, v), \quad f_1 = f(x, v_1) \quad [18]$$

and $B = B(v - v_1; n)$ is a suitable function of the relative velocity $v - v_1$ and the impact parameter $n$, which is proportional to the cross section relative to the potential $V$. Another equivalent, sometimes more convenient, way, to express eqn [17] is

$$Q(f, f) = \int dv_1 \int dv' \int dv'_1\, W(v, v_1 | v', v'_1) [f' f'_1 - f f_1] \quad [19]$$

with

$$W(v, v_1 | v', v'_1) = w(v, v_1 | v', v'_1) \times \delta(v + v_1 - v' - v'_1) \times \delta\left(\tfrac{1}{2}\left(v^2 + v_1^2 - (v')^2 - (v'_1)^2\right)\right) \quad [20]$$

where $w$ is a suitable kernel. All the qualitative properties, such as the conservation laws and the $H$-theorem, are obviously still valid.

## Consequences

The Boltzmann equation provoked a debate involving Loschmidt, Zermelo, and Poincaré, who outlined inconsistencies between the irreversibility of the equation and the reversible character of the Hamiltonian dynamics. Boltzmann argued the statistical nature of his equation and his answer to the irreversibility paradox was that "most" of the configurations behave as expected by the thermodynamical laws. However, he did not have the probabilistic tools for formulating in a precise way the statements of which he had a precise intuition.

Grad (1949) stated clearly the limit $N \to \infty$, $r \to 0$, $Nr^2 \to$ const., where $N$ is the number of particles and $r$ is the diameter of the molecules, in which the Boltzmann equation is expected to hold. This limit is usually called the Boltzmann–Grad limit (B–G limit in the sequel).

The problem of a rigorous derivation of the Boltzmann equation was an open and challenging problem for a long time. Lanford (1975) showed that, although for a very short time, the Boltzmann equation can be derived starting from the mechanical model of the hard-sphere system. The proof has a deep content but is relatively simple from a technical viewpoint.

## Existence

The mathematical study of the Boltzmann equation starts with the problem of proving the existence of the solutions. One would like to be able to show that, for all (or at least for a physically significant family of) initial distributions (which are positive and summable functions) with finite momentum, energy, and entropy, there exists a unique solution to eqn [1] with the same mass, momentum, and energy as of the initial distribution. Moreover, the entropy should decrease and the solution should approach the right Maxwellian as $t \to \infty$. The problem, in such a generality, is still unsolved, but several results in this direction have been achieved since the pioneering works due to Carleman (1933) for the homogeneous equation. Actually, there are satisfactory results for some special situations, such as the homogeneous solutions (independent of $x$) close to the equilibrium, to the vacuum, or to homogeneous data. The most general result we have up to now is, unfortunately, not constructive. This is due to Di Perna and Lions (1989), who showed the existence of suitable weak solutions to eqn [1]. However, we still do not know whether such solutions, which preserve mass and momentum, and satisfy the $H$-theorem, are unique and also preserve the energy.

## Hydrodynamics

The derivation of hydrodynamical equations from the Boltzmann equation is a problem as old as the equation itself and, in fact, it goes back to Maxwell and Hilbert. Preliminary to the discussion of the hydrodynamic limit, we establish a few properties of the collision kernel.

It is a well-known fact that the only solution to the equation

$$Q(f,f) = 0 \qquad [21]$$

is a local Maxwellian, namely

$$f(x,v) := M(x,v) = \frac{\rho(x)}{(2\pi T(x))^{3/2}} \mathrm{e}^{-|v-u(x)|^2/2T(x)} \qquad [22]$$

where the local parameters $\rho, \rho u$, and $T$ satisfy the relations

$$\int M \, \mathrm{d}v = \rho \qquad [23]$$

$$\int vM = \rho u \qquad [24]$$

$$\frac{1}{2}\int v^2 M \, \mathrm{d}v = \frac{3}{2}\rho T + \frac{1}{2}\rho u^2 \qquad [25]$$

Moreover, the only solution to the equation

$$\int h(v) Q(f,f) \, \mathrm{d}v = 0 \qquad [26]$$

is any linear combination of the quantities $(1, v, v^2)$, called collision invariants. The last property obviously corresponds to the mass, momentum, and energy conservation.

With this in mind, consider a change of variables in the Boltzmann equation [1], passing from microscopic to macroscopic variables, $x \to \varepsilon x$, $t \to \varepsilon t$. Here $\varepsilon$ is a small scale parameter expressing the ratio between the typical inter-particle distances and the typical distances over which the macroscopic equations are varying. Such a change yields

$$(\partial_t + v \cdot \nabla_x) f_\varepsilon = \frac{1}{\varepsilon} Q(f_\varepsilon, f_\varepsilon) \qquad [27]$$

We need to allow the small parameter $\varepsilon$ (mean free path or the Knudsen number) to tend to zero. In order to eliminate the singularity on the right-hand side of [27], we multiply both sides by the collision invariants $v^\alpha$ with $\alpha = 0, 1, 2$, and obtain the five equations:

$$\int \mathrm{d}v \, v^\alpha (\partial_t + v \cdot \nabla_x) f_\varepsilon = 0 \qquad [28]$$

On the other hand, if $f_\varepsilon$ converges to $f$, as $\varepsilon \to 0$, necessarily $Q(f,f) = 0$ and hence $f = M$. Therefore, we expect that in the limit $\varepsilon \to 0$,

$$\int \mathrm{d}v \, v^\alpha (\partial_t + v \cdot \nabla_x) M = 0 \qquad [29]$$

Equation [29] fixes a relation among the fields $\rho, u, T$ as functions of $x$ and $t$. A standard computation gives us the Euler equations for compressible gas

$$\partial_t \rho + \mathrm{div}(\rho u) = 0 \qquad [30]$$

$$\partial_t u + (u \cdot \nabla) u + \frac{1}{\rho} \nabla p = 0 \qquad [31]$$

$$\partial_t T + (u \cdot \nabla) T + \tfrac{2}{3} T \nabla u = 0 \qquad [32]$$

where the pressure $p$ is related to the density $\rho$ and the temperature $T$ by the perfect gas law

$$p = \rho T \qquad [33]$$

In order to make the above arguments rigorous, Hilbert (1916) developed a useful tool, called the Hilbert expansion, to control the limiting procedure.

Namely, he expressed a formal solution to eqn [27] in the form of a power series expansion:

$$f_\varepsilon = \sum_{j\geq 0} f_j\, \varepsilon^j \qquad [34]$$

where $f_0$ is the local Maxwellian, with the parameters $\rho, u, T$ satisfying the Euler equations. All the other coefficients $f_j$ of the developments can be determined by recurrence, inverting suitable operators. However, the series is not expected to be convergent, so that the way to show the validity of the hydrodynamical limit rigorously is to truncate the expansion and to control the remainder. The first result in this direction was obtained by Caflisch (1980). However, this approach is based on the regularity of the solutions to the Euler equations, which is known to hold only for short times since shocks can be formed. How to approximate the shocks in terms of a kinetic description is still a difficult and open problem.

Note that the hydrodynamical picture of the Boltzmann equation just means that we are looking at the solutions of this equation at a suitable macroscopic scale. The rarefaction hypothesis underlying the Boltzmann description is reflected in the law of perfect gas, which states that the particles, in the local thermal equilibrium, are free.

## Stationary Problems

Stationary non-Maxwellian solutions to the Boltzmann equation should describe stationary nonequilibrium states exhibiting nontrivial flows. In spite of the physical relevance of these problems, not many complete mathematical results are, at the moment, available. Among them, there is the traveling-wave problem, which can be formulated in the following way. We look for a solution $f = f(x - ct, v), f: \mathbb{R}\times\mathbb{R}^3 \to \mathbb{R}^+$, constant in form but traveling with a constant velocity $c > 0$, to

$$(v_1 - c)f' = Q(f, f) \qquad [35]$$

where $v_1$ is the first component of $v$ and $f'$ denotes the spatial derivative of $f$. Equation [35] must be complemented by the boundary conditions which are $f \to M_\pm$, as $x \to \infty$, where $M_\pm$ are the right and left Maxwellians, namely two prescribed equilibrium situations at infinity. The parameters (density, mean velocity, and temperature) of the Maxwellians, however, cannot be chosen arbitrarily. Indeed, the conservations of the mass, momentum, and energy (which are properties of $Q$) imply the conservations (in $x$) of the fluxes of these quantities. Hence, we have to impose five equations that relate the upstream and the downstream values of the densities, mean velocities, and temperatures. Such relations are known in gas dynamics as the Rankine–Hugoniot conditions. A solution of this problem has been found by Caflisch and Nikolaenko (1983) in case of a weak shock (namely, when $M_+$ and $M_-$ are close) by using Hilbert expansion techniques. More recently, Liu and Yu (2004) established also stability and positivity of this solution.

## Quantum Kinetic Theory

Uehling and Uhlembeck (1933) introduced the following kinetic equation for describing a large system of weakly interacting bosons or fermions:

$$\begin{aligned}(\partial_t + v\cdot\nabla_x)f = \int \mathrm{d}v_1 \int \mathrm{d}v' \int \mathrm{d}v_1'\, W(v, v_1|v', v_1') \\ \times \{(1\pm f)(1\pm f_1)f'f_1' \\ - (1\pm f')(1\pm f_1')ff_1\}\end{aligned} \qquad [36]$$

Here the +/− sign, stand for bosons/fermions, respectively, and

$$\begin{aligned}W(v, v_1|v', v_1') \\ = (\hat{V}(v' - v) - \hat{V}(v' - v_1))^2\delta(v + v_1 - v' - v_1') \\ \times \delta\left(\tfrac{1}{2}\left(v^2 + v_1^2 - (v')^2 - (v_1')^2\right)\right)\end{aligned} \qquad [37]$$

Moreover,

$$\hat{V}(p) = 4\pi \int \mathrm{d}x\, \mathrm{e}^{\mathrm{i}p\cdot x} \qquad [38]$$

where $V$ is the interaction potential. Note that eqn [37] is the expression of the cross section of a quantum scattering in the Born approximation.

The unknown $f = f(x, v; t)$ in eqn [37] is the expected number of molecules falling in the unit (quantum) cell of the phase space. This function is proportional to the one-particle Wigner function, introduced by Wigner (1932) to handle kinetic problems in quantum mechanics, and defined as (setting $\hbar = 1$):

$$\frac{1}{(2\pi)^3}\int \mathrm{d}y\, \mathrm{e}^{\mathrm{i}y\cdot v}\rho\left(x + \tfrac{1}{2}y; x - \tfrac{1}{2}y\right)$$

where $\rho(x; z)$ is the kernel of a one-particle density matrix. Basically, the Wigner function is an equivalent way to describe a state of a quantum system. For instance, eqn [40] below expresses the equilibrium distributions for bosons and fermions in terms of Wigner functions. In general, the Wigner functions, due to the uncertainty principle, are real but not necessarily positive; however, the integral with respect to $x$ and $v$ gives the probability

distributions of the velocity and the position, respectively. In the kinetic regime, in which we are interested, the scales are mesoscopic, namely the typical quantum oscillations are on a scale much smaller than the characteristic scales of the problem, so that we expect that $f$ should be a genuine probability distribution, since the Heisenberg principle does not play an essential role. However, the interaction occurs on a microscopic scale, so that we expect that the statistics play a role in addition to the quantum rules for the scattering.

In this framework, the entropy functional is

$$H(f) = \int \mathrm{d}x \int \mathrm{d}v\,[f(x,v)\log f(x,v) \mp (1 \pm f(x,v))\log(1 \pm f(x,v))] \qquad [39]$$

It is decreasing along the solutions to eqn [35] and it is also minimized (among the distributions with given mass, momentum, and energy) by the equilibria

$$M(v) = \frac{z}{\mathrm{e}^{(\beta/2)|v-u|^2} \mp z} \qquad [40]$$

namely the Bose–Einstein and the Fermi–Dirac distributions, respectively. Here $\beta > 1$ and $z > 0$ are the inverse temperature and the activity, respectively. Note that, for the Bose–Einstein distribution, $z < 1$. This creates, in a sense, an inconsistency with eqn [36]. Indeed, assuming $u = 0$ and an initial distribution $f = f_0(v)$ with the density larger than the maximal density allowed by eqn [40], namely

$$\rho_c := \int \mathrm{d}v \frac{1}{\mathrm{e}^{(\beta/2)v^2} - 1} \qquad [41]$$

it cannot converge to any equilibrium. In order to overcome this difficulty related to the Bose condensation, one can enlarge the definition of the equilibria family by setting

$$M(v) = \frac{1}{\mathrm{e}^{(\beta/2)v^2} - 1} + \mu\delta(v) \qquad [42]$$

to take care of excess of mass by means of a condensate component. However, it is not clear whether eqn [36] can actually describe the Bose condensation since its derivation from the Schrödinger equation requires, just from the very beginning, the existence of bosonic quasifree states which can be constructed only if the density is moderate. Further analyses are certainly needed to clarify the situation. A rigorous derivation of the Uehling and Uhlembeck equation is, up to now, far from being obtained even for short times; nevertheless, such an equation is extensively used in the applications. Equation [36] concerns a weakly interacting gas of quantum particles. From a mathematical viewpoint, it is expected to be valid in the so-called weak-coupling limit, which consists in scaling space and time and the interaction potential $\phi$ as

$$x \to \varepsilon x, \quad t \to \varepsilon t, \quad \phi \to \sqrt{\varepsilon}\phi \qquad [43]$$

where $\varepsilon^{-1} = N^{1/3}$ is a parameter diverging when the number of particles $N$ tends to infinity.

We mention, incidentally, that under such a scaling, a classical system is described by a transport equation, called Fokker–Planck–Landau equation, with a diffusion operator in the velocity space.

The B–G limit considered for classical particle systems is different from that considered here for weakly interacting quantum systems. It is actually equivalent to rescaling space and time according to

$$x \to \varepsilon x, \qquad t \to \varepsilon t \qquad [44]$$

leaving the interaction unscaled but, in order to control the total interaction, we make the density diverging gently as $\varepsilon^{-1} = N^{1/2}$.

A quantum system under such a scaling is expected to be described by a Boltzmann equation [1] with the collision operator $Q$ computed with the full quantum cross section. Now we do not have any effect of the statistics because in this rarefaction limit these corrections disappear. On the other hand, the cross section is that arising from the analysis of the quantum scattering. Since we do not rescale the interaction, all the other terms in the Born expansion of the cross section play a role. This kind of Boltzmann equation is a good description of a rarefied gas in which quantum effects are not negligible.

# Bose–Einstein Condensates

**F Dalfovo, L P Pitaevskii, and S Stringari**,
Università di Trento, Povo, Italy

## Introduction

In 1924 the Indian physicist S N Bose introduced a new statistical method to derive the blackbody radiation law in terms of a gas of light quanta (photons). His work, together with the contemporary de Broglie's idea of matter–wave duality, led A Einstein to apply the same statistical approach to a gas of $N$ indistinguishable particles of mass $m$. An amazing result of his theory was the prediction that below some critical temperature a finite fraction of all the particles condense into the lowest-energy single-particle state. This phenomenon, named Bose–Einstein condensation (BEC), is a consequence of purely statistical effects. For several years, such a prediction received little attention, until 1938, when F London argued that BEC could be at the basis of the superfluid properties observed in liquid $^4$He below 2.17 K. A strong boost to the investigation of Bose–Einstein condensates was given in 1995 by the observation of BEC in dilute gases confined in magnetic traps and cooled down to temperatures of the order of a few nK. Differently from superfluid helium, these gases allow one to tune the relevant parameters (confining potential, particle density, interactions, etc.), so to make them an ideal test-ground for concepts and theories on BEC.

## What Is BEC?

In nature, particles have either integer or half-integer spin. Those having half-integer spin, like electrons, are called fermions and obey the Fermi–Dirac statistics; those having integer spin are called bosons and obey the Bose–Einstein statistics. Let us consider a system of $N$ bosons. In order to introduce the concept of BEC on a general ground, one can start with the definition of the one-body density matrix

$$n^{(1)}(\boldsymbol{r},\boldsymbol{r}') = \left\langle \hat{\Psi}^\dagger(\boldsymbol{r})\hat{\Psi}(\boldsymbol{r}')\right\rangle \qquad [1]$$

The quantities $\hat{\Psi}^\dagger(\boldsymbol{r})$ and $\hat{\Psi}(\boldsymbol{r})$ are the field operators which create and annihilate a particle at point $\boldsymbol{r}$, respectively; they satisfy the bosonic commutation relations

$$[\hat{\Psi}(\boldsymbol{r}),\hat{\Psi}^\dagger(\boldsymbol{r}')] = \delta(\boldsymbol{r}-\boldsymbol{r}'), \quad [\hat{\Psi}(\boldsymbol{r}),\hat{\Psi}(\boldsymbol{r}')] = 0 \qquad [2]$$

If the system is in a pure state described by the $N$-body wave function $\Psi(\boldsymbol{r}_1,\ldots,\boldsymbol{r}_N)$, then the average [1] is taken following the standard rules of quantum mechanics and the one-body density matrix can be written as

$$n^{(1)}(\boldsymbol{r},\boldsymbol{r}') = N\int \mathrm{d}\boldsymbol{r}_2\cdots\mathrm{d}\boldsymbol{r}_N\Psi^*(\boldsymbol{r},\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N)\Psi(\boldsymbol{r}',\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N) \qquad [3]$$

involving the integration over the $N-1$ variables $\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N$. In the more general case of a statistical mixture of pure states, expression [3] must be averaged according to the probability for a system to occupy the different states.

Since $n^{(1)}(\boldsymbol{r},\boldsymbol{r}') = (n^{(1)}(\boldsymbol{r}',\boldsymbol{r}))^*$ the quantity $n^{(1)}$, when regarded as a matrix function of its indices $\boldsymbol{r}$ and $\boldsymbol{r}'$, is Hermitian. It is therefore always possible to find a complete orthonormal basis of single-particle eigenfunctions, $\varphi_i(\boldsymbol{r})$, in terms of which the density matrix takes the diagonal form

$$n^{(1)}(\boldsymbol{r},\boldsymbol{r}') = \sum_i n_i\varphi_i^*(\boldsymbol{r})\varphi_i(\boldsymbol{r}') \qquad [4]$$

The real eigenvalues $n_i$ are subject to the normalization condition $\sum_i n_i = N$ and have the meaning of occupation numbers of the single-particle states $\varphi_i$. BEC occurs when one of these numbers (say, $n_0$) becomes macroscopic, that is, when $n_0 \equiv N_0$ is a number of order $N$, all the others remaining of order 1.

In this case eqn [4] can be conveniently rewritten in the form

$$n^{(1)}(\boldsymbol{r},\boldsymbol{r}') = N_0\varphi_0^*(\boldsymbol{r})\varphi_0(\boldsymbol{r}') + \sum_{i\neq 0} n_i\varphi_i^*(\boldsymbol{r})\varphi_i(\boldsymbol{r}') \quad [5]$$

and the state represented by $\varphi_0(\boldsymbol{r})$ is called Bose–Einstein condensate. This definition is rather general, since it applies to any macroscopic ($N \gg 1$) system of indistinguishable bosons independently of mutual interactions and external fields.

The one-body density matrix [1] contains information on important physical observables. By setting $\boldsymbol{r} = \boldsymbol{r}'$ one finds the diagonal density of the system

$$n(\boldsymbol{r}) \equiv n^{(1)}(\boldsymbol{r},\boldsymbol{r}) = \langle\hat{\Psi}^\dagger(\boldsymbol{r})\hat{\Psi}(\boldsymbol{r})\rangle \quad [6]$$

with $N = \int \mathrm{d}\boldsymbol{r}\, n(\boldsymbol{r})$. The off-diagonal components can instead be used to calculate the momentum distribution

$$n(\boldsymbol{p}) = \langle\hat{\Psi}^\dagger(\boldsymbol{p})\hat{\Psi}(\boldsymbol{p})\rangle \quad [7]$$

where $\hat{\Psi}(\boldsymbol{p}) = (2\pi\hbar)^{-3/2}\int \mathrm{d}\boldsymbol{r}\hat{\Psi}(\boldsymbol{r})\exp[-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{r}/\hbar]$ is the field operator in momentum representation. By inserting this expression for $\hat{\Psi}(\boldsymbol{p})$ into eqn [7] one finds

$$n(\boldsymbol{p}) = \frac{1}{(2\pi\hbar)^3}\int \mathrm{d}\boldsymbol{R}\,\mathrm{d}\boldsymbol{s}\; n^{(1)}\left(\boldsymbol{R}+\frac{\boldsymbol{s}}{2}, \boldsymbol{R}-\frac{\boldsymbol{s}}{2}\right)\mathrm{e}^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{s}/\hbar} \quad [8]$$

where $\boldsymbol{s} = \boldsymbol{r} - \boldsymbol{r}'$ and $\boldsymbol{R} = (\boldsymbol{r}+\boldsymbol{r}')/2$.

Let us consider a uniform system of $N$ particles in a volume $V$ and take the thermodynamic limit $N, V \to \infty$ with density $N/V$ kept fixed. The eigenfunctions of the density matrix are plane waves and the lowest-energy state has zero momentum, $\boldsymbol{p} = 0$, and constant wave function $\varphi_0(\boldsymbol{r}) = V^{-1/2}$. BEC in this state implies a macroscopic number of particles having zero momentum and constant density $N_0/V$. The density matrix only depends on $\boldsymbol{s} = \boldsymbol{r} - \boldsymbol{r}'$ and can be written as

$$n^{(1)}(\boldsymbol{s}) = \frac{N_0}{V} + \frac{1}{V}\sum_{\boldsymbol{p}\neq 0} n_{\boldsymbol{p}}\,\mathrm{e}^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{s}/\hbar} \quad [9]$$

In the $s \to \infty$ limit, the sum on the right vanishes due to destructive interference between different plane waves, but the first term survives. One thus finds that, in the presence of BEC, the one-body density matrix tends to a constant finite value at large distances. This behavior is named *off-diagonal long-range order*, since it involves the off-diagonal components of the density matrix. Its counterpart in momentum space is the appearance of a singular term at $\boldsymbol{p} = 0$:

$$n(\boldsymbol{p}) = N_0\delta(\boldsymbol{p}) + \sum_{\boldsymbol{p}'\neq 0} n_{\boldsymbol{p}'}\delta(\boldsymbol{p}-\boldsymbol{p}') \quad [10]$$

The sum on the right is the number of noncondensed particles ($N - N_0$), and the quantity $N_0/N$ is called condensate fraction.

If the system is not uniform, the eigenfunctions of the density matrix are no longer plane waves but, provided $N$ is sufficiently large, the concept of BEC is still well defined, being associated with the occurrence of a macroscopic occupation of a single-particle eigenfunction $\varphi_0(\boldsymbol{r})$ of the density matrix. Thus, the condensed bosons can be described by means of the function $\Psi(\boldsymbol{r}) = \sqrt{N_0}\varphi_0(\boldsymbol{r})$, which is a classical complex field playing the role of an *order parameter*. This is the analog of the classical limit of quantum electrodynamics, where the electromagnetic field replaces the microscopic description of photons. The function $\Psi$ may also depend on time and can be written as

$$\Psi(\boldsymbol{r},t) = |\Psi(\boldsymbol{r},t)|\,\mathrm{e}^{\mathrm{i}S(\boldsymbol{r},t)} \quad [11]$$

Its modulus determines the contribution of the condensate to the diagonal density [6], while the phase $S$ is crucial in characterizing the coherence and superfluid properties of the system. The order parameter [11], also named *macroscopic wave function* or *condensate wave function*, is defined only up to a constant phase factor. One can always multiply this function by the numerical factor $\mathrm{e}^{\mathrm{i}\alpha}$ without changing any physical property. This reflects the gauge symmetry exhibited by all the physical equations of the problem. Making an explicit choice for the value of the order parameter, and hence for the phase, corresponds to a formal breaking of gauge symmetry.

## BEC in Ideal Gases

Once we have defined what is a Bose–Einstein condensate, the next question is when such a condensation occurs in a given system. The ideal Bose gas provides the simplest example. So, let us consider a gas of noninteracting bosons described by the Hamiltonian $\hat{H} = \sum_i \hat{H}_i^{(1)}$, where the Schrödinger equation $\hat{H}^{(1)}\varphi_i(\boldsymbol{r}) = \epsilon_i\varphi_i(\boldsymbol{r})$ gives the spectrum of single-particle wave functions and energies. One can define an occupation number $n_i$ as the number of particles in the state with energy $\epsilon_i$. Thus, any given state of the many-body system is specified by a set $\{n_i\}$. The mean occupation numbers, $\bar{n}_i$, can be calculated by using the standard rules of statistical mechanics. For instance, by considering a grand canonical ensemble at temperature $T$, one finds

$$\bar{n}_i = \{\exp[\beta(\epsilon_i - \mu)] - 1\}^{-1} \quad [12]$$

with $\beta = 1/(k_B T)$. The chemical potential $\mu$ is fixed by the normalization condition $\sum_i \bar{n}_i = N$, where $N$ is the average number of particles in the gas. For $T \to \infty$ the chemical potential is negative and large. It increases monotonically when $T$ is lowered. Let us call $\epsilon_0$ the lowest single-particle level in the spectrum. If at some critical temperature $T_c$ the normalization condition can be satisfied with $\mu \to \epsilon_0^-$, then the occupation of the lowest state, $\bar{n}_0 = N_0$, becomes of order $N$ and BEC is realized. Below $T_c$ the normalization condition must be replaced with $N = N_0 + N_T$, where $N_T = \sum_{i \neq 0} \bar{n}_i$ is the number of particles out of the condensate, that is, the *thermal* component of the gas. Whether BEC occurs or not, and what is the value of $T_c$ depends on the dimensionality of the system and the type of single-particle spectrum.

The simplest case is that of a gas confined in a cubic box of volume $V = L^3$ with periodic boundary conditions, where $\hat{H}^{(1)} = -(\hbar^2/2m)\nabla^2$. The eigenfunctions are plane waves $\varphi_p(\boldsymbol{r}) = V^{-1/2} \exp[-i\boldsymbol{p} \cdot \boldsymbol{r}/\hbar]$, with energy $\epsilon_p = p^2/2m$ and momentum $\boldsymbol{p} = 2\pi\hbar\boldsymbol{n}/L$. Here $\boldsymbol{n}$ is a vector whose components $n_x, n_y, n_z$ are 0 or $\pm$ integers. The lowest eigenvalue has zero energy ($\epsilon_0 = 0$) and zero momentum. The mean occupation numbers are given by $\bar{n}_p = \{\exp[\beta(p^2/2m - \mu)] - 1\}^{-1}$. In the thermodynamic limit ($N, V \to \infty$ with $N/V$ kept constant), one can replace the sum $\sum_p$ with the integral $\int \mathrm{d}\epsilon \rho(\epsilon)$, where $\rho(\epsilon) = (2\pi)^{-2} V (2m/\hbar^2)^{3/2} \sqrt{\epsilon}$ is the density of states. In this way, one can calculate the thermal component of the gas as a function of $T$, finding the critical temperature

$$k_B T_c = \frac{2\pi\hbar^2}{m} \left( \frac{N}{V\zeta(3/2)} \right)^{2/3} \qquad [13]$$

where $\zeta$ is the Riemann zeta function and $\zeta(3/2) \simeq 2.612$. For $T > T_c$, one has $\mu < 0$ and $N_T = N$. For $T < T_c$ one instead has $\mu = 0, N_T = N - N_0$ and

$$N_0(T) = N[1 - (T/T_c)^{3/2}] \qquad [14]$$

The critical temperature turns out to be fully determined by the density $N/V$ and by the mass of the constituents. These results were first obtained by A Einstein in his seminal paper and used by F London in the context of superfluid helium. We notice that the replacement of the sum with an integral in the above derivation is justified only if the thermal energy $k_B T$ is much larger than the energy spacing between single-particle levels, that is, if $k_B T \gg \hbar^2/2mV^{2/3}$. Is is also worth noticing that the above expression for $T_c$ can be written as $\lambda_T^3 N/V \simeq 2.612$, where $\lambda_T = [2\pi\hbar^2/(mk_B T)]^{1/2}$ is the thermal de Broglie wavelength. This is equivalent to saying that BEC occurs when the mean distance between bosons is of the order of their de Broglie wavelength.

Another interesting case, which is relevant for the recent experiments with BEC in dilute gases confined in magnetic and/or optical traps, is that of an ideal gas subject to harmonic potentials. Let us consider, for simplicity, an isotropic external potential $V_{ext}(r) = (1/2)m\omega_{ho}^2 r^2$. The single-particle Hamiltonian is $\hat{H}^{(1)} = -(\hbar^2/2m)\nabla^2 + V_{ext}(r)$ and its eigenvalues are $\epsilon_{n_x,n_y,n_z} = (n_x + n_y + n_z + 3/2)\hbar\omega_{ho}$. The corresponding density of states is $\rho(\epsilon) = (1/2)(\hbar\omega_{ho})^{-3}\epsilon^2$. A natural thermodynamic limit for this system is obtained by letting $N \to \infty$ and $\omega_{ho} \to 0$, while keeping the product $N\omega_{ho}^3$ constant. The condition for BEC to occur is that $\mu$ approaches the value $\epsilon_{000} = (3/2)\hbar\omega_{ho}$ from below by cooling the gas down to $T_c$. Following the same procedure as for the uniform gas, one finds

$$k_B T_c = \hbar\omega_{ho}[N/\zeta(3)]^{1/3} = 0.94\hbar\omega_{ho} N^{1/3} \qquad [15]$$

and

$$N_0(T) = N[1 - (T/T_c)^3] \qquad [16]$$

Notice that the condensate is not uniform in this case, since it corresponds to the lowest eigenfunction of the harmonic oscillator, which is a Gaussian of width $a_{ho} = [\hbar/(m\omega_{ho})]^{1/2}$. Correspondingly, the condensate in the momentum space is also a Gaussian, of width $a_{ho}^{-1}$. This implies that, differently from the gas in a box, here the condensate can be seen both in coordinate and momentum space in the form of a narrow distribution emerging from a wider thermal component. Finally, results [15] and [16] remain valid even for anisotropic harmonic potentials, with trapping frequencies $\omega_x, \omega_y$, and $\omega_z$, provided the frequency $\omega_{ho}$ is replaced by the geometric average $(\omega_x\omega_y\omega_z)^{1/3}$.

## BEC in Interacting Gases

Actual condensates are made of interacting particles. The full many-body Hamiltonian is

$$\hat{H} = \int \mathrm{d}\boldsymbol{r} \hat{\Psi}^\dagger(\boldsymbol{r}) \hat{H}_0 \hat{\Psi}(\boldsymbol{r}) + \frac{1}{2} \int \mathrm{d}\boldsymbol{r}' \mathrm{d}\boldsymbol{r}\, \hat{\Psi}^\dagger(\boldsymbol{r}) \hat{\Psi}^\dagger(\boldsymbol{r}') V(\boldsymbol{r} - \boldsymbol{r}') \hat{\Psi}(\boldsymbol{r}') \hat{\Psi}(\boldsymbol{r}) \qquad [17]$$

where $V(\boldsymbol{r} - \boldsymbol{r}')$ is the particle–particle interaction and $\hat{H}_0 = -(\hbar^2/2m)\nabla^2 + V_{ext}(\boldsymbol{r})$. Differently from the case of ideal gases, $\hat{H}$ is no longer a sum of single-particle Hamiltonians. However, the general definitions given in the section "What is BEC?" are still valid. In particular, the one-body density matrix, in the presence of BEC, can be separated as in eqn [5]. One

can write $n^{(1)}(\boldsymbol{r},\boldsymbol{r}')=\Psi^*(\boldsymbol{r})\Psi(\boldsymbol{r}')+\tilde{n}^{(1)}(\boldsymbol{r},\boldsymbol{r}')$, where $\Psi$ is the order parameter of the condensate ($\Psi^*(\boldsymbol{r})\Psi(\boldsymbol{r}')$ being of order $N$), while $\tilde{n}^{(1)}(\boldsymbol{r},\boldsymbol{r}')$ vanishes for large $|\boldsymbol{r}-\boldsymbol{r}'|$. This is equivalent to say that the bosonic field operator splits in two parts,

$$\hat{\Psi}(\boldsymbol{r}) = \Psi(\boldsymbol{r}) + \delta\hat{\Psi}(\boldsymbol{r}) \quad [18]$$

where the first term is a complex function and the second one is the field operator associated with the noncondensed particles. This decomposition is particularly useful when the depletion of the condensate, that is, the fraction of noncondensed particles, is small. This happens when the interaction is weak, but also for particles with arbitrary interaction, provided the gas is dilute. In this case, one can expand the many-body Hamiltonian by treating the operator $\delta\hat{\Psi}$ as a small quantity.

A suitable strategy consists in writing the Heisenberg equation for the evolution of the field operators, $\mathrm{i}\hbar\partial_t\hat{\Psi}=[\hat{\Psi},\hat{H}]$, using the many-body Hamiltonian [17]:

$$\mathrm{i}\hbar\partial_t\hat{\Psi}(\boldsymbol{r},t) = \left(\hat{H}_0 + \int \mathrm{d}\boldsymbol{r}'\hat{\Psi}^\dagger(\boldsymbol{r}',t)V(\boldsymbol{r}-\boldsymbol{r}')\hat{\Psi}(\boldsymbol{r}',t)\right) \times \hat{\Psi}(\boldsymbol{r},t) \quad [19]$$

The zeroth-order is thus obtained by replacing the operator $\hat{\Psi}$ with the classical field $\Psi$. In the integral containing the interaction $V(\boldsymbol{r}-\boldsymbol{r}')$, this replacement is, in general, a poor approximation when short distances $(\boldsymbol{r}-\boldsymbol{r}')$ are involved. In a dilute and cold gas, one can nevertheless obtain a proper expression for the interaction term by observing that, in this case, only binary collisions at low energy are relevant and these collisions are characterized by a single parameter, the *s*-wave scattering length, $a$, independently of the details of the two-body potential. This allows one to replace $V(\boldsymbol{r}-\boldsymbol{r}')$ in $\hat{H}$ with an effective interaction $V(\boldsymbol{r}-\boldsymbol{r}')=g\delta(\boldsymbol{r}-\boldsymbol{r}')$, where the coupling constant $g$ is given by $g=4\pi\hbar^2a/m$. The scattering length can be measured with several experimental techniques or calculated from the exact two-body potential. Using this pseudopotential and replacing the operator $\hat{\Psi}$ with the complex function $\Psi$ in the Heisenberg equation of motion, one gets

$$\mathrm{i}\hbar\partial_t\Psi(\boldsymbol{r},t) = \left(-\frac{\hbar^2\nabla^2}{2m} + V_{\mathrm{ext}}(\boldsymbol{r}) + g|\Psi(\boldsymbol{r},t)|^2\right)\Psi(\boldsymbol{r},t) \quad [20]$$

This is known as Gross–Pitaevskii (GP) equation and it was first introduced in 1961. It has the form of a *nonlinear Schrödinger equation*, the nonlinearity coming from the mean-field term, proportional to $|\Psi|^2$. It has been derived assuming that $N$ is large while the fraction of noncondensed atoms is negligible. On the one hand, this means that quantum fluctuations of the field operator have to be small, which is true when $n|a|^3 \ll 1$, where $n$ is the particle density. In fact, one can show that, at $T=0$ the quantum depletion of the condensate is proportional to $(n|a|^3)^{1/2}$. On the other hand, thermal fluctuations have also to be negligible and this means that the theory is limited to temperatures much lower than $T_{\mathrm{c}}$. Within these limits, one can identify the total density with the condensate density.

The stationary solution of eqn [20] corresponds to the condensate wave function in the ground state. One can write $\Psi(\boldsymbol{r},t)=\Psi_0(\boldsymbol{r})\exp(-\mathrm{i}\mu t/\hbar)$, where $\mu$ is the chemical potential. Then the GP equation [20] becomes

$$\left(-\frac{\hbar^2\nabla^2}{2m} + V_{\mathrm{ext}}(\boldsymbol{r}) + g|\Psi_0(\boldsymbol{r})|^2\right)\Psi_0(\boldsymbol{r}) = \mu\Psi_0(\boldsymbol{r}) \quad [21]$$

where $n(\boldsymbol{r})=|\Psi_0(\boldsymbol{r})|^2$ is the particle density. The same equation can be obtained by minimizing the energy of the system written as a functional of the density:

$$E[n] = \int \mathrm{d}\boldsymbol{r}\left[\frac{\hbar^2}{2m}|\boldsymbol{\nabla}\sqrt{n}|^2 + nV_{\mathrm{ext}}(\boldsymbol{r}) + \frac{gn^2}{2}\right] \quad [22]$$

The first term on the right corresponds to the quantum kinetic energy coming from the uncertainty principle; it is usually named "quantum pressure" and vanishes for uniform systems.

The next order in $\delta\hat{\Psi}$ gives the excited states of the condensate. In a uniform gas the ground-state order parameter, $\Psi_0$, is a constant and the first-order expansion of $\hat{H}$ was introduced by N Bogoliubov in 1947. In particular, he found an elegant way to diagonalize the Hamiltonian by using simple linear combinations of particle creation and annihilation operators. These are known as Bogoliubov's transformations and stay at the basis of the concept of *quasiparticle*, one of the most important concepts in quantum many-body theory.

A generalization of Bogoliubov's approach to the case of nonuniform condensates is obtained by considering small deviations around the ground state in the form

$$\Psi(\boldsymbol{r},t) = \mathrm{e}^{-\mathrm{i}\mu t/\hbar}\left[\Psi_0(\boldsymbol{r}) + u(\boldsymbol{r})\mathrm{e}^{-\mathrm{i}\omega t} + v^*(\boldsymbol{r})\mathrm{e}^{\mathrm{i}\omega t}\right] \quad [23]$$

Inserting this expression into eqn [20] and keeping terms linear in the complex functions $u$ and $v$, one gets

$$\hbar\omega u(\boldsymbol{r}) = [\hat{H}_0 - \mu + 2g\Psi_0^2(\boldsymbol{r})]u(\boldsymbol{r}) + g\Psi_0^2(\boldsymbol{r})v(\boldsymbol{r}) \quad [24]$$

$$-\hbar\omega v(\boldsymbol{r}) = [\hat{H}_0 - \mu + 2g\Psi_0^2(\boldsymbol{r})]v(\boldsymbol{r}) + g\Psi_0^2(\boldsymbol{r})u(\boldsymbol{r}) \quad [25]$$

These coupled equations allow one to calculate the energies $\varepsilon=\hbar\omega$ of the excitations. They also give the so-called quasiparticle amplitudes $u$ and $v$, which obey the normalization condition

$$\int \mathrm{d}\boldsymbol{r}[u_i^*(\boldsymbol{r})u_j(\boldsymbol{r}) - v_i^*(\boldsymbol{r})v_j(\boldsymbol{r})] = \delta_{ij}$$

In a uniform gas, $u$ and $v$ are plane waves and one recovers the famous Bogoliubov's spectrum

$$\hbar\omega = \left[\frac{\hbar^2 q^2}{2m}\left(\frac{\hbar^2 q^2}{2m} + 2gn\right)\right]^{1/2} \qquad [26]$$

where $\boldsymbol{q}$ is the wave vector of the excitations. For large momenta the spectrum coincides with the free-particle energy $\hbar^2q^2/2m$. At low momenta, it instead gives the phonon dispersion $\omega=cq$, where $c=[gn/m]^{1/2}$ is the Bogoliubov sound velocity. The transition between the two regimes occurs when the excitation wavelength is of the order of the *healing length*,

$$\xi = [8\pi na]^{-1/2} = \hbar/(mc\sqrt{2}) \qquad [27]$$

which is an important length scale for superfluidity. When the order parameter is forced to vanish at some point (by an impurity, a wall, etc.), the healing length provides the typical distance over which it recovers its bulk value. In a nonuniform condensate the excitations are no longer plane waves but, at low energy, they have still a phonon-like character, in the sense that they involve a collective motion of the condensate.

The GP equation [20] is the starting point for an accurate mean-field description of BEC in dilute cold gases, which is rigorous at $T=0$ and for $n|a|^3 \ll 1$. Static and dynamics properties of condensates in different geometries can be calculated by solving the GP equation numerically or using suitable approximated methods. The inclusion of effects beyond mean field is a highly nontrivial and interesting problem. A rather extreme case is represented by liquid $^4$He, which is a dense system where the interaction between atoms causes a large depletion of the condensate even at $T=0$ ($N_0/N$ being less than 10%) and thus a full many-body treatment is required for its rigorous description. Nevertheless, even in this case, the general definitions of the section "What is BEC?" are still useful.

## Superfluidity and Coherence

With the word superfluidity, one summarizes a complex of macroscopic phenomena occurring in quantum fluids under particular conditions: persistent currents, equilibrium states at rest in rotating vessels, viscousless motion, quantized vorticity, and others. These features can also be observed in BEC. The link between BEC and superfluidity is given by the phase of the order parameter [11]. To understand this point, let us consider a uniform system. If $\hat{\Psi}(\boldsymbol{r},t)$ is a solution of the Heisenberg equation [19] with $V_{\mathrm{ext}}=0$, then

$$\hat{\Psi}'(\boldsymbol{r},t) = \hat{\Psi}(\boldsymbol{r}-\boldsymbol{v}t,t)\exp\left[\frac{\mathrm{i}}{\hbar}\left(m\boldsymbol{v}\cdot\boldsymbol{r} - \frac{1}{2}mv^2t\right)\right] \qquad [28]$$

where $\boldsymbol{v}$ is a constant vector, is also a solution. This equation gives the Galilean transformation of the field operator and also applies to its condensate component $\Psi$. At equilibrium, the ground-state order parameter is given by $\Psi_0=\sqrt{n}\exp(-\mathrm{i}\mu t/\hbar)$, where $n$ is a constant independent of $\boldsymbol{r}$. In a frame where the condensate moves with velocity $\boldsymbol{v}$, the order parameter instead takes the form $\Psi_0=\sqrt{n}\exp(\mathrm{i}S)$, with $S(\boldsymbol{r},t)=\hbar^{-1}[m\boldsymbol{v}\cdot\boldsymbol{r}-(mv^2/2+\mu)t]$. The velocity of the condensate can thus be identified with the gradient of the phase $S$:

$$\boldsymbol{v}(\boldsymbol{r},t) = \frac{\hbar}{m}\nabla S(\boldsymbol{r},t) \qquad [29]$$

This definition is also valid for $\boldsymbol{v}$ varying slowly in space and time. The modulus of the order parameter plays a minor role in this definition and it is not necessary to assume the gas to be dilute and close to $T=0$. Indeed, the relation [29] between the velocity field and the phase of the order parameter also applies in the presence of large quantum depletion, as in superfluid $^4$He, and at $T\neq 0$. In this case, $n$ should not be identified with the condensate density. Conversely, in dilute gases at $T=0$, $n$ is the condensate density and the velocity [29] can be simply obtained by applying the usual definition of current density operator, $\hat{\boldsymbol{j}}$, to the order parameter [11].

The velocity [29] describes a potential flow and corresponds to a collective motion of many particles occupying a single quantum state. Being equal to the gradient of a scalar function, it is irrotational ($\nabla\times\boldsymbol{v}_{\mathrm{s}}=0$) and satisfies the Onsager–Feynman quantization condition $\oint \boldsymbol{v}_{\mathrm{s}}\cdot\mathrm{d}\boldsymbol{l}=\kappa h/m$, with $\kappa$ non-negative integer. These conditions are not satisfied by a classical fluid, where the hydrodynamic velocity field, $\boldsymbol{v}(\boldsymbol{r},t)=\boldsymbol{j}(\boldsymbol{r},t)/n(\boldsymbol{r},t)$, is the average over many different states and does not correspond to a potential flow.

By using the definition of the phase $S$ and velocity $\boldsymbol{v}$, together with particle conservation, one can show that the dynamics of a condensate, as far as macroscopic motions are concerned, is governed by the hydrodynamic equations of an irrotational

nonviscous fluid. Within the mean-field theory, this can be easily seen by rewriting the GP equation [20] in terms of the density $n = |\Psi|^2$ and the velocity [29]. Neglecting the quantum pressure term $\nabla^2\sqrt{n}$ (hence limiting the description to length scales larger than the healing length $\xi$), one gets

$$\frac{\partial}{\partial t} n + \boldsymbol{\nabla} \cdot (\boldsymbol{v} n) = 0 \qquad [30]$$

and

$$m \frac{\partial}{\partial t} \boldsymbol{v} + \boldsymbol{\nabla}\left( V_{\text{ext}} + \mu(n) + \frac{m v^2}{2} \right) = 0 \qquad [31]$$

with the local chemical potential $\mu(n) = gn$. These equations have the typical structure of the dynamic equations of superfluids at zero temperature and can be viewed as the $T = 0$ case of the more general Landau's two-fluid theory.

One of the most striking evidences of superfluidity is the observation of quantized vortices, that is, vortices obeying the Onsager–Feynman quantization condition. A vast literature is devoted to vortices in superfluid helium and, more recently, vortices have also been produced and studied in condensates of ultracold gases, including nice configurations of many vortices in regular triangular lattices, similar to the Abrikosov lattices in superconductors. Other phenomena, such as the reduction of the moment of inertia, the occurrence of Josephson tunneling through barriers, the existence of thresholds for dissipative processes (Landau criterion), and others, are typical subjects of intense investigation.

Another important consequence of the fact that BEC is described by an order parameter with a well-defined phase is the occurrence of coherence effects which, in different words, mean that condensates behave like *matter waves*. For instance, one can measure the phase difference between two condensates by means of interference. This can be done in coordinate space by confining two condensates in two potential minima, $a$ and $b$, at a distance $d$. Let us take $d$ along $z$ and assume that, at $t = 0$, the order parameter is given by the linear combination $\Psi(\boldsymbol{r}) = \Psi_a(\boldsymbol{r}) + \exp(\mathrm{i}\phi)\Psi_b(\boldsymbol{r})$ with $\Psi_a$ and $\Psi_b$ real and without overlap. Then let us switch off the confining potentials so that the condensates expand and overlap. If the overlap occurs when the density is small enough to neglect interactions, the motion is ballistic and the phase of each condensate evolves as $S(\boldsymbol{r}, t) \simeq mr^2/(2\hbar t)$, so that $\boldsymbol{v} = \boldsymbol{r}/t$. This implies a relative phase $\phi + S(x, y, z + d/2) - S(x, y, z - d/2) = \phi + mdz/\hbar t$. The total density $n = |\Psi|^2$ thus exhibits periodic modulations along $z$ with wavelength $\hbar t/md$. This interference pattern has indeed been observed in condensates of ultracold atoms. In these systems it was also possible to measure the coherence length, that is, the distance $|\boldsymbol{r} - \boldsymbol{r}'|$ at which the one-body density vanishes and the phase of the order parameter is no more well defined. In most situations, the coherence length turns out to be of the order of, or larger than the size of the condensates. However, interesting situations exist when the coherence length is shorter but the system still preserves some features of BEC (quasicondensates).

## Final Remarks

Bose–Einstein condensates of ultracold atoms are easily manipulated by changing and tuning the external potentials. This means, for instance, that one can prepare condensates in different geometries, including very elongated (quasi-1D) or disk-shaped (quasi-2D) condensates. This is conceptually important, since BEC in lower dimensions is not as simple as in three dimensions: thermal and quantum fluctuations play a crucial role, superfluidity must be properly re-defined, and very interesting limiting cases can be explored (Tonks–Girardeau regime, Luttinger liquid, etc.). Another possibility is to use laser beams to produce standing waves acting as an external periodic potential (optical lattice). Condensates in optical lattices behave as a sort of perfect crystal, whose properties are the analog of the dynamic and transport properties in solid-state physics, but with controllable spacing between sites, no defects and tunable lattice geometry. One can investigate the role of phase coherence in the lattice, looking, for instance, at Josephson effects as in a chain of junctions. By tuning the lattice depth one can explore the transition from a superfluid phase and a Mott-insulator phase, which is a nice example of quantum phase transition. Controlling cold atoms in optical lattice can be a good starting point for application in quantum engineering, interferometry, and quantum information.

Another interesting aspect of BECs is that the key equation for their description in mean-field theory, namely the GP equation [20], is a nonlinear Schrödinger equation very similar to the ones commonly used, for instance, in nonlinear quantum optics. This opens interesting perspectives in exploiting the analogies between the two fields, such as the occurrence of dynamical and parametric instabilities, the possibility to create different types of solitons, the occurrence of nonlinear processes like, for example, higher harmonic generation and mode mixing.

A relevant part of the current research also involves systems made of mixtures of different gases, Bose–Bose or Fermi–Bose, and many activities with ultracold atoms now involve fermionic gases, where BEC can

also be realized by condensing molecules of fermionic pairs. An extremely active research now concerns the BCS–BEC crossover, which can be obtained in Fermi gases by tuning the scattering length (and hence the interaction) by means of Feshbach resonances.

Ten years after the first observation of BEC in ultracold gases, it is almost impossible to summarize all the researches done in this field. A large amount of work has already been devoted to characterize the condensates and several new lines have been opened. Rather detailed review articles and books are already available for the interested readers.

# Bosons and Fermions in External Fields

**E Langmann**, KTH Physics, Stockholm, Sweden

## Introduction

In this article we discuss quantum theories which describe systems of nondistinguishable particles interacting with external fields. Such models are of interest also in the nonrelativistic case (in quantum statistical mechanics, nuclear physics, etc.), but the relativistic case has additional, interesting complications: relativistic models are genuine quantum field theories, that is, quantum theories with an infinite number of degrees of freedom, with nontrivial features like divergences and anomalies. Since interparticle interactions are ignored, such models can be regarded as a first approximation to more complicated theories, and they can be studied by mathematically precise methods.

Models of relativistic particles in external electromagnetic fields have received considerable attention in the physics literature, and interesting phenomena like the Klein paradox or particle–antiparticle pair creation in overcritical fields have been studied; see Rafelski *et al.* (1978) for an extensive review. We will not discuss these physics questions but only describe some prototype examples and a general Hamiltonian framework which has been used in mathematically precise work on such models. The general framework for this latter work is the mathematical theory of Hilbert space operators (see, e.g., Reed and Simon (1975)), but in our discussion we try to avoid presupposing knowledge of that theory. As mentioned briefly in the end, this work has had close relations to various topics of recent interest in mathematical physics, including anomalies, infinite-dimensional geometry and group theory, conformal field theory, and noncommutative geometry.

We restrict our discussion to spin-0 bosons and spin-1/2 fermions, and we will not discuss models of particles in external gravitational fields but only refer the interested reader to DeWitt (2003). We also only mention in passing that external field problems have also been studied using functional integral approaches, and mathematically precise work on this can be found in the extensive literature on determinants of differential operators.

## Examples

Consider the Schrödinger equation describing a nonrelativistic particle of mass $m$ and charge $e$

moving in three-dimensional space and interacting with an external vector and scalar potentials $\boldsymbol{A}$ and $\phi$, respectively,

$$\mathrm{i}\partial_t\psi = H\psi, \quad H = \frac{1}{2m}(-\mathrm{i}\nabla + e\boldsymbol{A})^2 - e\phi \qquad [1]$$

(we set $\hbar = c = 1$, $\partial_t = \partial/\partial t$, and $\psi$,$\phi$, and $\boldsymbol{A}$ can depend on the space and time variables $\boldsymbol{x} \in \mathbb{R}^3$ and $t \in \mathbb{R}$). This is a standard quantum-mechanical model, with $\psi$ the one-particle wave function allowing for the usual probabilistic interpretation.

One interesting generalization to the relativistic regime is the Klein–Gordon equation

$$\left[(\mathrm{i}\partial_t + e\phi)^2 - (-\mathrm{i}\nabla + e\boldsymbol{A})^2 - m^2\right]\psi = 0 \qquad [2]$$

with a $\mathbb{C}$-valued function $\psi$. There is another important relativistic generalization, the Dirac equation

$$[(\mathrm{i}\partial_t + e\phi) - (-\mathrm{i}\nabla + e\boldsymbol{A})\cdot\boldsymbol{\alpha} + m\beta]\psi = 0 \qquad [3]$$

with $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \alpha_3)$ and $\beta$ Hermitian $4 \times 4$ matrices satisfying the relations

$$\alpha_i\alpha_j + \alpha_j\alpha_i = \delta_{ij}, \quad \alpha_i\beta = -\beta\alpha_i, \quad \beta^2 = 1 \qquad [4]$$

and a $\mathbb{C}^4$-valued function $\psi$ (we also write 1 for the identity). These two relativistic equations differ by the transformation properties of $\psi$ under Lorentz transformations: in [2] it transforms like a scalar and thus describes spin-0 particles, and it transforms like a spinor describing spin-1/2 particles in [3]. While these equations are natural relativistic generalizations of the Schrödinger equation, they no longer allow to consistently interpret $\psi$ as one-particle wave functions. The physical reason is that, in a relativistic theory, high-energy processes can create particle–antiparticle pairs, and this makes the restriction to a fixed particle number inconsistent. This problem can be remedied by constructing a many-body model allowing for an arbitrary number of particles and antiparticles. The requirement that this many-body model should have a ground state is an important ingredient in this construction.

It is obviously of interest to formulate and study many-body models of nondistinguishable particles already in the nonrelativistic case. An important empirical fact is that such particles come in two kinds, bosons and fermions, distinguished by their exchange statistics (we ignore the interesting possibility of exotic statistics). For example, the fermion many-particle version of [1] for suitable $\phi$ and $\boldsymbol{A}$ is a useful model for electrons in a metal. An elegant method to go from the one- to the many-particle description is the formalism of second quantization: one promotes $\psi$ to a quantum field operator with certain (anti-) commutator relations, and this is a convenient way to construct the appropriate many-particle Hilbert space, Hamiltonian, etc. In the nonrelativistic case, this formalism can be regarded as an elegant reformulation of a pedestrian construction of a many-body quantum-mechanical model, which is useful since it provides convenient computational tools. However, this formalism naturally generalizes to the relativistic case where the one-particle model no longer has an acceptable physical interpretation, and one finds that one can nevertheless give a consistent physical interpretation to [2] and [3] provided that $\psi$ are interpreted as quantum field operators describing bosons and fermions. This particular exchange statistics of the relativistic particles is a special case of the spin-statistics theorem: *integer-spin particles are bosons and half-integer spin particles are fermions*. While many structural features of this formalism are present already in the simpler nonrelativistic models, the relativistic models add some nontrivial features typical for quantum field theories.

In the following, we discuss a precise mathematical formulation of the quantum field theory models described above. We emphasize the functorial nature of this construction, which makes manifest that it also applies to other situations, for example, where the bosons and fermions are also coupled to a gravitational background, are considered in other spacetime dimensions than $3 + 1$, etc.

## Second Quantization: Nonrelativistic Case

Consider a quantum system of nondistinguishable particles where the quantum-mechanical description of one such particle is known. In general, this one-particle description is given by a Hilbert space $h$ and one-particle observables and transformations which are self-adjoint and unitary operators on $h$, respectively. The most important observable is the Hamiltonian $H$. We will describe a general construction of the corresponding many-body system.

**Example** As a motivating example we take the Hilbert space $h = L^2(\mathbb{R}^3)$ of square-integrable functions $f(\boldsymbol{x})$, $\boldsymbol{x} \in \mathbb{R}^3$, and the Hamiltonian $H$ in [1]. A specific example for a unitary operator on $h$ is the gauge transformation $(Uf)(\boldsymbol{x}) = \exp(\mathrm{i}\chi(\boldsymbol{x}))f(\boldsymbol{x})$ with $\chi$ a smooth, real-valued function on $\mathbb{R}^3$.

In this example, the corresponding wave functions for $N$ identical such particles are the $L^2$-functions $f_N(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N)$, $\boldsymbol{x}_j \in \mathbb{R}^3$. It is obvious how to extend

one-particle observables and transformations to such $N$-particle states: for example, the $N$-particle Hamiltonian corresponding to $H$ in [1] is

$$H_N = \sum_{j=1}^{N} \frac{1}{2m}(-\mathrm{i}\nabla_{x_j} + e\boldsymbol{A}(t,\boldsymbol{x}_j))^2 - e\phi(t,\boldsymbol{x}_j) \quad [5]$$

and the $N$-particle gauge transformation $U_N$ is defined through multiplication with $\prod_{j=1}^{N} \exp(\mathrm{i}\chi(\boldsymbol{x}_j))$.

For systems of indistinguishable particles it is enough to restrict to wave functions which are even or odd under particle exchanges,

$$\begin{aligned} &f_N(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_j,\ldots,\boldsymbol{x}_k,\ldots,\boldsymbol{x}_N) \\ &\quad = \pm f_N(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_k,\ldots,\boldsymbol{x}_j,\ldots,\boldsymbol{x}_N) \end{aligned} \quad [6]$$

for all $1 \le j < k \le N$, with the upper and lower signs corresponding to bosons and fermions, respectively (this empirical fact is usually taken as a postulate in nonrelativistic many-body quantum physics). It is convenient to define the zero-particle Hilbert space as $\mathbb{C}$ (complex numbers) and to introduce a Hilbert space containing states with all possible particle numbers: this so-called Fock space contains all states

$$\begin{pmatrix} f_0 \\ f_1(\boldsymbol{x}_1) \\ f_2(\boldsymbol{x}_1,\boldsymbol{x}_2) \\ f_3(\boldsymbol{x}_1,\boldsymbol{x}_2,\boldsymbol{x}_3) \\ \vdots \end{pmatrix} \quad [7]$$

with $f_0 \in \mathbb{C}$. The definition of $H_N$ and $U_N$ then naturally extends to this Fock space; see below.

### General Construction

The construction of Fock spaces and many-particle observables and transformations just outlined in a specific example is conceptually simple. An alternative, more efficient construction method is to use "quantum fields," which we denote as $\psi(\boldsymbol{x})$ and $\psi^\dagger(\boldsymbol{x})$, $\boldsymbol{x} \in \mathbb{R}^3$. They can be fully characterized by the following (anti-) commutator relations:

$$[\psi(\boldsymbol{x}),\psi^\dagger(\boldsymbol{y})]_\mp = \delta^3(\boldsymbol{x}-\boldsymbol{y}), \quad [\psi(\boldsymbol{x}),\psi(\boldsymbol{y})]_\mp = 0 \quad [8]$$

where $[a,b]_\mp \equiv ab \mp ba$, with the commutator and anticommutators (upper and lower signs, respectively) corresponding to the boson and fermion case, respectively. It is convenient to "smear" these fields with one-particle wave functions and define

$$\begin{aligned} \psi(f) &= \int_{\mathbb{R}^3} \mathrm{d}^3x\overline{f(\boldsymbol{x})}\psi(\boldsymbol{x}) \\ \psi^\dagger(f) &= \int_{\mathbb{R}^3} \mathrm{d}^3x\psi^\dagger(\boldsymbol{x})f(\boldsymbol{x}) \end{aligned} \quad [9]$$

for all $f \in h$. Then the relations characterizing the field operators can be written as

$$\begin{aligned} &[\psi(f),\psi^\dagger(g)]_\mp = (f,g) \\ &[\psi(f),\psi(g)]_\mp = 0 \\ &\quad \forall f,g \in h \end{aligned} \quad [10]$$

where

$$(f,g) = \int_{\mathbb{R}^3} \mathrm{d}^3x\overline{f(\boldsymbol{x})}g(\boldsymbol{x})$$

is the inner product in $h$. The Fock space $\mathcal{F}_\mp(h)$ can then be defined by postulating that it contains a normalized vector $\Omega$ called "vacuum" such that

$$\psi(f)\Omega = 0 \quad \forall f \in h \quad [11]$$

and that all $\psi^{(\dagger)}(f)$ are operators on $\mathcal{F}_\mp(h)$ such that $\psi^\dagger(f) = \psi(f)^*$, where $*$ is the Hilbert space adjoint. Indeed, from this we conclude that $\mathcal{F}_\mp(h)$, as vector space, is generated by

$$f_1 \wedge f_2 \wedge \cdots \wedge f_N \equiv \psi^\dagger(f_1)\psi^\dagger(f_2)\cdots\psi^\dagger(f_N)\Omega \quad [12]$$

with $f_j \in h$ and $N = 0,1,2,\ldots$, and that the Hilbert space inner product of such vectors is

$$\begin{aligned} &\langle f_1 \wedge f_2 \wedge \cdots \wedge f_N, g_1 \wedge g_2 \wedge \cdots \wedge g_M\rangle \\ &\quad = \delta_{N,M} \sum_{P\in S_N} (\pm 1)^{|P|} \prod_{j=1}^{N} (f_j, g_{Pj}) \end{aligned} \quad [13]$$

with $S_N$ the permutation group, with $(+1)^{|P|} = 1$ always, and $(-1)^{|P|} = +1$ and $-1$ for even and odd permutations, respectively. The many-body Hamiltonian $q(H)$ corresponding to the one-particle Hamiltonian $H$ can now be defined by the following relations:

$$q(H)\Omega = 0, \quad [q(H),\psi^\dagger(f)] = \psi^\dagger(Hf) \quad [14]$$

for all $f \in h$ such that $Hf$ is defined. Indeed, this implies that

$$\begin{aligned} &q(H) f_1 \wedge f_2 \wedge \cdots \wedge f_N \\ &\quad = \sum_{j=1}^{N} f_1 \wedge f_2 \wedge \cdots \wedge (Hf_j) \wedge \cdots \wedge f_N \end{aligned} \quad [15]$$

which defines a self-adjoint operator on $\mathcal{F}_\mp(h)$, and it is easy to check that this coincides with our down-to-earth definition of $H_N$ above. Similarly, the many-body transformation $Q(U)$ corresponding to a one-particle transformation $U$ can be defined as

$$Q(U)\Omega = \Omega, \quad Q(U)\psi^\dagger(f) = \psi^\dagger(Uf)Q(U) \quad [16]$$

for all $f \in h$, which implies that

$$\begin{aligned} &Q(U) f_1 \wedge f_2 \wedge \cdots \wedge f_N \\ &\quad = (Uf_1) \wedge (Uf_2) \wedge \cdots \wedge (Uf_N) \end{aligned} \quad [17]$$

and thus coincides with our previous definition of $U_N$.

While we presented the construction above for a particular example, it is important to note that it actually does not make reference to what the one-particle formalism actually is. For example, if we had a model of particles on a space $\mathcal{M}$ given by some "nice" manifold of any dimension and with $M$ internal degrees of freedom, we would take $h = L^2(\mathcal{M}) \otimes \mathbb{C}^M$ and replace [9] by

$$\psi(f) = \int_{\mathcal{M}} \mathrm{d}\mu(\boldsymbol{x}) \sum_{j=1}^{M} \overline{f_j(\boldsymbol{x})}\psi_j(\boldsymbol{x}) \qquad [18]$$

and its Hermitian conjugate, with the measure $\mu$ on $\mathcal{M}$ defining the inner product in $h$,

$$(f, g) = \int \mathrm{d}\mu(\boldsymbol{x}) \sum_j \overline{f_j(\boldsymbol{x})} g_j(\boldsymbol{x})$$

With that, all formulas after [9] hold true as they stand. *Given any one-particle Hilbert space $h$ with inner product $(\cdot\,,\cdot)$, observable $H$, and transformation $U$, the formulas above define the corresponding Fock spaces $\mathcal{F}_\mp(h)$ and many-body observable $q(H)$ and transformation $Q(U)$.* It is also interesting to note that this construction has various beautiful general (functorial) properties: the set of one-particle observables has a natural Lie algebra structure with the Lie bracket given by the commutator (strictly speaking: i times the commutator, but we drop the common factor i for simplicity). The definitions above imply that

$$[q(A), q(B)] = q([A, B]) \qquad [19]$$

for one-particle observables $A$, $B$, that is, the above-mentioned Lie algebra structure is preserved under this map $q$. In a similar manner, the set of one-particle transformations has a natural group structure preserved by the map $Q$,

$$Q(U)Q(V) = Q(UV), \quad Q(U)^{-1} = Q(U^{-1}) \qquad [20]$$

Moreover, if $A$ is self-adjoint, then $\exp(\mathrm{i}A)$ is unitary, and one can show that

$$Q(\exp(\mathrm{i}A)) = \exp(\mathrm{i}q(A)) \qquad [21]$$

For later use, we note that, if $\{f_n\}_{n\in\mathbb{Z}}$ is some complete, orthonormal basis in $h$, then operators $A$ on $h$ can be represented by infinite matrices $(A_{mn})_{m,n\in\mathbb{Z}}$ with $A_{mn} = (f_m, Af_n)$, and

$$q(A) = \sum_{m,n} A_{mn}\psi_m^\dagger\psi_n \qquad [22]$$

where $\psi_n^{(\dagger)} = \psi^{(\dagger)}(f_n)$ obey

$$[\psi_m, \psi_n^\dagger]_\mp = \delta_{m,n}, \qquad [\psi_m, \psi_n^\dagger]_\mp = 0 \qquad [23]$$

for all $m$, $n$. We also note that, in our definition of $q(A)$, we made a convenient choice of normalization, but there is no physical reason to not choose a different normalization and define

$$q'(A) = q(A) - b(A) \qquad [24]$$

where $b$ is some linear function mapping self-adjoint operators $A$ to real numbers. For example, one may wish to use another reference vector $\tilde{\Omega}$ instead of $\Omega$ in the Fock space, and then would choose $b(A) = \langle\tilde{\Omega}, q(A)\tilde{\Omega}\rangle$. Then the relations in [19] are changed to

$$[q'(A), q'(B)] = q'([A, B]) + S_0(A, B) \qquad [25]$$

where $S_0(A, B) = b([A, B])$. However, the $\mathbb{C}$-number term $S_0(A, B)$ in the relations [25] is trivial, since it can be removed by going back to $q(A)$.

### Physical Interpretation

The Fock space $\mathcal{F}_\mp(h)$ is the direct sum of subspaces of states with different particle numbers $N$,

$$\mathcal{F}_\mp(h) = \bigoplus_{N=0}^{\infty} h_\mp^{(N)} \qquad [26]$$

where the zero-particle subspace $h_\mp^{(0)} = \mathbb{C}$ is generated by the vacuum $\Omega$, and $h_\mp^{(N)}$ is the $N$-particle subspace generated by the states $f_1 \wedge f_2 \wedge \cdots \wedge f_N$, $f_j \in h$. We note that

$$\mathcal{N} \equiv q(1) \qquad [27]$$

is the "particle-number operator," $\mathcal{N}F_N = NF_N$ for all $F_N \in h_\mp^{(N)}$. The field operators obviously change the particle number: $\psi^\dagger(f)$ increases the particle number by one (maps $h_\mp^{(N)}$ to $h_\mp^{(N+1)}$), and $\psi(f)$ decreases it by one. Since every $f \in h$ can be interpreted as one-particle state, it is natural to interpret $\psi^\dagger(f)$ and $\psi(f)$ as "creation" and "annihilation" operators, respectively: they create and annihilate one particle in the state $f \in h$. It is important to note that, in the fermion case, [10] implies that $\psi^\dagger(f)^2 = 0$, which is a mathematical formulation of the Pauli exclusion principle: *it is not possible to have two fermions in the same one-particle state*. In the boson case, there is no such restriction. Thus, even though the formalisms used to describe boson and fermion systems look very similar, they describe dramatically different physics.

### Applications

In our example, the many-body Hamiltonian $\mathcal{H}_0 \equiv q(H)$ can also be written in the following suggestive form:

$$\mathcal{H}_0 = \int \mathrm{d}^3x\, \psi^\dagger(\boldsymbol{x})(H\psi)(\boldsymbol{x}) \qquad [28]$$

and similar formulas hold true for other observables and other Hilbert spaces $h = L^2(\mathcal{M}) \otimes \mathbb{C}^n$. It is rather easy to solve the model defined by such Hamiltonian: all necessary computations can be reduced to one-particle computations. For example, in the static case, where $\boldsymbol{A}$ and $\phi$ are time independent, a main quantity of interest in statistical physics is the free energy

$$\mathcal{E} \equiv -\beta^{-1} \log(\mathrm{tr}(\exp(-\beta[\mathcal{H}_0 - \mu\mathcal{N}]))) \qquad [29]$$

where $\beta > 0$ is the inverse temperature, $\mu$ the chemical potential, and the trace over the Fock space $\mathcal{F}_\mp(h)$. One can show that

$$\mathcal{E} = \pm\mathrm{tr}\big(\beta^{-1}\log(1 \mp \exp(-\beta[H - \mu]))\big) \qquad [30]$$

where the trace is over the one-particle Hilbert space $h$. Thus, to compute $\mathcal{E}$, one only needs to find the eigenvalues of $H$.

It is important to mention that the framework discussed here is not only for external field problems but can be equally well used to formulate and study more complicated models with interparticle interactions. For example, while the model with the Hamiltonian $\mathcal{H}_0$ above is often too simple to describe systems in nature, it is easy to write down more realistic models, for example, the Hamiltonian

$$\mathcal{H} = \mathcal{H}_0 + (e^2/2)\int \mathrm{d}^3\boldsymbol{x}\int \mathrm{d}^3\boldsymbol{y}\,\psi^\dagger(\boldsymbol{x})\psi^\dagger(\boldsymbol{y}) \times |\boldsymbol{x}-\boldsymbol{y}|^{-1}\psi(\boldsymbol{y})\psi(\boldsymbol{x}) \qquad [31]$$

describes electrons in an external electromagnetic field interacting through Coulomb interactions. This illustrates an important point which we would like to stress: the task in quantum theory is twofold, namely to formulate and to solve (exact of otherwise) models. Obviously, in the nonrelativistic case, it is equally simple to formulate many-body models with and without interparticle interactions, and only the latter are simpler because they are easier to solve: the two tasks of formulating and solving models can be clearly separated. As we will see, in the relativistic case, even the formulation of an external field problem is nontrivial, and one finds that one cannot formulate the model without at least partially solving it. This is a common feature of quantum field theories making them challenging and interesting.

## Relativistic Fermion and Boson Systems

We now generalize the formalism developed in the previous section to the relativistic case.

### Field Algebras and Quasifree Representations

In the previous section, we identified the field operators $\psi^{(\dagger)}(f)$ with particular Fock space operators. This is analogous to identifying the operators $p_j = -\mathrm{i}\partial_{x_j}$ and $q_j = x_j$ on $L^2(\mathbb{R}^M)$ with the generators of the Heisenberg algebra, as usually done. (We recall: the Heisenberg algebra is the star algebra generated by $P_j$ and $Q_j$, $j = 1, 2, \ldots, M < \infty$, with the well-known relations

$$[P_j, P_k] = -\mathrm{i}\delta_{jk}, \qquad [P_j, P_k] = [P_j, Q_k] = 0$$
$$P_j^\dagger = P_j, \qquad Q_j^\dagger = Q_j \qquad [32]$$

for all $j$, $k$.) Identifying the Heisenberg algebra with a particular representation is legitimate since, as is well known, all its irreducible representations are (essentially) the same (this statement is made precise by a celebrated theorem due to von Neumann).

However, in case of the algebra generated by the field operators $\psi^{(\dagger)}(f)$, there exist representations which are truly different from the ones discussed in the last section, and such representations are needed to construct relativistic external field problems. It is therefore important to distinguish the fields as generators of an algebra from the operators representing them. We thus define the (boson or fermion) field algebra $\mathcal{A}_\mp(h)$ over a Hilbert space $h$ as the star algebra generated by $\Psi^\dagger(f), f \in h$, such that the map $f \to \Psi(f)$ is linear and the relations

$$[\Psi(f), \Psi^\dagger(g)]_\mp = (f, g)$$
$$[\Psi(f), \Psi(g)]_\mp = 0 \qquad [33]$$
$$\Psi^\dagger(f)^\dagger = \Psi(f)$$

are fulfilled for all $f, g \in h$, with $\dagger$ the star operation in $\mathcal{A}_\mp(h)$. The particular representation of this algebra discussed in the last section will be denoted by $\pi_0$, $\pi_0(\Psi^{(\dagger)}(f)) = \psi^{(\dagger)}(f)$. Other representations $\pi_{P_-}$ can be constructed from any projection operators $P_-$ on $h$, that is, any operator $P_-$ on $h$ satisfying $P_-^* = P_-^2 = P_-$. Writing $\hat{\psi}^{(\dagger)}(f)$ short for $\pi_{P_-}(\Psi^{(\dagger)}(f))$, this so-called quasifree representation is defined by

$$\hat{\psi}^\dagger(f) = \psi^\dagger(P_+f) + \psi(\overline{P_-f})$$
$$\hat{\psi}(f) = \psi(P_+f) \mp \psi^\dagger(\overline{P_-f}) \qquad [34]$$

where the bar means complex conjugation. It is important to note that, while the star operation is identical with the Hilbert space adjoint $*$ in the fermion case, we have

$$\hat{\psi}(f)^\dagger = \psi(Ff)^* \quad \text{with}$$
$$F = P_+ - P_- \quad \text{for bosons} \qquad [35]$$

where $F$ is a grading operator, that is, $F^* = F$ and $F^2 = 1$. We stress that the "physical" star operation always is $*$, that is, physical observables $A$ obey $A = A^*$.

The present framework suggests to regard quantization as the procedure which amounts to going from a one-particle Hilbert space $h$ to the corresponding field algebra $\mathcal{A}_+(h)$. Indeed, the Heisenberg algebra is identical with the boson field algebra $\mathcal{A}_-(\mathbb{C}^M)$ (since the latter is obviously identical with the algebra of $M$ harmonic oscillators), and thus conventional quantum mechanics can be regarded as boson quantization in the special case where the one-particle Hilbert space is finite dimensional. It is interesting to note that "fermion quantum mechanics" $\mathcal{A}_-(\mathbb{C}^M)$ is the natural framework for formulating and studying lattice fermion and spin systems which play an important role in condensed matter physics.

In the following, we elaborate the naive interpretations of the relativistic equations in [2] and [3] as a quantum theory of one particle, and we discuss why they are unphysical. For simplicity, we assume that the electromagnetic fields $\phi$, $\boldsymbol{A}$ are time independent. We then show that quasifree representations as discussed above can provide physically acceptable many-particle theories. We first consider the Dirac case, which is somewhat simpler.

### Fermions

**One-particle formalism** Recalling that $\mathrm{i}\partial_t$ is the energy operator, we define the Dirac Hamiltonian $D$ by rewriting [3] in the following form:

$$\mathrm{i}\partial_t\psi = D\psi, \quad D = (-\mathrm{i}\nabla + e\boldsymbol{A}) \cdot \boldsymbol{\alpha} + m\beta - e\phi \qquad [36]$$

This Dirac Hamiltonian is obviously a self-adjoint operator on the one-particle Hilbert space $h = L^2(\mathbb{R}^4) \otimes \mathbb{C}^4$, but, different from the Schrödinger Hamiltonian in [1], it is not bounded from below: for any $E_0 > -\infty$, one can find a state $f$ such that the energy expectation value $(f, Df)$ is less than $E_0$. This can be easily seen for the simplest case where the external potential vanishes, $\boldsymbol{A} = \phi = 0$. Then the eigenvalues of $D$ can be computed by Fourier transformation, and one finds

$$E = \pm\sqrt{\boldsymbol{p}^2 + m^2}, \quad \boldsymbol{p} \in \mathbb{R}^3 \qquad [37]$$

Due to the negative energy eigenvalues we conclude that there is no ground state, and the Dirac Hamiltonian thus describes an unstable system, which is physically meaningless.

To summarize: a (unphysical) one-particle description of relativistic fermions is given by a Hilbert space $h$ together with a self-adjoint Hamiltonian $D$ unbounded from below. Other observables and transformations are given by self-adjoint and unitary operators on $h$, respectively.

**Many-body formalism** We now explain how to construct a physical many-body description from these data. To simplify notation, we first assume that $D$ has a purely discrete spectrum (which can be achieved by using a compact space). We can then label the eigenfunctions $f_n$ by integers $n$ such that the corresponding eigenvalues $E_n \geq 0$ for $n \geq 0$ and $E_n < 0$ for $n < 0$. Using the naive representation of the fermion field algebra discussed in the last section, we get (we use the notation introduced in [22])

$$q(D) = \sum_{n\geq 0} |E_n|\psi_n^\dagger\psi_n - \sum_{n<0} |E_n|\psi_n^\dagger\psi_n \qquad [38]$$

which is obviously not bounded from below and thus not physically meaningful. However, $\psi_n^\dagger\psi_n = 1 - \psi_n\psi_n^\dagger$, which suggests that we can remedy this problem by interchanging the creation and annihilation operators for $n < 0$. This is possible: it is easy to see that

$$\hat{\psi}_n \equiv \psi_n \quad \forall n \geq 0 \quad \text{and} \quad \hat{\psi}_n \equiv \psi_n^\dagger \quad \forall n < 0 \qquad [39]$$

provides a representation of the algebra in [23]. We thus define

$$\hat{q}(D) \equiv \sum_{n\in\mathbb{Z}} E_n : \hat{\psi}_n^\dagger\hat{\psi}_n : \qquad [40]$$

with the so-called normal ordering prescription

$$:\psi_m^\dagger\psi_n :\equiv \psi_m^\dagger\psi_n - \langle\Omega, \psi_m^\dagger\psi_n\Omega\rangle \qquad [41]$$

where we made use of the freedom of normalization explained after [23] to eliminate unwanted additive constants. We get $q(D) = \sum_{n\in\mathbb{Z}} |E_n|\psi_n^\dagger\psi_n$, which is manifestly a non-negative self-adjoint operator with $\Omega$ as ground state. We thus found a physical many-body description for our model. We can now define for other one-particle observables,

$$\hat{q}(A) \equiv \sum_{n\in\mathbb{Z}} A_{mn} : \hat{\psi}_m^\dagger\hat{\psi}_n : \qquad [42]$$

and, by straightforward computations, we obtain

$$[\hat{q}(A), \hat{q}(B)] = \hat{q}([A, B]) + S(A, B) \qquad [43]$$

where $S(A, B) = \sum_{m<0}\sum_{n\geq 0}(A_{mn}B_{nm} - B_{mn}A_{nm})$, that is,

$$S(A, B) = \mathrm{tr}(P_-AP_+BP_- - P_-BP_+AP_-) \qquad [44]$$

with $P_- = \sum_{n<0} f_n(f_n, \cdot)$ the projection onto the subspace spanned by the negative energy eigenvectors of $D$ and $P_+ = 1 - P_-$. One can show that $\hat{q}(A)$ is no longer defined for all operators but only if

$$P_-AP_+ \text{ and } P_+AP_- \text{ are Hilbert–Schmidt operators} \qquad [45]$$

(we recall that $a$ is a Hilbert–Schmidt operator if $\mathrm{tr}(a^*a) < \infty$). The $\mathbb{C}$-number term $S(A,B)$ in [43] is

often called Schwinger term and, different from the similar term in [25], it is now nontrivial, that is, it is no longer possible to remove it by a redefinition $\hat{q}'(A) = \hat{q}(A) - b(A)$. This Schwinger term is an example of an anomaly, and it has various interesting implications.

In a similar manner, one can construct the many-body transformations $\hat{Q}(U)$ of unitary operators $U$ on $h$ satisfying the very Hilbert–Schmidt condition in [45], and one obtains

$$\hat{Q}(U)\hat{Q}(V) = \chi(U, V)\hat{Q}(UV) \qquad [46]$$

with interesting phase-valued functions $\chi$.

More generally, for any one-particle Hilbert space $h$ and Dirac Hamiltonian $D$, the physical representation is given by the quasifree representation $\pi_{P_-}$ in [34] with $P_-$ the projection onto the negative energy subspace of $D$. The results about $\hat{q}$ and $\hat{Q}$ mentioned hold true in any such representation.

Thus the one-particle Hamiltonian $D$ determines which representation one has to use, and one therefore cannot construct the "physical" representation without specific information about $D$. However, not all these representations are truly different: if there is a unitary operator $\mathcal{U}$ on the Fock space $\mathcal{F}_+(h)$ such that

$$\mathcal{U}^* \pi_{P_-^{(1)}}(\psi^{(\dagger)}(f))\mathcal{U} = \pi_{P_-^{(2)}}(\psi^{(\dagger)}(f)) \qquad [47]$$

for all $f \in h$, then the quasifree representations associated with the different projections $P_-^{(1)}$ and $P_-^{(2)}$ are physically equivalent: one could equally well formulate the second model using the representation of the first. Two such quasifree representations are called unitarily equivalent, and a fundamental theorem due to Shale and Stinespring states that *two quasifree representations* $\pi_{P^{(1,2)}_-}$ *are unitarily equivalent if and only if* $P_-^{(1)} - P_-^{(2)}$ *is a Hilbert–Schmidt operator* (a similar result holds true in the boson case).

## Bosons

**One-particle formalism** Similarly as for the Dirac case, the solutions of the Klein–Gordon equation in [2] also do not define a physically acceptable one-particle quantum theory with a ground state: the energy eigenvalues in [37] for $A = \phi = 0$ are a consequence the relativistic invariance and thus equally true for the Klein–Gordon case. However, in this case there is a further problem. To find the one-particle Hamiltonian, one can rewrite the second-order equation in [2] as a system of first-order equations,

$$\mathrm{i}\partial_t \Phi = K\Phi$$
$$\Phi = \begin{pmatrix} \psi \\ \pi^\dagger \end{pmatrix}, \quad K = \begin{pmatrix} C & \mathrm{i} \\ -\mathrm{i}B^2 & C \end{pmatrix} \qquad [48]$$

with

$$B^2 \equiv (-\mathrm{i}\nabla + e\mathbf{A})^2 + m^2, \qquad C \equiv -e\phi \qquad [49]$$

Thus, one sees that the natural one-particle Hilbert space for the Klein–Gordon equation is $h = L^2(\mathbb{R}^3) \otimes \mathbb{C}^2$; here, and in the following, we identify $h$ with $h_0 \oplus h_0, h_0 = L^2(\mathbb{R}^3)$, and use a convenient $2 \times 2$ matrix notation naturally associated with that splitting. However, the one-particle Hamiltonian is not self-adjoint but rather obeys

$$K^* = JKJ, \quad J \equiv \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix} \qquad [50]$$

with $*$ the Hilbert space adjoint. It is important to note that $J$ is a grading operator. Thus, we can define a sesquilinear form

$$(f, g)_J \equiv (f, Jg) \quad \forall f, g \in h \qquad [51]$$

with $(\cdot\,, \cdot)$ the standard inner product, and [50] is equivalent to $K$ being self-adjoint with respect to this sesquilinear form; in this case, we say that $K$ is $J$-self-adjoint. Thus, in the Klein–Gordon case, this sesquilinear form takes the role of the Hilbert space inner product and, in particular, not $(\Phi,\Phi)$ but $(\Phi,\Phi)_J$ is preserved under time evolution. However, different from $\Phi^\dagger\Phi$, $\Phi^\dagger J\Phi$ is not positive definite, and it is therefore not possible to interpret it as probability density as in conventional quantum mechanics. For consistency, one has to require that one-particle transformations $U$ are unitary with respect to $(\Phi,\Phi)_J$, that is, $U^{-1} = JUJ$. We call such operators $J$-unitary.

To summarize: a (unphysical) one-particle description of relativistic bosons is given by a Hilbert space of the form $h = h_0 \oplus h_0$, the grading operator $J$ in [50], and a $J$-self-adjoint Hamiltonian $K$ of the form as in eqn [48], where $B \geq 0$ and $C$ are self-adjoint operators on $h_0$. Other observables and transformations are given by $J$-self-adjoint and $J$-unitary operators on $h$, respectively.

**Many-body formalism** We first consider the quasifree representation $\pi_{P_-^{(0)}}$ of the boson field algebra $\mathcal{A}_-(h)$ so that the grading operator in [35] is equal to $J$, that is, $P_-^{(0)} = (1 - J)/2$. Writing $\pi_{P_-^{(0)}}(\Psi^{(\dagger)}(f)) = \psi^{(\dagger)}(f)$, one finds that

$$q(A)^* = q(JAJ), \qquad Q(U)^* = Q(JU^*J) \qquad [52]$$

and thus $J$-self-adjoint operators and $J$-unitary operators are mapped to proper observables and transformations. In particular, $q(K)$ is a self-adjoint

operator, which resolves one problem of the one-particle theory. However, $q(K)$ is not bounded from below, and thus $\pi_{P_{\underline{-}}(0)}$ is not yet the physical representation.

The physical representation can be constructed using the operators

$$T = \frac{1}{\sqrt{2}}\begin{pmatrix} B^{1/2} & \mathrm{i}B^{-1/2} \\ B^{1/2} & \mathrm{i}B^{-1/2} \end{pmatrix}, \quad F = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad [53]$$

(for simplicity, we restrict ourselves to the case $C=0$ and $B > 0$; we use the calculus of self-adjoint operators here) with the following remarkable properties:

$$T^{-1} = JT^{*}F$$
$$TKT^{-1} = \begin{pmatrix} B & 0 \\ 0 & -B \end{pmatrix} \equiv \hat{K} \qquad [54]$$

One can check that

$$\hat{\psi}^{\dagger}(f) \equiv \psi^{\dagger}(Tf), \qquad \hat{\psi}(f) \equiv \psi(T^{-1}f) \qquad [55]$$

is a quasifree representation $\pi_{P_{-}}$ of $\mathcal{A}_{-}(h)$ with $P_{-}=(1-F)/2$. With that the construction of $\hat{q}$ and $\hat{Q}$ is very similar to the fermion case described above (the crucial simplification is that $\hat{K}$ and $F$ now are diagonal). In particular, $\hat{q}(K)$ is a non-negative operator with the ground state $\Omega$, and $\hat{q}(A)$ and $\hat{Q}(U)$ are self-adjoint and unitary for every one-particle observable $A$ and transformation $U$, respectively. One also gets relations as in [43] and [46].

## Related Topics of Recent Interest

The impossibility to construct relativistic quantum-mechanical models played an important role in the early history of quantum field theory, as beautifully discussed in chapter 1 of Weinberg (1995).

The abstract formalism of quasifree representations of fermion and boson field algebras was developed in many papers (see, e.g., Ruijsenaars (1977), Grosse and Langmann (1992), and Langmann (1994) for explicit results on $\hat{Q}$ and $\chi$). A nice textbook presentation with many references can be found in chapter 13 of Gracia-Bondía *et al.* (2001) (this chapter is rather self-contained but mainly restricted to the fermion case).

Based on the Shale–Stinespring theorem, there has been considerable amount of work to investigate whether the quasifree representations associated with different external electromagnetic fields $\psi_1, \boldsymbol{A}_1$ and $\psi_2, \boldsymbol{A}_2$ are unitarily equivalent, if and which time-dependent many-body Hamiltonians exist, etc. (see chapter 13 of Gracia-Bondía *et al.* (2001), and references therein).

The infinite-dimensional Lie algebra $g_2$ of Hilbert space operators satisfying the condition in [45] is an interesting infinite-dimensional Lie algebra with a beautiful representation theory. This subject is closely related to conformal field theory (see, e.g., Kac and Raina (1987) for a textbook presentation and Carey and Ruijsenaars (1987) for a detailed mathematical account within the framework described by us).

It turns out that the mathematical framework discussed in the previous section is sufficient for constructing fully interacting quantum field theories, in particular Yang–Mills gauge theories, in $1+1$ but not in higher dimensions. The reason is that, in $3+1$ dimensions, the one-particle observables $A$ of interest do not obey the Hilbert–Schmidt condition in [45] but only the weaker condition

$$\mathrm{tr}(a^{*}a)^{n} < \infty, \quad a = P_{\mp}AP_{\pm} \qquad [56]$$

with $n=2$, and the natural analog of $g_2$ in $3+1$ dimensions thus seems to be the Lie algebra $g_{2n}$ of operators satisfying this condition with $n=2$. Various results on the representation theory of such Lie algebras $g_{2n>2}$ have been developed (see Mickelsson (1989), where various interesting relations to infinite-dimensional geometry are also discussed).

As mentioned, the Schwinger term $S(A,B)$ in [44] is an example of an anomaly. Mathematically, it is a nontrivial 2-cocycle of the Lie algebra $g_2$, and analogs for the groups $g_{2n>2}$ have been found. These cocycles provide a natural generalization of anomalies (in the meaning of particle physics) to operator algebras. They not only shed some interesting light on the latter, but also provide a link to notions and results from noncommutative geometry (see, e.g., Gracia-Bondía *et al.* (2001)). We believe that this link can provide a fruitful driving force and inspiration to find ways to deepen our understanding of quantum Yang–Mills theories in $3+1$ dimensions (Langmann 1996).

# Boundaries for Spacetimes

**S G Harris**, St. Louis University, St. Louis, MO, USA

## Introduction

There is a common practice in mathematics of placing a boundary on an object which may not appear to come naturally equipped with one; this is often thought of as adding ideal points to the object. Perhaps the most famous example is the addition of a single "point at infinity" to the complex plane, resulting in the Riemann sphere: this is a boundary point in the sense of providing an ideal endpoint for lines and other endless curves in the plane. Often, there is more than one reasonable way to construct a boundary for a given object, depending on the intent; for instance, the plane is sometimes equipped, not with a single point at infinity, but with a circle at infinity, resulting in a space homeomorphic to a closed disk. Both these boundaries on the plane have useful but different things to tell us about the nature of the plane; the common feature is that, by bringing the infinite reach of the plane within the confines of a more finite object, we are better able to grasp the behavior of the original object.

The general usefulness of the construction of boundaries for an object is to allow behavior of structures in the "completed" object to aid in visualization of behavior in the original object, such as by providing a degree of measurement or other classification of processes at infinity. This utility has not been overlooked for spacetimes. A variety of purposes may be served by various boundary construction methods: providing a locale for singularities (as the spacetime itself is modeled by a smooth manifold with a smooth metric, free of singular points); providing a platform from which to measure global properties such as total energy or angular momentum; displaying in finite form the causal structure at infinity; or providing a compact (or quasicompact) topological envelope for the spacetime while preserving the causal structure.

This article will consider several of the methods that have been used or proposed for constructing boundaries for spacetimes, ranging from the *ad hoc* (but practical) to the universal. Perhaps the simplest way to classify these methods is into those which employ or analyze embeddings of the spacetime in question and those that do not.

## Boundaries from Embeddings

### General

The simplest and most common method of constructing a boundary for a spacetime $M$ is to find a suitable manifold $N$ (of the same dimension) and an appropriate map $\phi : M \to N$ which is a topological embedding, that is, a homeomorphism onto its image $\phi(M)$. We can consider $\bar{M}_\phi$, the closure of $\phi(M)$ in $N$, as the $\phi$-completion of $M$, and $\partial_\phi(M) = \bar{M}_\phi - \phi(M)$ as the $\phi$-boundary. Typically, this embedding is chosen in such a way that curves of interest in $M$ – such as timelike or null geodesics or causal curves of bounded acceleration – which have no endpoints in $M$, do have endpoints in $\partial_\phi(M)$; in other words, if $c : [0, \infty) \to M$ is such a curve of interest, then $\lim_{t \to \infty} \phi(c(t))$ exists in $N$.

The common practice, initiated by Penrose in 1967, is to choose $N$ to be another spacetime – often called the unphysical spacetime, while $M$ is considered the spacetime of physical interest – and to require the embedding $\phi$ to be a conformal mapping, that is, $\phi$ carries the spacetime metric in $M$ to a scalar multiple of the spacetime metric in $N$. As conformal maps preserve the local causal structure, leaving unchanged the notions of timelike curve or null curve, this means that $\bar{M}_\phi$ inherits from $N$ a causal structure which, locally, is an extension of that of $M$. This allows us to speak of causal relationships within $\bar{M}_\phi$, closely related to those in $M$.

### Minkowski Space

The prototypical example is the conformal embedding of Minkowski space into the Einstein static spacetime.

Let $\mathbb{R}^n$ denote Euclidean $n$-space, $\mathbb{S}^n$ the unit $n$-sphere, and $\mathbb{L}^n$ Minkowski $n$-space, that is, $\mathbb{R}^n$ with metric $ds^2 = dx_1^2 + \cdots + dx_{n-1}^2 - dt^2$ (so $\mathbb{L}^n = \mathbb{R}^{n-1} \times \mathbb{L}^1$). The $n$-dimensional Einstein static spacetime is the product spacetime $\mathbb{E}^n = \mathbb{S}^{n-1} \times \mathbb{L}^1$. Consider $\mathbb{S}^{n-1}$ as embedded in $\mathbb{R}^n = \mathbb{R}^{n-1} \times \mathbb{R}^1$. Then the conformal embedding is $\phi : \mathbb{L}^n \to \mathbb{E}^n$, expressed as $\phi : \mathbb{R}^{n-1} \times \mathbb{L}^1 \to \mathbb{S}^{n-1} \times \mathbb{L}^1 \subset \mathbb{R}^{n-1} \times \ \mathbb{R}^1 \times \mathbb{L}^1$ given by $\phi(x,t) = ((x/|x|) \sin\theta, \cos\theta, \tau)$, where $\theta = \tan^{-1}(t+|x|) - \tan^{-1}(t-|x|)$ and $\tau = \tan^{-1}(t+|x|) + \tan^{-1}(t-|x|)$. The boundary $\partial_\phi(\mathbb{L}^n)$ consists of the following: the points $\{\theta + \tau = \pi; 0 < \tau \le \pi\}$, composed of an $\mathbb{S}^{n-2}$ of null lines coming together at the point $i^+ = (0, 1, \pi)$; a similar cone of null lines $\{\theta - \tau = \pi; -\pi \le \tau < 0\}$ with vertex at $i^- = (0, 1, -\pi)$; and a single limit-point for both cones at $i^0 = (0, -1, 0)$. The $\tau > 0$ null cone is called $\mathfrak{I}^+$ (the letter is read "scri" for "script-I"), its counterpart $\mathfrak{I}^-$ (Figures 1 and 2). As all future-directed timelike geodesics in $\mathbb{L}^n$ have $i^+$ as an endpoint in $\mathbb{E}^n$, $i^+$ is called future-timelike infinity; similarly, $i^-$ is past-timelike infinity. Every future-directed null geodesic ends up on $\mathfrak{I}^+$, which is thus termed future-null infinity, and $\mathfrak{I}^-$ is past-null infinity. All spacelike geodesics come to $i^0$, spacelike infinity.

For $n = 2$, this picture produces the familiar diamond representation of $\mathbb{L}^2$ (Figure 3): as $\mathbb{E}^2$ is easily unrolled into another copy of $\mathbb{L}^2$ (metric

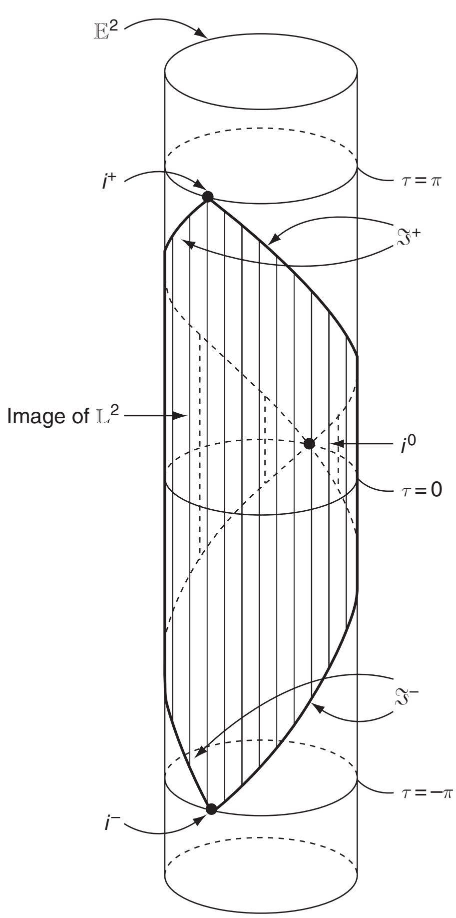

**Figure 1** $\mathbb{L}^2$ conformally embedded in $\mathbb{E}^2 = \mathbb{S}^1 \times \mathbb{L}^1$.

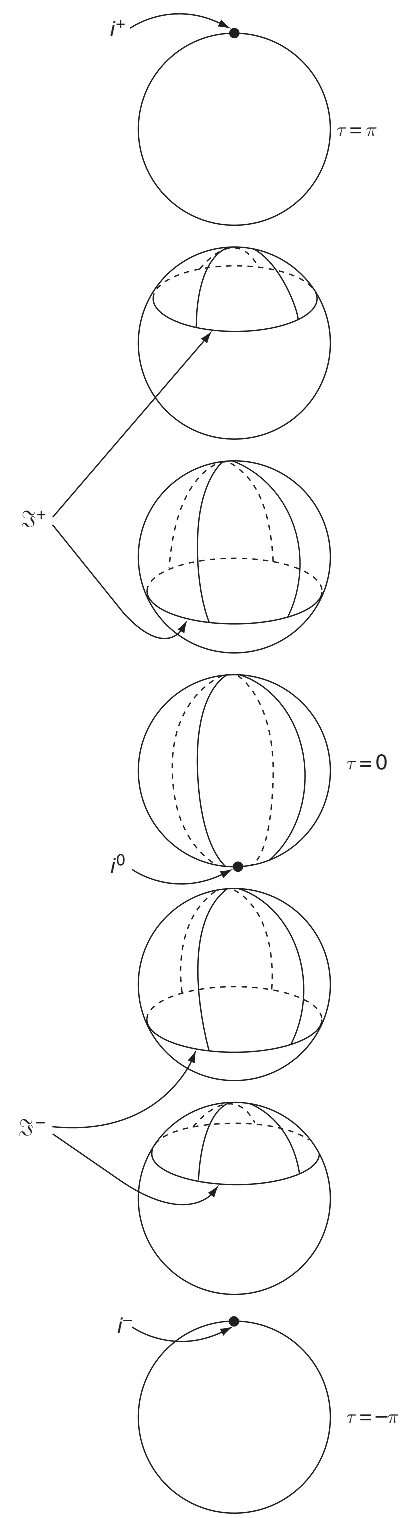

**Figure 2** $\mathbb{L}^3$ conformally embedded in $\mathbb{E}^3 = \mathbb{S}^2 \times \mathbb{L}^1$.

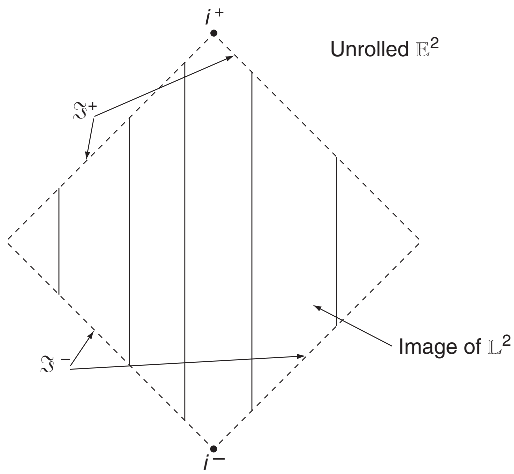

**Figure 3** $\mathbb{L}^2$ conformally embedded in unrolled $\mathbb{E}^2$, i.e., $\mathbb{R}^1 \times \mathbb{L}^1 = \mathbb{L}^2$.

$\mathrm{d}\theta^2 - \mathrm{d}\tau^2$), this means that $\phi(\mathbb{L}^2)$ is the region $|\theta| + |\tau| < \pi$ in $\mathbb{L}^2$; timelike curves and null geodesics in the original $\mathbb{L}^2$ are the same as in $\phi(\mathbb{L}^2)$, and their endpoints in the boundary of the diamond are evident. For higher dimensions, the picture is not as visually obvious, since $\mathbb{E}^n$ cannot be unrolled; but the principle of reading the causal structure at infinity of $\mathbb{L}^n$ via its boundary points in $\mathbb{E}^n$ remains the same.

### Conformal Embeddings

There have been various formulations designed to emulate the conformal mapping of $\mathbb{L}^n$ with respect to spacetimes, which are, in some sense, asymptotically like Minkowski space being conformally mapped into larger spacetimes. A spacetime $M$ with metric $g$ is called asymptotically simple or (alternatively) asymptotically flat if there is a spacetime $N$ with metric $h$, an embedding $\phi: M \to N$, and a scalar function $\Omega$ defined on $N$ with $\phi^* h = (\Omega \circ \phi)^2 g$ (i.e., $\phi$ is conformal with $\Omega^2$ the conformal factor) and $\Omega = 0$ on $\partial_\phi(M), \mathrm{d}\Omega \neq 0$ on $\partial_\phi(M)$, and various other restrictions on $\Omega$, depending on the intent. One can define asymptotic symmetries of $M$ by means of motions within $\partial_\phi(M)$, leading to notions of global energy and angular momentum (see Hawking and Ellis (1973) and Wald (1984) for details).

### Classifications of Embeddings

As a general rule, there is no uniqueness in the choice of an embedding $\phi$ for a spacetime $M$ to construct a boundary, nor in the topology of the resulting boundary $\partial_\phi(M)$, or even of which curves of interest end up having endpoints in the boundary. In an attempt to categorize which embeddings yield equivalent results and what sort of results there are in terms of endpoints of curves, Scott and Szekeres (1994) formulated what they called the abstract boundary of a spacetime. This depends on a choice of class of "interesting" curves, each characterizable as having either infinite or finite parameter length; typical choices for this class would be timelike geodesics or causal geodesics or timelike curves of bounded acceleration. For instance, a boundary point may be said to represent a singularity with respect to the chosen class of curves if it is the endpoint of one such curve with finite parameter length; nonsingular points are points at infinity. These classifications do not require conformal embeddings, nor even that the target of the embeddings be spacetimes; they accommodate boundaries of a far more general type than Penrose's notion stemming from conformal embeddings.

A somewhat different study of boundaries from embeddings has been formulated by García-Parrado and Senovilla (2003), classifying points at infinity and singularities in $\partial_\phi(M)$ for embeddings $\phi: M \to N$ in which $N$ is a spacetime, $\phi$ preserves the chronology relation $\ll$, and there is also a diffeomorphism $\psi: \phi(M) \to N$ which again preserves $\ll$ (the chronology relation in a spacetime is defined thus: $x \ll y$ if and only if there is a future-directed timelike curve from $x$ to $y$). This scheme applies more generally than to conformal embeddings, but the requirement for chronology-preserving maps in both directions guarantees a strong sensitivity to causality; it amounts to a mild extension of Penrose's notion that is often much easier to construct.

## Universal Constructions

### B-Boundary

Attempts have been made to formulate boundary concepts specifically for defining singularities as ideal endpoints for finite-length geodesics. The most complete venture in this direction is the b-boundary ("b" for "bundle") of Schmidt (Hawking and Ellis 1973, pp. 276–284). This is a formulation that takes note only of the connection in the linear frames bundle $L(M)$ of a spacetime $M$ (or of any manifold with a linear connection, metric or otherwise); in other words, it takes no particular note of the spacetime metric or even of the causal structure of the spacetime, but only of the notion of parallel translation of tangent vectors along curves. Parallel translation of a frame (a basis for the tangent space) along a curve is used to obtain an *ad hoc* length for the curve by treating the translated frame as positive-definite orthonormal at each point; whether this length is finite or infinite is independent of the choice of the original frame. The Schmidt construction

defines a boundary on $M$ which gives an endpoint for each curve, endless in $M$, which is finite in that sense: Select a positive-definite metric on $L(M)$, give it a boundary by means of Cauchy completion, and then take the appropriate quotient by the bundle group. This has an appealing universality of application, but the problems of putting it into practice are quite formidable. Also, the fact that it takes no special note of the spacetime character of $M$ suggests that it may not be of particular utility for physical insights.

### Causal Boundary: Basics

In 1972 Geroch, Kronheimer, and Penrose (GKP) formulated a notion of boundary – the causal boundary – that is specifically adapted to the causal character of a spacetime $M$; indeed, it is defined in such a way that one need know only the chronology relation $\ll$ on $M$ without any further reference to the metric (another way of saying this is that the causal boundary is conformally invariant). Like Schmidt's b-boundary, the causal boundary is a universal construction, not depending on any extraneous choices; however, although it has an obvious clarity in its causal structure, there are subtleties in the choice of an appropriate topology which are perhaps not yet fully resolved. As this boundary construction appears to embody the best hopes for a practical universal construction, it is detailed here in some depth.

The causal boundary construction applies only to strongly causal spacetimes; essentially, this means that the local causal structure at each point is exactly reflective of the global causal structure.

The basic construction of the causal boundary of a spacetime $M$ starts with two separate parts: the future and past (pre-)boundaries of $M$, intended as yielding endpoints for, respectively, future- and past-endless causal curves. Part of the difficulty of the causal boundary is knowing how best to meld these two into one; currently, there are several answers to this conundrum.

The elements of the future causal boundary of $M$ are defined in terms of the past-set operator $I^-$. For a point $x \in M$, the past of $x$ is $I^-(x) = \{y \mid y \ll x\}$; for a set $A \subset M, I^-[A] = \bigcup_{x \in A} I^-(x)$. A set $P \subset M$ is called a past set if $I^-[P] = P$; anything of the form $P = I^-[A]$ is a past set, and all past sets have this form. A past set $P$ is an indecomposable past set (IP) if $P$ cannot be written as $P_1 \cup P_2$ for past sets which are proper subsets $P_i \subsetneq P$. IPs come in exactly two varieties: pointlike IPs (PIPs), of the form $I^-(x)$ (Figure 4), and terminal IPs (TIPs), of the form $I^-[c]$ for $c$ a future-endless causal curve (Figure 5). (Of course, any $I^-(x)$ can also be expressed as $I^-[c]$ for $c$ a causal curve ending at $x$.) The future causal boundary of $M$, $\hat{\partial}(M)$, consists of all the TIPs of $M$; the future causal completion of $M$ is $\hat{M} = \hat{\partial}(M) \cup M$. But that is just a set; the causal structure of $M$ needs to be extended to $\hat{M}$.

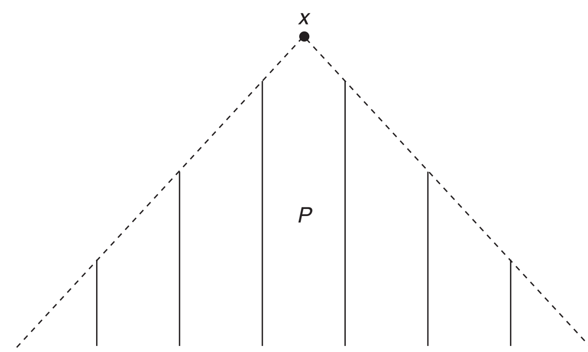

**Figure 4** PIP $P = I^-(x)$.

For any $x \in M$ and $P \in \hat{\partial}(M)$, set $x \ll P$ if and only if $x \in P$; set $P \ll x$ if and only if $P \subset I^-(y)$ for some $y \ll x$ $(y \in M)$; and for $P$ and $Q$ in $\hat{\partial}(M)$, set $P \ll Q$ if and only if $P \subset I^-(y)$ for some $y \in Q$. If we consider this an extension of the $\ll$ relation on $M$, then we end up with a relation which, like that on $M$, is transitive and antireflexive. Furthermore, it has the property that for all $\alpha, \beta \in \hat{M}, \alpha \ll \beta$ if and only if for some $x \in M, \alpha \ll x \ll \beta$. (One can also amend the chronology relation within $M$ to be more like the definition in the extension; that is not of major import.)

We can also extend the causality relation $\prec$ on $M$ to one on $\hat{M}$ (in $M, x \prec y$ if there is a future-directed

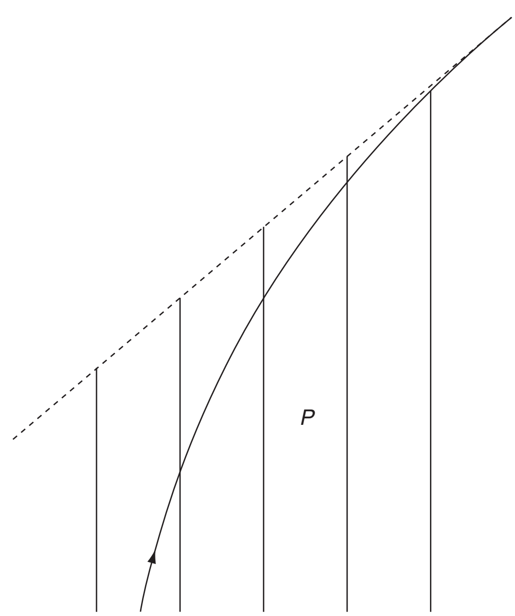

**Figure 5** TIP $P = I^- c$.

causal curve from $x$ to $y$): for $x \in M$ and $P, Q \in \hat{\partial}(M)$, $x \prec P$ for $I^-(x) \subset P$, $P \prec x$ for $P \subset I^-(x)$, and $P \prec Q$ for $P \subset Q$.

The intent is to have the elements of $\hat{\partial}(M)$ provide future endpoints for future-endless causal curves in $M$; in particular, we want two such curves, $c_1$ and $c_2$, to be assigned the same future endpoint precisely when $I^-[c_1] = I^-[c_2]$. This is accomplished by the simple expedient of defining the future endpoint of a future-endless causal curve $c$ to be $P = I^-[c]$. We do not have a topology on $\hat{M}$ as yet, but it is worth noting that if $P$ is the assigned future endpoint of $c$, then $I^-(P) = I^-[c]$; this is at least the correct causal behavior for a putative future endpoint of $c$.

We can perform all the operations above in the time-dual manner, obtaining the past causal boundary $\check{\partial}(M)$, consisting of terminal indecomposable future sets (TIFs), and the past causal completion $\check{M} = \check{\partial}(M) \cup M$. The full causal boundary of $M$ consists of the union of $\hat{\partial}(M)$ with $\check{\partial}(M)$ with some sort of identifications to be made.

As an example of the need for identifications, consider $M$ to be $\mathbb{L}^2$ with a closed timelike line segment deleted, say $M = \mathbb{L}^2 - \{(0, t) \mid 0 \le t \le 1\}$. For $\hat{\partial}(M)$, we have first the boundary elements at infinity: the TIP $i^+ = M$ (the past of the positive time axis) and the set of TIPs making up $\Im^+$ (the pasts of null lines going out to infinity in $\mathbb{L}^2$); and then, the boundary elements coming from the deleted points: for each $t$ with $0 < t \le 1$, two IPs emanating from $(0, t)$, that is, $P_t^+$, the past of the null line going pastwards from $(0, t)$ toward $x > 0$, and $P_t^-$, the past of the null line going pastwards from $(0, t)$ toward $x < 0$; and $P_0$, emanating from $(0, 0)$, that is, the past of the negative time axis. Similarly, $\check{\partial}(M)$ consists of $i^-, \Im^-$, TIFs $F_t^+$ and $F_t^-$ emanating from $(0, t)$ for $0 \le t < 1$, and the TIF $F_1$ emanating from $(0, 1)$. We probably want to make at least the following identifications for each $t$ with $0 < t < 1$, $P_t^+ \equiv F_t^+$ and $P_t^- \equiv F_t^-; P_1^+ \equiv F_1 \equiv P_1^-$; and $F_0^+ \equiv P_0 \equiv F_0^-$. This results in a two-sided replacement for the deleted segment; for some purposes, it might be deemed desirable to identify the two sides as one, but a universal boundary is probably a good idea, leaving further identifications as optional quotients of the universal object.

How best to define the appropriate identifications in general is a matter of some controversy. GKP defined a somewhat complicated topology on $\bar{M} = \hat{\partial}(M) \cup \check{\partial}(M) \cup M$, then used an identification intended to result in a Hausdorff space. There are significant problems with this approach in some *outré* spacetimes, as pointed out by Budic and Sachs (1974) and Szabados (1989), both of whom recommended a different set of identifications. But what is of more concern is that the topology prescribed by GKP is not what might be expected in even the simplest of cases, for example, Minkowski space: $\overline{\mathbb{L}^n}$ needs no identifications among boundary points (no matter whose identification procedure is followed). The GKP topology on $\overline{\mathbb{L}^n}$, restricted to $\hat{\partial}(\mathbb{L}^n)$, is not that of a cone ($\mathbb{S}^{n-2} \times \mathbb{R}^1$ with a point added), as is the case for $\Im^+$ in the conformal embedding into $\mathbb{E}^n$; but, instead, each null line in $\hat{\partial}(\mathbb{L}^n)$ (not including $i^+$) is an open set, and $i^+$ has no neighborhood in $\hat{\partial}(\mathbb{L}^n)$ save for the entire boundary. This is a topology bearing no relation at all to that of any embedding.

### Future Causal Boundary

**Construction** An alternative approach, initiated by Harris (1998), is to forego the full causal boundary and concentrate only on $\hat{M}$ and $\check{M}$ separately. There is an advantage to this in that the process of future causal completion – that is to say, forming $\hat{M}$ from $M$ – can be made functorial in an appropriate category of "chronological sets": a set $X$ with a relation $\ll$ which is transitive and antireflexive such that it possesses a countable subset $S$ which is "chronologically dense," that is, for any $x, y \in X$, there is some $s \in S$ with $x \ll s \ll y$. Any strongly causal spacetime $M$ is a chronological set, as is $\hat{M}$. The entire construction of the future causal boundary works just as well for a chronological set. The role of a timelike curve in a chronological set is taken by a future chain: a sequence $c = \{x_n\}$ with $x_n \ll x_{n+1}$ for all $n$. For any future chain $c$, $I^-[c]$ is an IP, and any IP can be so expressed; but unlike in spacetimes, $I^-(x)$ may or may not be an IP for $x \in X$. Then, $\hat{X}$ is always future complete in the sense that for any future chain $c$ in $\hat{X}$, there is an element $\alpha \in \hat{X}$ with $I^-(\alpha) = I^-[c]$: for instance, if the chain $c$ lies in $X$ but there is no $x \in X$ with $I^-(x) = I^-[c]$, just let $\alpha = I^-[c]$, which is an element of $\hat{\partial}(X)$. This yields a functor of future completion from the category of chronological sets to the category of future-complete chronological sets, and the embedding $X \to \hat{X}$ is a universal object in the sense of the category theory; this implies that it is categorically unique and is the minimal future-completion process.

However, it is crucial to have more than the chronology relation operating in what is to be a boundary; topology of some sort is needed. This is accomplished by defining what might be called the future-chronological topology for any chronological set – including for $\hat{M}$ when $M$ is a strongly causal spacetime. This topology is defined by means of a limit-operator $\hat{L}$ on sequences: if $X$ is the chronological set, then for any sequence of points $\sigma = \{x_n\}$ in $X, \hat{L}(\sigma)$ denotes a subset of $X$ which is the set of

limits of $\sigma$. It is explicitly recognized that there may be more than one limit of a sequence, as the space may not be Hausdorff; no attempt is made to remove any non-Hausdorffness, as this is viewed as giving important information on how, possibly, two points in the future causal boundary represent very similar and yet not identical pieces of information about the causal structure at infinity. Once the limit operator is in place, the actual topology on $X$ is defined thus: a subset $A \subset X$ is said to be closed if and only if for any sequence $\sigma \subset A, \hat{L}(\sigma) \subset A$ (and open sets are complements of closed sets). This yields the elements of $\hat{L}(\sigma)$ as topological limits of $\sigma$.

The definition of $\hat{L}$ is simplest when $X$ has the property that $I^-(x)$ is an IP for any $x \in X$; as this is true for $X$ being either a spacetime $M$ or the future causal completion $\hat{M}$ of a spacetime, the discussion here is restricted to this situation. Let us also make the common assumption that $X$ is past-distinguishing, that is, $I^-(x) = I^-(y)$ implies $x = y$.

Let $\sigma = \{x_n\}$ be a sequence of points in a past-distinguishing chronological set $X$ in which the past of any point is an IP. Then $\hat{L}(\sigma)$ consists of those points $x$ for which (see Figures 6 and 7)

1. for all $y \in I^-(x)$, for $n$ sufficiently large, $y \ll x_n$, and
2. for any IP $P \supsetneq I^-(x)$, there is some $z \in P$ such that for $n$ sufficiently large, $z \not\ll x_n$.

Then the future-chronological topology on $X$ has these features:

1. It is a $T_1$ topology, that is, points are closed.
2. If $I^-(x) = I^-[c]$ for a future chain $c = \{x_n\}$, then $x$ is a topological limit of the sequence $\{x_n\}$.
3. If $X = M$, a strongly causal spacetime, then the future-chronological topology is precisely the manifold topology.
4. If $X = \hat{M}$, the future causal completion of a strongly causal spacetime $M$, then the induced topology on $M$ is the manifold topology, $\hat{\partial}(M)$ is a closed subset of $\hat{M}$, and $M$ is dense in $\hat{M}$. As per property (2), for any future-endless causal curve $c$ in $M$, the point $I^-[c]$ in $\hat{\partial}(M)$ is the topological endpoint of $c$ in $\hat{M}$.
5. If $X = \widehat{\mathbb{L}^n}$, then $X$ is homeomorphic to the conformal image of $\mathbb{L}^n$ in $\mathbb{E}^n$ together with $\Im^+$ and $i^+$; in particular, $\hat{\partial}(\mathbb{L}_n)$ has the topology of a cone.

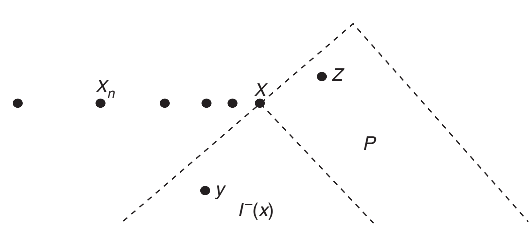

**Figure 6** $x \in \hat{L}(\{x_n\})$: for all $y \in I^-(x)$, eventually $y \ll x_n$, and for all IP $P \supsetneq I^-(x)$, there is some $z \in P$ such that eventually $z \not\ll x_n$.

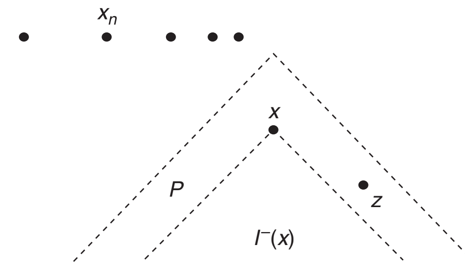

**Figure 7** $x \notin \hat{L}(\{x_n\})$: there is some IP $P \supsetneq I^-(x)$ such that for all $z \in P$, $z \ll x_n$ for infinitely many $n$.

**Examples** The future causal boundary with the future-chronological topology can be calculated with a fair degree of success. For instance, if $M$ is conformal to a simple product spacetime $Q \times \mathbb{L}^1$ ($Q$ a Riemannian manifold), then $\hat{\partial}(M)$ is much like $\hat{\partial}(\mathbb{L}^n)$ in that it consists of null or timelike lines factored over a particular boundary construction $\partial(Q)$ on $Q$, coming together at a single point $i^+$ (the IP which is all of $M$); if $Q$ is complete, then these are all null lines, and together they may be called $\Im^+$.

The elements of $\partial(Q)$ are defined in terms of the Lipschitz-1 functions on $Q$ known as Busemann functions: if $c : [\alpha, \omega) \to Q$ is any endless unit-speed curve (typically, $\omega = \infty$), then the Busemann function $b_c : Q \to \mathbb{R}$ is defined by $b_c(q) = \lim_{s \to \omega} (s - d(c(s), q))$, where $d$ is the distance function in $Q$; this function is either finite for all $q$ or infinite for all $q$. The set $B(Q)$ of finite Busemann functions has an $\mathbb{R}$-action defined by $a \cdot b_c = b_{a \cdot c}$, where $(a \cdot c)(s) = c(s + a)$. Then $\partial(Q) = B(Q)/\mathbb{R}$. For any $P \in \hat{\partial}(M)$, the boundary of $P$, as a subset of $Q \times \mathbb{L}^1 \cong Q \times \mathbb{R}$, is the graph of a Busemann function (the function is $b_c$ for $P$ generated by a null curve projecting to $c$); and a point $x = (q, t)$ in $M$ can be represented by $\partial(I^-(x))$, which is the graph of the function $t - d(-, q)$. Thus, one could use the function-space topology on $B(Q)$ to topologize $\hat{M}$; in that function-space topology $\hat{\partial}(M)$ is a cone on $\partial(Q)$, and $\hat{M}$, apart from $i^+$, is the topological product of $\mathbb{R}$ with $Q \cup \partial(Q)$. The future-chronological topology is sometimes different from the function-space topology, allowing more convergent sequences than the function-space topology does. When this happens, the result is non-Hausdorff, revealing pairs of points in $\hat{\partial}(M)$ which are more closely related to one another than the function-space

topology reveals; but it is still the case that $\hat{\partial}(M)$, apart from $i^+$, is fibered by $\mathbb{R}$ over $\partial(Q)$.

If $Q$ is a warped product $Q = (a, b) \times K$ for a compact manifold $K$ with metric $\mathrm{d}r^2 + \mathrm{e}^{\phi(r)}h$ with $h$ a metric on $K$, then one can calculate more precisely: if, for instance, $\phi$ has a minimum in the interior of $(a, b)$ and has suitable growth on either end, then $\partial(Q)$ represents two copies of $K$ (one for each end of $(a, b) \times K$), the future-chronological topology is the same as the function-space topology, and $\hat{M}$ (apart from $i^+$) is a simple product of $\mathbb{R}$ with $Q \cup \partial(Q)$: $\hat{\partial}(M)$ is precisely a null cone over two copies of $K$. This applies, for instance, to exterior Schwarzschild, where $K = \mathbb{S}^2$; the boundary at one end of exterior Schwarzschild is the usual $\Im^+$, and the boundary at the other end is the null cone $\{r = 2m\}$, where exterior attaches to interior Schwarzschild.

Calculations for the future-chronological topology become much easier when $\hat{\partial}(M)$ is purely spacelike, that is, no $P \in \hat{\partial}(M)$ is contained in the past of any other element of $\hat{M}$. For instance, if $M$ is conformal to a multiwarped product, $Q_1 \times \cdots \times Q_m \times (a, b)$ with metric $f_1(t)^2 h_1 + \cdots + f_m(t)^2 h_m - \mathrm{d}t^2$, where $h_i$ is a Riemannian metric on $Q_i$, then $\hat{\partial}(M)$ will be purely spacelike if all the Riemannian factors are complete and for each $i$, $\int_{b^-}^{b} 1/f_i(t)\,\mathrm{d}t < \infty$; in that case, $\hat{\partial}(M) \cong Q$, where $Q = Q_1 \times \cdots \times Q_m$ and $\hat{M} \cong Q \times (a, b)$. This applies, for instance, to interior Schwarzschild, where $Q_1 = \mathbb{R}^1$ and $Q_2 = \mathbb{S}^2$, yielding the topology of $\mathbb{R}^1 \times \mathbb{S}^2$ for the Schwarzschild singularity.

There is a categorical universality for spacelike boundaries and the future-chronological topology. This means that any other reasonable way of future-completing interior Schwarzschild must yield $\mathbb{R}^1 \times \mathbb{S}^2$ or a topological quotient of that for the singularity; and if the result is to be past-distinguishing, $\mathbb{R}^1 \times \mathbb{S}^2$ is the only possibility.

Of course, all this can be done in the time-dual fashion, using the past-chronological topology on $\check{M}$. It would be desirable to combine the future and past causal boundaries with a suitable topology as well as appropriate identifications. There has been some work in that direction.

### Causal Boundary: Revisited

Marolf and Ross (2003) have proposed an identification of TIPs and TIFs that relies on the equivalence relation defined by Szabados. For an IP $P$ and IF $F$, call $(P, F)$ a Szabados pair if $P \subset I^-(x)$ for all $x \in F$, $P$ is maximal among IPs for that property, and dually for $F$ with respect to $P$. For instance, for any $x \in M$, $(I^-(x), I^+(x))$ is a Szabados pair. The Marolf–Ross version of the causal boundary, $\bar{\partial}(M)$, consists of all Szabados pairs formed of TIPs and TIFs, plus any TIP or TIF that cannot be paired; this produces an appropriate set of identifications within $\hat{\partial}(M) \cup \check{\partial}(M)$. The chronology relation on $M$ is extended to $\bar{M} = \bar{\partial}(M) \cup M$ by treating each point $x$ in $M$ as the Szabados pair $(I^-(x), I^+(x))$ and each unpaired IP $P$ as $(P, \emptyset)$ and unpaired IF $F$ as $(\emptyset, F)$, and then defining $(P, F) \ll (P', F')$ whenever $F \cap P' \neq \emptyset$.

The resulting chronological set is not necessarily either past- or future-distinguishing, but it is (past and future)-distinguishing. The topology they propose places endpoints in $\bar{\partial}(M)$ for all causal curves which are endless in $M$, but there may be multiple future endpoints for a single future-endless curve. The topology need not be $\mathrm{T}_1$: points can fail to be closed. For a product spacetime $M = Q \times \mathbb{L}^1$, the Marolf–Ross topology on $\bar{M}$ is always the function-space topology.

As of this writing, there is active research by J L Flores to institute a Marolf–Ross type of identification of $\hat{\partial}(M)$ with $\check{\partial}(M)$ using a topology that partakes more of the future- and past-chronological topologies.

# Boundary Conformal Field Theory

**J Cardy**, Rudolf Peierls Centre for Theoretical Physics, Oxford, UK

Boundary conformal field theory (BCFT) is simply the study of conformal field theory (CFT) in domains with a boundary. It gains its significance [1] because, in some ways, it is mathematically simpler: the algebraic and geometric structures of CFT appear in a more straightforward manner; and [2] because it has important applications: in string theory in the physics of open strings and D-branes, and in condensed matter physics in boundary critical behavior and quantum impurity models.

This article, however, describes the basic ideas from the point of view of quantum field theory, without regard to particular applications or to any deeper mathematical formulations.

## Review of CFT

### Stress Tensor and Ward Identities

Two-dimensional CFTs are massless, local, relativistic renormalized quantum field theories. Usually they are considered in imaginary time, that is, on two-dimensional manifolds with Euclidean signature. In this article, the metric is also taken to be Euclidean, although the formulation of CFTs on general Riemann surfaces is also of great interest, especially for string theory. For the time being, the domain is the entire complex plane.

Heuristically, the correlation functions of such a field theory may be thought of as being given by the Euclidean path integral, that is, as expectation values of products of local densities with respect to a Gibbs measure $Z^{-1}\,e^{-S_E(\{\psi\})}[d\psi]$, where the $\{\psi(x)\}$ are some set of fundamental local fields, $S_E$ is the Euclidean action, and the normalization factor $Z$ is the partition function. Of course, such an object is not in general well defined, and this picture should be seen only as a guide to formulating the basic principles of CFT which can then be developed into a mathematically consistent theory.

In two dimensions, it is useful to use the so-called complex coordinates $z = x^1 + ix^2, \bar{z} = x^1 - ix^2$. In CFT, there are local densities $\phi_j(z, \bar{z})$, called primary fields, whose correlation functions transform covariantly under conformal mappings $z \to z' = f(z)$:

$$\langle \phi_1(z_1, \bar{z}_1)\phi_2(z_2, \bar{z}_2)\cdots\rangle = \prod_i f'(z_j)^{h_j}\bar{f}'(z_j)^{\bar{h}_j}\langle \phi_1(z'_1, \bar{z}'_1)\phi_2(z'_2, \bar{z}'_2)\cdots\rangle \qquad [1]$$

where $(h_j, \bar{h}_j)$ (usually real numbers, not complex conjugates of each other) are called the conformal weights of $\phi_j$. These local fields can in general be normalized so that their two-point functions have the form

$$\langle \phi_j(z_j, \bar{z}_j)\phi_k(z_k, \bar{z}_k)\rangle = \delta_{jk}/(z_j - z_k)^{2h_j}(\bar{z}_j - \bar{z}_k)^{2\bar{h}_j} \qquad [2]$$

They satisfy an algebra known as the operator product expansion (OPE)

$$\phi_i(z_1, \bar{z}_1)\cdot\phi_j(z_2, \bar{z}_2) = \sum_k c_{ijk}(z_1 - z_2)^{-h_i - h_j + h_k} \times (\bar{z}_1 - \bar{z}_2)^{-\bar{h}_i - \bar{h}_j + \bar{h}_k}\phi_k(z_1, \bar{z}_1) + \cdots \qquad [3]$$

which is supposed to be valid when inserted into higher-order correlation functions in the limit when $|z_1 - z_2|$ is much less than the separations of all the other points. The ellipses denote the contributions of other nonprimary scaling fields to be described below. The structure constants $c_{ijk}$, along with the conformal weights, characterize the particular CFT.

An essential role is played by the energy–momentum tensor, or, in Euclidean field theory language, the stress tensor $T^{\mu\nu}$. Heuristically, it is defined as the response of the partition function to a local change in the metric:

$$T^{\mu\nu}(x) = -(2\pi)\,\delta \ln Z/\delta g_{\mu\nu}(x) \qquad [4]$$

(the factor of $2\pi$ is included so that similar factors disappear in later equations).

The symmetry of the theory under translations and rotations implies that $T^{\mu\nu}$ is conserved, $\partial_\mu T^{\mu\nu} = 0$, and symmetric. Scale invariance implies that it is also traceless $\Theta \equiv T^\mu_\mu = 0$. It should be noted that the vanishing of the trace of the stress tensor for a scale invariant classical field theory does

not usually survive when quantum corrections are taken into account: indeed, $\Theta \propto \beta(g)$, the renormalization group (RG) beta-function. A quantum field theory is thus only a CFT when this vanishes, that is, at an RG fixed point. In complex coordinates, the components $T_{z\bar{z}} = T_{\bar{z}z} = 4\Theta$ vanish, while the conservation equations read

$$\partial_{\bar{z}} T_{zz} = \partial_z T_{\bar{z}\bar{z}} = 0 \qquad [5]$$

Thus, correlators of $T(z) \equiv T_{zz}$ are locally analytic (in fact, globally meromorphic) functions of $z$, while those of $\bar{T}(\bar{z}) \equiv T_{\bar{z}\bar{z}}$ are antianalytic. It is this property of analyticity which makes CFTs tractable in two dimensions.

Since an infinitesimal conformal transformation $z \to z + \alpha(z)$ induces a change in the metric, its effect on a correlation function of primary fields, given by [1], may also be expressed through an appropriate integral involving an insertion of the stress tensor. This leads to the conformal Ward identity:

$$\int_C \langle T(z) \prod_j \phi_j(z_j, \bar{z}_j) \rangle \, \alpha(z) \, dz = \sum_j \left(h_j \alpha'(z_j) + \alpha(z_j)(\partial/\partial z_j)\right) \left\langle \prod_j \phi_j(z_j, \bar{z}_j) \right\rangle \qquad [6]$$

where $C$ is a contour encircling all the points $\{z_j\}$. (A similar equation holds for the insertion of $\bar{T}$.) Using Cauchy's theorem, this determines the first few terms in the OPE of $T$ with any primary density:

$$T(z) \cdot \phi_j(z_j, \bar{z}_j) = \frac{h_j}{(z - z_j)^2} \phi(z_j, \bar{z}_j) + \frac{1}{z - z_j} \partial_{z_j} \phi(z_j, \bar{z}_j) + O(1) \qquad [7]$$

The other, regular, terms in the OPE generate new scaling fields, which are not in general primary, called descendants. One way of defining a density to be primary is by the condition that the most singular term in its OPE with $T$ is a double pole.

The OPE of $T$ with itself has the form

$$T(z) \cdot T(z_1) = \frac{c/2}{(z - z_1)^4} + \frac{2}{(z - z_1)^2} T(z_1) + \cdots \qquad [8]$$

The first term is present because $\langle T(z) T(z_1) \rangle$ is nonvanishing, and must take the form shown, with $c$ being some number (which cannot be scaled to unity, since the normalization of $T$ is fixed by its definition) which is a property of the CFT. It is known as the conformal anomaly number or the central charge. This term implies that $T$ is not itself primary. In fact, under a finite conformal transformation $z \to z' = f(z)$,

$$T(z) \to f'(z)^2 T(z') + \frac{c}{12} \{z', z\} \qquad [9]$$

where $\{z', z\} = (f'''f' - \frac{3}{2} f''2)/f'^2$ is the Schwartzian derivative.

### Virasoro Algebra

As with any quantum field theory, the local fields can be realized as linear operators acting on a Hilbert space. In ordinary QFT, it is customary to quantize on a constant-time hypersurface. The generator of infinitesimal time translations is the Hamiltonian $\hat{H}$, which itself is independent of which time slice is chosen, because of time translational symmetry. It is also given by the integral over the hypersurface of the time–time component of the stress tensor. In CFT, because of scale invariance, one may instead quantize on fixed circle of a given radius. The analog of the Hamiltonian is the dilatation operator $\hat{D}$, which generates scale transformations. Unlike $\hat{H}$, the spectrum of $\hat{D}$ is usually discrete, even in an infinite system. It may also be expressed as an integral over the radial component of the stress tensor:

$$\begin{aligned} \hat{D} &= \frac{1}{2\pi} \int_0^{2\pi} r \, \hat{T}_{rr} \, r d\theta \\ &= \frac{1}{2\pi i} \int_C z \hat{T}(z) dz - \frac{1}{2\pi i} \int_C \bar{z} \hat{\bar{T}}(\bar{z}) d\bar{z} \\ &\equiv \hat{L}_0 + \hat{\bar{L}}_0 \end{aligned} \qquad [10]$$

where, because of analyticity, $C$ can be any contour encircling the origin.

This suggests that one define other operators

$$\hat{L}_n \equiv \frac{1}{2\pi} \int_C z^{n+1} \hat{T}(z) dz \qquad [11]$$

and similarly the $\hat{\bar{L}}_n$. From the OPE [8] then follows the Virasoro algebra $\mathcal{V}$:

$$[\hat{L}_n, \hat{L}_m] = (n - m) \hat{L}_{n+m} + \frac{c}{12} n(n^2 - 1) \delta_{n+m,0} \qquad [12]$$

with an isomorphic algebra $\bar{\mathcal{V}}$ generated by the $\hat{\bar{L}}_n$.

In radial quantization, there is a vacuum state $|0\rangle$. Acting on this with the operator corresponding to a scaling field gives a state $|\phi_j\rangle \equiv \hat{\phi}_j(0,0)|0\rangle$ which is an eigenstate of $\hat{D}$: in fact,

$$\hat{L}_0 |\phi_j\rangle = h_j |\phi_j\rangle, \quad \hat{\bar{L}}_0 |\phi_j\rangle = \bar{h}_j |\phi_j\rangle \qquad [13]$$

From the OPE [7], one sees that $|L_n \phi_j\rangle \propto \hat{L}_n |\phi_j\rangle$, and, if $\phi_j$ is primary, $\hat{L}_n |\phi_j\rangle = 0$ for all $n \geq 1$.

The states corresponding to a given primary field, and those generated by acting on these with all the $\hat{L}_n$ with $n < 0$ an arbitrary number of times, form a

highest-weight representation of $\mathcal{V}$. However, this is not necessarily irreducible. There may be null vectors, which are linear combinations of states at a given level which are themselves annihilated by all the $\hat{L}_n$ with $n > 0$. They exist whenever $h$ takes a value from the Kac table:

$$h = h_{r,s} = \frac{(r(m+1) - sm)^2 - 1}{4m(m+1)} \qquad [14]$$

with the central charge parametrized as $c = 1 - 6/(m(m+1))$, and $r$, $s$ are non-negative integers. These null states should be projected out, giving an irreducible representation $\mathcal{V}_h$.

The full Hilbert space of the CFT is then

$$\mathcal{H} = \bigoplus_{h,\bar{h}} n_{h,\bar{h}} \mathcal{V}_h \otimes \bar{\mathcal{V}}_{\bar{h}} \qquad [15]$$

where the non-negative integers $n_{h,\bar{h}}$ specify how many distinct primary fields of weights $(h, \bar{h})$ there are in the CFT.

The consistency of the OPE [3] with the existence of null vectors leads to the fusion algebra of the CFT. This applies separately to the holomorphic and antiholomorphic sectors, and determines how many copies of $\mathcal{V}_c$ occur in the fusion of $\mathcal{V}_a$ and $\mathcal{V}_b$:

$$\mathcal{V}_a \odot \mathcal{V}_b = \sum_c N_{ab}^c \mathcal{V}_c \qquad [16]$$

where the $N_{ab}^c$ are non-negative integers.

A particularly important subset of all CFTs consists of the minimal models. These have rational central charge $c = 1 - 6(p-q)^2/pq$, in which case the fusion algebra closes with a finite number of possible values $1 \leq r \leq q, 1 \leq s \leq p$ in the Kac formula [14]. For these models, the fusion algebra takes the form

$$\mathcal{V}_{r_1,s_1} \odot \mathcal{V}_{r_2,s_2} = \sum_{r=|r_1-r_2|}^{r_1+r_2-1\,\prime} \sum_{s=|s_1-s_2|}^{s_1+s_2-1\,\prime} \mathcal{V}_{r,s} \qquad [17]$$

where the prime on the sums indicates that they are to be restricted to the allowed intervals of $r$ and $s$.

There is an important theorem which states that the only unitary CFTs with $c < 1$ are the minimal models with $p/q = (m+1)/m$, where $m$ is an integer $\geq 3$.

## Modular Invariance

The fusion algebra limits which values of $(h, \bar{h})$ might appear in a consistent CFT, but not which ones actually occur, that is, the values of the $n_{h,\bar{h}}$. This is answered by the requirement of modular invariance on the torus. First consider the theory on an infinitely long cylinder, of unit circumference. This is related to the (punctured) plane by the conformal mapping $z \to (1/2\pi) \ln z \equiv t + ix$. The result is a QFT on the circle $0 \leq x < 1$, in imaginary time $t$. The generator of infinitesimal time translations is related to that for dilatations in the plane:

$$\hat{H} = 2\pi\hat{D} - \frac{\pi c}{6} = 2\pi(\hat{L}_0 + \hat{\bar{L}}_0) - \frac{\pi c}{6} \qquad [18]$$

where the last term comes from the Schwartzian derivative in [9]. Similarly, the generator of translations in $x$, the total momentum operator, is $\hat{P} = 2\pi(\hat{L}_0 - \hat{\bar{L}}_0)$.

A general torus is, up to a scale transformation, a parallelogram with vertices $(0, 1, \tau, 1+\tau)$ in the complex plane, with the opposite edges identified. We can make this by taking a cylinder of unit circumference and length Im, $\tau$, twisting the ends by a relative amount Re $\tau$, and sewing them together. This means that the partition function of the CFT on the torus can be written as

$$Z(\tau, \bar{\tau}) = \mathrm{tr}\, e^{-(\mathrm{Im}\,\tau)\hat{H} + i(\mathrm{Im}\,\tau)\hat{P}} = \mathrm{tr}\, q^{\hat{L}_0 - c/24} \bar{q}^{\hat{\bar{L}}_0 - c/24} \qquad [19]$$

using the above expressions for $\hat{H}$ and $\hat{P}$ and introducing $q \equiv e^{2\pi i \tau}$.

Through the decomposition [15] of $\mathcal{H}$, the trace sum can be written as

$$Z(\tau, \bar{\tau}) = \sum_{h,\bar{h}} n_{h,\bar{h}} \chi_h(q)\, \chi_{\bar{h}}(q) \qquad [20]$$

where

$$\chi_h(q) \equiv \mathrm{tr}_{\mathcal{V}_h} q^{\hat{L}_0 - c/24} = \sum_N d_h(N) q^{h-(c/24)+N} \qquad [21]$$

is the character of the representation of highest weight $h$, which counts the degeneracy $d_h(N)$ at level $N$. It is purely an algebraic property of the Virasoro algebra, and its explicit form is known in many cases.

All of this would be less interesting were it not for the observation that the parametrization of the torus through $\tau$ is not unique. In fact, the transformations $S : \tau \to -1/\tau$ and $T : \tau \to \tau + 1$ give the same torus (see Figure 1). Together, these

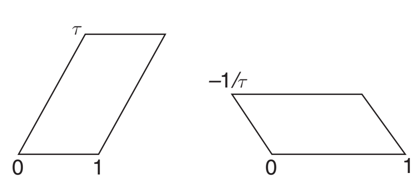

**Figure 1** Two equivalent parametrizations of the same torus.

operations generate the modular group SL(2, Z), and the partition function $Z(\tau, \bar{\tau})$ should be invariant under them. $T$-invariance is simply implemented by requiring that $h - \bar{h}$ is an integer, but the $S$-invariance of the right-hand side of [20] places highly nontrivial constraints on the $n_{h,\bar{h}}$. That this can be satisfied at all relies on the remarkable property of the characters that they transform linearly under $S$:

$$\chi_h(\mathrm{e}^{-2\pi\mathrm{i}/\tau}) = \sum_{h'} S_h^{h'} \chi_{h'}(\mathrm{e}^{2\pi\mathrm{i}\tau}) \qquad [22]$$

This follows from applying the Poisson sum formula to the explicit expressions for the characters, which are related to Jacobi theta-functions. In many cases (e.g., the minimal models) this representation is finite dimensional, and the matrix $S$ is symmetric and orthogonal. This means that one can immediately obtain a modular invariant partition function by forming the diagonal sum

$$Z = \sum_h \chi_h(q)\chi_h(\bar{q}) \qquad [23]$$

so that $n_{h,\bar{h}} = \delta_{h\bar{h}}$. However, because of various symmetries of the characters, other modular invariants are possible: for the minimal models (and some others) these have been classified. Because of an analogy of the results with the classification of semisimple Lie algebras, the diagonal invariants are called the A-series.

## Boundary CFT

In any field theory in a domain with a boundary, one needs to consider how to impose a set of consistent boundary conditions. Since CFT is formulated independently of a particular set of fundamental fields and a Lagrangian, this must be done in a more general manner. A natural requirement is that the off-diagonal component $T_{\parallel\perp}$ of the stress tensor parallel/perpendicular to the boundary should vanish. This is called the conformal boundary condition. If the boundary is parallel to the time axis, it implies that there is no momentum flow across the boundary. Moreover, it can be argued that, under the RG, any uniform boundary condition will flow into a conformally invariant one. For a given bulk CFT, however, there may be many possible distinct such boundary conditions, and it is one task of BCFT to classify these.

To begin with, take the domain to be the upper-half plane, so that the boundary is the real axis. The conformal boundary condition then implies that $T(z) = \bar{T}(\bar{z})$ when $z$ is on the real axis. This has the immediate consequence that correlators of $\bar{T}$ are those of $T$, analytically continued into the lower-half plane. The conformal Ward identity, cf. [7], now reads

$$\left\langle T(z) \prod_j \phi_j(z_j, \bar{z}_j) \right\rangle = \sum_j \left( \frac{h_j}{(z - z_j)^2} + \frac{1}{z - z_j}\partial_{z_j} + \frac{\bar{h}_j}{(\bar{z} - \bar{z}_j)^2} + \frac{1}{\bar{z} - \bar{z}_j}\partial_{\bar{z}_j} \right) \left\langle \prod_j \phi_j(z_j, \bar{z}_j) \right\rangle \qquad [24]$$

In radial quantization, in order that the Hilbert spaces defined on different hypersurfaces be equivalent, one must choose semicircles centered on some point on the boundary, conventionally the origin. The dilatation operator is now

$$\hat{D} = \frac{1}{2\pi\mathrm{i}} \int_S z\hat{T}(z)\mathrm{d}z - \frac{1}{2\pi\mathrm{i}} \int_S \bar{z}\hat{\bar{T}}(\bar{z})\,\mathrm{d}\bar{z} \qquad [25]$$

where $S$ is a semicircle. Using the conformal boundary condition, this can also be written as

$$\hat{D} = \hat{L}_0 = \frac{1}{2\pi\mathrm{i}} \int_C z\hat{T}(z)\,\mathrm{d}z \qquad [26]$$

where $C$ is a complete circle around the origin. As before, one may similarly define the $\hat{L}_n$, and they satisfy a Virasoro algebra.

Note that there is now only one Virasoro algebra. This is related to the fact that conformal mappings which preserve the real axis correspond to real analytic functions. The eigenstates of $\hat{L}_0$ correspond to boundary operators $\hat{\phi}_j(0)$ acting on the vacuum state $|0\rangle$. It is well known that in a renormalizable QFT operators at the boundary require a different renormalization from those in the bulk, and this will in general lead to a different set of conformal weights. It is one of the tasks of BCFT to determine these, for a given allowed boundary condition.

However, there is one feature unique to boundary CFT in two dimensions. Radial quantization also makes sense, leading to the same form [26] for the dilation operator, if the boundary conditions on the negative and positive real axes are different. As far as the structure of BCFT goes, correlation functions with this mixed boundary condition behave as though a local scaling field were inserted at the origin. This has led to the term "boundary condition changing (bcc) operator," but it must be stressed that these are not local operators in the conventional sense.

## The Annulus Partition Function

Just as consideration of the partition function on the torus illuminates the bulk operator content $n_{h,\bar{h}}$, it

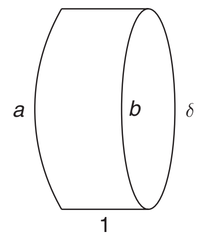

**Figure 2** The annulus, with boundary conditions $a$ and $b$ on either boundary.

turns out that consistency on the annulus helps classify both the allowed boundary conditions, and the boundary operator content. To this end, consider a CFT in an annulus formed of a rectangle of unit width and height $\delta$, with the top and bottom edges identified (see Figure 2). The boundary conditions on the left and right edges, labeled by $a, b, \ldots$, may be different. The partition function with boundary conditions $a$ and $b$ on either edge is denoted by $Z_{ab}(\delta)$.

One way to compute this is by first considering the CFT on an infinitely long strip of unit width. This is conformally related to the upper-half plane (with an insertion of bcc operators at 0 and $\infty$ if $a \neq b$) by the mapping $z \to (1/\pi)\ln z$. The generator of infinitesimal translations along the strip is

$$\hat{H}_{ab} = \pi\hat{D} - \pi c/24 = \pi\hat{L}_0 - \pi c/24 \qquad [27]$$

Thus, for the annulus,

$$Z_{ab}(\delta) = \operatorname{tr} e^{-\delta \hat{H}_{ab}} = \operatorname{tr} q^{\hat{L}_0 - \pi c/24} \qquad [28]$$

with $q \equiv e^{-\pi\delta}$. As before, this can be decomposed into characters:

$$Z_{ab}(\delta) = \sum_h n_h^{ab} \chi_h(q) \qquad [29]$$

but note that now the expression is linear. The nonnegative integers $n_{ab}^h$ give the operator content with the boundary conditions $(ab)$: the lowest value of $h$ with $n_{ab}^h > 0$ gives the conformal weight of the bcc operator, and the others give conformal weights of the other allowed primary fields which may also sit at this point.

On the other hand, the annulus partition function may be viewed, up to an overall rescaling, as the path integral for a CFT on a circle of unit circumference, being propagated for (imaginary) time $\delta^{-1}$. From this point of view, the partition function is no longer a trace, but rather the matrix element of $e^{-\hat{H}/\delta}$ between boundary states:

$$Z_{ab}(\delta) = \langle a | e^{-\hat{H}/\delta} | b \rangle \qquad [30]$$

Note that $\hat{H}$ is the same Hamiltonian that appears in [18], and the boundary states lie in $\mathcal{H}$, [15].

How are these boundary states to be characterized? Using the transformation law [9] the conformal boundary condition applied to the circle implies that $L_n = \bar{L}_{-n}$. This means that any boundary state $|B\rangle$ lies in the subspace satisfying

$$\hat{L}_n |B\rangle = \hat{\bar{L}}_{-n} |B\rangle \qquad [31]$$

Moreover, because of the decomposition [15] of $\mathcal{H}$, $|B\rangle$ is also some linear superposition of states from $\mathcal{V}_h \otimes \bar{\mathcal{V}}_{\bar{h}}$. This condition can therefore be applied in each subspace. Taking $n = 0$ in [31] constrains $\bar{h} = h$. For simplicity, consider only the diagonal CFTs with $n_{h,\bar{h}} = \delta_{h,\bar{h}}$. It can then be shown that the solution of [31] is unique and has the following form. The subspace at level $N$ of $\mathcal{V}_h$ has dimension $d_h(N)$. Denote an orthonormal basis by $|h, N; j\rangle$, with $1 \le j \le d_h(N)$, and the same basis for $\bar{\mathcal{V}}_h$ by $\overline{|h, N; j\rangle}$. The solution to [31] in this subspace is then

$$|h\rangle\rangle \equiv \sum_{N=0}^{\infty} \sum_{j=1}^{d_h(N)} |h, N; j\rangle \otimes \overline{|h, N; j\rangle} \qquad [32]$$

These are called Ishibashi states. Matrix elements of the translation operator along the cylinder between them are simple:

$$\begin{aligned} &\langle\langle h' | e^{-\hat{H}/\delta} | h \rangle\rangle \\ &= \sum_{N'=0}^{\infty} \sum_{j'=1}^{d_{h'}(N')} \sum_{N=0}^{\infty} \sum_{j=1}^{d_h(N)} \langle h', N'; j'| \\ &\quad \otimes \overline{\langle h', N'; j'|} e^{-(2\pi/\delta)(\hat{L}_0 + \hat{\bar{L}}_0 - c/12)} \end{aligned} \qquad [33]$$

$$\begin{aligned} &|h, N; j\rangle \otimes \overline{|h, N; j\rangle} \\ &= \delta_{h'h} \sum_{N=0}^{\infty} \sum_{j=1}^{d_h(N)} e^{-(4\pi/\delta)(h + N - (c/24))} \end{aligned} \qquad [34]$$

$$= \delta_{h'h} \chi_h(e^{-4\pi/\delta}) \qquad [35]$$

Note that the characters which appear are related to those in [29] by the modular transformation $S$.

The physical boundary states satisfying [29], sometimes called the Cardy states, are linear combinations of the Ishibashi states:

$$|a\rangle = \sum_h \langle\langle h | a \rangle |h\rangle\rangle \qquad [36]$$

Equating the two different expressions [29] and [30] for $Z_{ab}$, and using the modular transformation law

[22] and the linear independence of the characters gives the (equivalent) conditions:

$$n_{ab}^h = \sum_{h'} S_{h'}^h \langle a|h'\rangle\rangle\langle\langle h'|b\rangle \qquad [37]$$

$$\langle a|h'\rangle\rangle\langle\langle h'|b\rangle = \sum_h S_h^{h'} n_{ab}^h \qquad [38]$$

These are called the Cardy conditions. The requirements that the right-hand side of [37] should give a non-negative integer, and that the right-hand side of [38] should factorize in $a$ and $b$, give highly nontrivial constraints on the allowed boundary states and their operator content.

For the diagonal CFTs considered here (and for the nondiagonal minimal models) a complete solution is possible. It can be shown that the elements $S_0^h$ of $S$ are all non-negative, so one may choose $\langle\langle h|\tilde{0}\rangle = (S_0^h)^{1/2}$. This defines a boundary state

$$|\tilde{0}\rangle \equiv \sum_h \left(S_0^h\right)^{1/2} |h\rangle\rangle \qquad [39]$$

and a corresponding boundary condition such that $n_{00}^h = \delta_{h0}$. Then, for each $h' \neq 0$, one may define a boundary state

$$\langle\langle h|\tilde{h'}\rangle \equiv S_{h'}^h / (S_0^h)^{1/2} \qquad [40]$$

From [37], this gives $n_{h'0}^h = \delta_{h'h}$. For each allowed $h'$ in the torus partition function, there is therefore a boundary state $|\tilde{h'}\rangle$ satisfying the Cardy conditions. However, there is a further requirement:

$$n_{h'h''}^h = \frac{S_{h'}^h S_{h''}^h}{S_0^h} \qquad [41]$$

should be a non-negative integer. Remarkably, this combination of elements of $S$ occurs in the Verlinde formula, which follows from considering consistency of the CFT on the torus. This states that the right-hand side of [41] is equal to the fusion algebra coefficient $N_{h'h''}^h$. Since these are non-negative integers, the consistency of the above ansatz for the boundary states is consistent.

We conclude that, at least for the diagonal models, there is a bijection between the allowed primary fields in the bulk CFT and the allowed conformally invariant boundary conditions. For the minimal models, with a finite number of such primary fields, this correspondence has been followed through explicitly.

**Example** The simplest example is the diagonal $c = \frac{1}{2}$ unitary CFT corresponding to $m = 3$. The allowed values of the conformal weights are $h = 0, \frac{1}{2}, \frac{1}{16}$, and

$$S = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} & \frac{1}{\sqrt{2}} \\ \frac{1}{2} & \frac{1}{2} & -\frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} & 0 \end{pmatrix} \qquad [42]$$

from which one finds the allowed boundary states

$$|\tilde{0}\rangle = \frac{1}{\sqrt{2}}|0\rangle\rangle + \frac{1}{\sqrt{2}}\left|\frac{1}{2}\right\rangle\right\rangle + \frac{1}{2^{1/4}}\left|\frac{1}{16}\right\rangle\right\rangle \qquad [43]$$

$$\left|\tilde{\frac{1}{2}}\right\rangle = \frac{1}{\sqrt{2}}|0\rangle\rangle + \frac{1}{\sqrt{2}}\left|\frac{1}{2}\right\rangle\right\rangle - \frac{1}{2^{1/4}}\left|\frac{1}{16}\right\rangle\right\rangle \qquad [44]$$

$$\left|\tilde{\frac{1}{16}}\right\rangle = |0\rangle\rangle - \left|\frac{1}{2}\right\rangle\right\rangle \qquad [45]$$

The nontrivial part of the fusion algebra of this CFT is

$$\mathcal{V}_{\frac{1}{16}} \odot \mathcal{V}_{\frac{1}{16}} = \mathcal{V}_0 + \mathcal{V}_{\frac{1}{2}} \qquad [46]$$

$$\mathcal{V}_{\frac{1}{16}} \odot \mathcal{V}_{\frac{1}{2}} = \mathcal{V}_{\frac{1}{16}} \qquad [47]$$

$$\mathcal{V}_{\frac{1}{2}} \odot \mathcal{V}_{\frac{1}{2}} = \mathcal{V}_0 \qquad [48]$$

from which can be read off the boundary operator content

$$n_{\tilde{h}}^h = 1 \quad n_{\tilde{\frac{1}{16}}\tilde{\frac{1}{16}}}^0 = n_{\tilde{\frac{1}{16}}\tilde{\frac{1}{16}}}^{\frac{1}{2}} = n_{\tilde{\frac{1}{16}}\tilde{\frac{1}{16}}}^{\frac{1}{2}} = n_{\tilde{\frac{1}{2}}\tilde{\frac{1}{16}}}^{\frac{1}{16}} = 1 \qquad [49]$$

The $c = \frac{1}{2}$ CFT is known to describe the continuum limit of the critical Ising model, in which spins $s = \pm 1$ are localized on the sites of a regular lattice. The above boundary conditions may be interpreted as the continuum limit of the lattice boundary conditions $s = 1$, free and $s = -1$, respectively. Note there is a symmetry of the fusion rules which means that one could equally well have inverted the ordering of this correspondence.

## Other Topics

### Boundary Entropy

The partition function on annulus of length $L$ and circumference $\beta$ can be thought of as the quantum statistical mechanics partition function for a one-dimensional QFT in an interval of length $L$, at temperature $\beta^{-1}$. It is interesting to consider this in the thermodynamic limit when $\delta = L/\beta$ is large. In that case, only the ground state of $\hat{H}$ contributes in [30], giving

$$Z_{ab}(L, \beta) \sim \langle a|0\rangle\langle 0|b\rangle e^{\pi cL/6\beta} \qquad [50]$$

from which the free energy $F_{ab} = -\beta^{-1} \ln Z_{ab}$ and the entropy $\mathcal{S}_{ab} = -\beta^2(\partial F_{ab}/\partial\beta)$ can be obtained. The result is

$$\mathcal{S}_{ab} = (\pi c/3\beta)L + s_a + s_b + o(1) \qquad [51]$$

where the first term is the usual extensive contribution. The other two pieces $s_a \equiv \ln(\langle a|0\rangle)$ and $s_b \equiv \ln(\langle b|0\rangle)$ may be identified as the boundary entropy associated with the corresponding boundary states. A similar definition may be made in massive QFTs. It is an unproven but well-verified conjecture that the boundary entropy is a nonincreasing function along boundary RG flows, and is stationary only for conformal boundary states.

### Bulk–Boundary OPE

The boundary Ward identity [24] has the implication that, from the point of view of the dependence of its correlators on $z_j$ and $\bar{z}_j$, a primary field $\phi_j(z_j, \bar{z}_j)$ may be thought of as the product of two local fields which are holomorphic functions of $z_j$ and $\bar{z}_j$, respectively. These will satisfy OPEs as $|z_j - \bar{z}_j| \to 0$, with the appearance of primary fields on the right-hand side being governed by the fusion rules. These fields are localized on the real axis: they are the boundary operators. There is therefore a kind of bulk–boundary OPE:

$$\phi_j(z_j, \bar{z}_j) = \sum_k d_{jk}(\mathrm{Im}\, z_j)^{-h_j - \bar{h}_j + h_k} \phi_k^b(\mathrm{Re}\, z_j) \qquad [52]$$

where the sum on the right-hand side is, in principle, over all the boundary fields consistent with the boundary condition, and the coefficients $d_{jk}$ are analogous to the OPE coefficients in the bulk. As before, they are nonvanishing only if allowed by the fusion algebra: a boundary field of conformal weight $h_k$ is allowed only if $N^{h_k}_{h_j \bar{h}_j} > 0$.

For example, in the $c = \frac{1}{2}$ CFT, the bulk operator with $h = \bar{h} = \frac{1}{16}$ goes over into the boundary operator with $h = 0$, or that with $h = \frac{1}{2}$, depending on the boundary condition. The bulk operator with $h = \bar{h} = \frac{1}{2}$, however, can only go over into the identity boundary operator with $h = 0$ (or a descendent thereof.)

The fusion rules also apply to the boundary operators themselves. The consistency of these with bulk–boundary and bulk–bulk fusion rules, as well as the modular properties of partition functions, was examined by Lewellen.

### Extended Algebras

CFTs may contain other conserved currents apart from the stress tensor, which generate algebras (Kac–Moody, superconformal, W-algebras) which extend the Virasoro algebra. In BCFT, in addition to the conformal boundary condition, it is possible (but not necessary) to impose further boundary conditions relating the holomorphic and antiholomorphic parts of the other currents on the boundary. It is believed that all rational CFTs can be obtained from Kac–Moody algebras via the coset construction. The classification of boundary conditions from this point of view is fruitful and also important for applications, but is beyond the scope of this article.

### Stochastic Loewner Evolution

In recent years, there has emerged a deep connection between BCFT and conformally invariant measures on curves in the plane which start at a boundary of a domain. These arise naturally in the continuum limit of certain statistical mechanics models. The measure is constructed dynamically as the curve is extended, using a sequence of random conformal mappings called stochastic Loewner evolution (SLE). In CFT, the point where the curve begins can be viewed as the insertion of a boundary operator. The requirement that certain quantities should be conserved in mean under the stochastic process is then equivalent to this operator having a null state at level two. Many of the standard results of CFT correspond to an equivalent property of SLE.

# Boundary Control Method and Inverse Problems of Wave Propagation

**M I Belishev**, Petersburg Department of Steklov Institute of Mathematics, St. Petersburg, Russia

## Introduction

Inverse problems are generally positioned as the problems of determination of a system (its structure, parameters, etc.) from its "input → output" correspondence.

The boundary-value inverse problems deal with systems which describe processes (wave, heat, electromagnetic ones, etc.) occurring in media occupying a spatial domain. The process is initiated by a boundary source (input) and is described by a solution of a certain partial differential equation in the domain. Certain additional information about the solution, which can be extracted from measurements on the boundary, plays the role of the output. The objective is to determine the parameters of the medium – in particular, the coefficients in the equation – from this information.

The boundary control (BC) method (Belishev 1986) is an approach to the boundary-value inverse problems based on their links with the control theory and system theory. The present article is a version of the BC method which solves the problem of reconstruction of a Riemannian manifold from its boundary spectral or dynamical data.

## Forward Problems

### Manifold

Let $(\Omega, d)$ be a smooth compact Riemannian manifold with the boundary $\Gamma$, $\dim \Omega \geq 2$; $d$ is the distance determined by the metric tensor $g$. For $A \subset \Omega$ denote

$$\langle A \rangle^r := \{x \in \Omega \,|\, d(x, A) \leq r\}, \quad r \geq 0$$

the hypersurfaces $\Gamma^T := \{x \in \Omega \,|\, d(x, \Gamma) = T\}$, $T > 0$ are equidistant to $\Gamma$. In terms of the dynamics of the system, the value

$$T_* := \min\{T > 0 \,|\, \langle \Gamma \rangle^T = \Omega\} = \max_{\Omega} d(\cdot\,, \Gamma)$$

means the time needed for waves, moving from $\Gamma$ with the unit speed, to fill $\Omega$.

A point $x \in \Omega$ is said to belong to the set $c_0 \subset \Omega$ if $x$ is connected with $\Gamma$ via more than one shortest geodesic. The set $c := \bar{c}_0$ is called the separation set (cut locus) of $\Omega$ with respect to $\Gamma$. It is a closed set of zero volume. Let $\tau_*(\gamma)$ be the length of the geodesic emanating from $\gamma \in \Gamma$ orthogonally to $\Gamma$ and connecting $\gamma$ with $c$. The function $\tau_*(\cdot)$ is continuous on $\Gamma$.

For $x \in \Omega \setminus c$ the pair $(\gamma, \tau)$, such that $\tau = d(x, \Gamma) = d(x, \gamma)$, constitutes the semigeodesic coordinates of $x$. The set of these coordinates

$$\Theta := \{(\gamma, \tau) \,|\, \gamma \in \Gamma, 0 \leq \tau < \tau_*(\gamma)\} \subset \Gamma \times [0, T_*]$$

is called the pattern of $\Omega$. Pictorially, to get the pattern, one needs to slit $\Omega$ along $c$ and then pull it on the cylinder $\Gamma \times [0, T_*]$. The part $\Theta^T := \Theta \cap (\Gamma \times [0, T])$ of the pattern consists of the semigeodesic coordinates of the points $x \in \langle \Gamma \rangle^T \setminus c$ (**Figure 1**).

### Dynamical System

Propagation of waves in the manifold is described by a dynamical system $\alpha^T$ of the form

$$u_{tt} - \Delta_g u = h \qquad \text{in } \Omega \times (0, T) \qquad [1]$$

$$u\,|_{t=0} = u_t\,|_{t=0} = 0 \quad \text{in } \Omega \qquad [2]$$

$$u = f \qquad \text{on } \Gamma \times [0, T] \qquad [3]$$

where $\Delta_g$ is the Beltrami–Laplace operator, $0 < T \leq \infty$, $f$ and $h$ are the boundary and volume sources (controls), $u = u^{f,h}(x,t)$ is the solution (wave).

Set $\mathcal{H} := L_2(\Omega)$; the spaces of the controls are

$$\mathcal{F}^T := L_2(\Gamma \times [0, T]), \quad \mathcal{G}^T := L_2([0, T]; \mathcal{H})$$

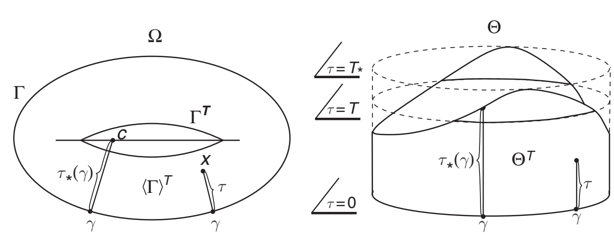

**Figure 1** Manifold and pattern. (Data from Belishev (1997).)

The "input $\mapsto$ state" map of the system $\alpha^T$ is realized by the control operator $W^T$:

$$\mathcal{F}^T \times \mathcal{G}^T \to \mathcal{H}, \quad W^T\{f, h\} := u^{f,h}(\cdot, T)$$

and its parts

$$W^T_{\mathrm{bd}} : \mathcal{F}^T \to \mathcal{H}, \quad W^T_{\mathrm{vol}} : \mathcal{G}^T \to \mathcal{H}$$
$$W^T_{\mathrm{bd}} f := u^{f,0}(\cdot, T), W^T_{\mathrm{vol}} h := u^{0,h}(\cdot, T)$$

In the case $f = 0$ the evolution of the system is governed by the operator $L := -\Delta_g$ defined on the Sobolev class $H^2(\Omega) \cap H^1_0(\Omega)$ of functions vanishing on $\Gamma$, and the semigroup representation

$$u^{0,h}(\cdot, r) = W^r_{\mathrm{vol}} h = \int_0^r L^{-1/2} \sin\left[(r-t)L^{1/2}\right] h(\cdot, t)\mathrm{d}t \quad [4]$$

holds for all $r \geq 0$.

The "input $\mapsto$ output" map is implemented by the response operator $R^T: \mathcal{F}^T \to \mathcal{F}^T$,

$$R^T f := \partial_\nu u^{f,0} \quad \text{on } \Gamma \times [0, T]$$

defined on controls $f \in H^1(\Gamma \times [0, T])$ vanishing on $\Gamma \times \{t = 0\}$; here $\nu = \nu(\gamma)$ is the outward normal to $\Gamma$. The normal derivative $\partial_\nu u^{f,0}$ describes the forces appearing on $\Gamma$ as a result of interaction of the wave with the boundary.

The map $C^T : \mathcal{F}^T \to \mathcal{F}^T, C^T := (W^T_{\mathrm{bd}})^* W^T_{\mathrm{bd}}$, which is called the connecting operator, can be represented via the response operator of the system $\alpha^{2T}$:

$$C^T = \tfrac{1}{2}(S^T)^* R^{2T} J^{2T} S^T \quad [5]$$

$S^T: \mathcal{F}^T \to \mathcal{F}^{2T}$ being the extension of controls from $\Gamma \times [0, T]$ onto $\Gamma \times [0, 2T]$ as odd functions of $t$ with respect to $t = T$, and $J^{2T}: \mathcal{F}^{2T} \to \mathcal{F}^{2T}$ being the integration

$$(J^{2T} f)(\cdot, t) = \int_0^t f(\cdot, s)\mathrm{d}s$$

### Controllability

Open subsets $\sigma \subset \Gamma$ and $\omega \subset \Omega$ determine the subspaces

$$\mathcal{F}^T_\sigma := \{f \in \mathcal{F}^T \mid \mathrm{supp}\, f \subset \overline{\sigma} \times [0, T]\}$$
$$\mathcal{G}^T_\omega := \{h \in \mathcal{G}^T \mid \mathrm{supp}\, h \subset \overline{\omega} \times [0, T]\}$$

of controls acting from $\sigma$ and $\omega$, respectively. In view of hyperbolicity of the problem [1]–[3], the relation

$$\mathrm{supp}\, u^{f,h}(\cdot, t) \subset \langle\overline{\sigma}\rangle^t \cup \langle\overline{\omega}\rangle^t, \quad t \geq 0 \quad [6]$$

holds for $f \in \mathcal{F}^T_\sigma$ and $h \in \mathcal{G}^T_\omega$. This means that the waves propagate in $\Omega$ with the speed $= 1$.

The sets of waves

$$\mathcal{U}^T_\sigma := W^T_{\mathrm{bd}} \mathcal{F}^T_\sigma, \qquad \mathcal{U}^T_\omega := W^T_{\mathrm{vol}} \mathcal{G}^T_\omega$$

are said to be reachable at time $t = T$ from $\sigma$ and $\omega$, respectively. Denoting

$$\mathcal{H}A := \{y \in \mathcal{H} \mid \mathrm{supp}\ y \subset \overline{A}\}$$

by virtue of [6] one has the embeddings $\mathcal{U}^T_\sigma \subset \mathcal{H}\langle\overline{\sigma}\rangle^T$ and $\mathcal{U}^T_\omega \subset \mathcal{H}\langle\overline{\omega}\rangle^T$. The property of the system $\alpha^T$ that plays the key role in inverse problems is that these embeddings are dense:

$$\mathrm{cl}\,\mathcal{U}^T_\sigma = \mathcal{H}\langle\overline{\sigma}\rangle^T, \qquad \mathrm{cl}\,\mathcal{U}^T_\omega = \mathcal{H}\langle\overline{\omega}\rangle^T \quad [7]$$

for any $T > 0$ (cl denotes the closure in $\mathcal{H}$).

In control theory, relations [7] are interpreted as an approximate controllability of the system in subdomains filled with waves; the name "BC method" is derived from the first one (boundary controllability). This property means that the sets of waves are rich enough: any function supported in the subdomain $\langle\overline{\sigma}\rangle^T$ reachable for waves excited on $\sigma$ can be approximated with any precision in $\mathcal{H}$-norm by the wave $u^{f,0}(\cdot, T)$ due to appropriate choice of the control $f$ acting from $\sigma$. The proof of [7] relies on the fundamental Holmgren–John–Tataru unique continuation theorem for the wave equation (Tataru 1993).

### Laplacian on Waves

If $h = 0$, so that the system is governed only by boundary controls, its trajectory $\{u^{f,0}(\cdot, t) | 0 \leq t \leq T\}$ does not leave the reachable set $\mathcal{U}^T_\Gamma$. In this case, the system possesses one more intrinsic operator $L^T$ which acts in the subspace $\mathrm{cl}\,\mathcal{U}^T_\Gamma$ and is introduced through its graph

$$\mathrm{gr}\, L^T := \mathrm{cl}\left\{\{W^T_{\mathrm{bd}} f, -W^T_{\mathrm{bd}} f_{tt}\} | f \in C^\infty_0(\Gamma \times (0, T))\right\} \quad [8]$$

(closure in $\mathcal{H} \times \mathcal{H}$). By virtue of the relation $L^T W^T_{\mathrm{bd}} f = -\Delta_g W^T_{\mathrm{bd}} f$ following from the wave equation [1] and [6], the operator $L^T$ is interpreted as Laplacian on waves filling the subdomain $\langle\Gamma\rangle^T$.

In the case $T > T_*$, one has $\langle\Gamma\rangle^T = \Omega$, $\mathrm{cl}\,\mathcal{U}^T_\Gamma = \mathcal{H}$, and $L^T$ is a densely defined operator in $\mathcal{H}$, satisfying $L^T \subset L$. Using [7], one proves the equality $L^T = L$. This equality and representation [4] imply that

$$W^r_{\mathrm{vol}} h = \int_0^r (L^T)^{-1/2} \sin\left[(r-t)(L^T)^{1/2}\right] h(\cdot, t)\mathrm{d}t \quad [9]$$

for all $r \geq 0$ and any fixed $T > T^*$.

### Spectral Problem

The Dirichlet homogeneous boundary-value problem is to find nontrivial solutions of the system

$$-\Delta_g \varphi = \lambda \varphi \quad \text{in } \Omega \qquad [10]$$

$$\varphi = 0 \quad \text{on } \Gamma \qquad [11]$$

This problem is equivalent to the spectral analysis of the operator $L$; it has the discrete spectrum $\{\lambda_k\}_{k=1}^{\infty}, 0 < \lambda_1 < \lambda_2 \leq \cdots, \lambda_k \to \infty$; the eigenfunctions $\{\varphi_k\}_{k=1}^{\infty}, L\varphi_k = \lambda_k \varphi_k$, form an orthonormal basis in $\mathcal{H}$.

Expanding the solutions of the problem (1)–(3) over the eigenfunctions of the problem [10], [11] one derives the spectral representation of waves:

$$u^{f,0}(\cdot, T) = W_{\text{bd}}^T f = \sum_{k=1}^{\infty} (f, s_k^T)_{\mathcal{F}^T} \varphi_k(\cdot) \qquad [12]$$

where

$$s_k^T(\gamma, t) := \lambda_k^{-1/2} \sin\left[(T-t)\lambda_k^{1/2}\right] \partial_\nu \varphi_k(\gamma)$$

Thus, for a given control $f$, the Fourier coefficients of the wave $u^{f,0}$ are determined by the spectrum $\{\lambda_k\}_{k=1}^{\infty}$ and the derivatives $\{\partial_\nu \varphi_k\}_{k=1}^{\infty}$.

## Inverse problems

### General Setup

The set of pairs $\Sigma := \{\lambda_k; \partial_\nu \varphi_k\}_{k=1}^{\infty}$ associated with the problem [10], [11] is said to be the Dirichlet spectral data of the manifold $(\Omega, d)$. The spectral (frequency domain) inverse problem is to recover the manifold from its spectral data.

Since the speed of wave propagation is unity, the response operator $R^T$ contains the information not about the entire manifold but only about its part $\langle \Gamma \rangle^{T/2}$. This fact is taken into account in the dynamical (time domain) inverse problem which aims to recover the manifold from the operator $R^{2T}$ given for a fixed $T > T_*$.

If the manifolds $(\Omega', d')$ and $(\Omega'', d'')$ are isometric via an isometry $i : \Omega' \to \Omega''$, then, identifying the boundaries by $i(\gamma) \equiv \gamma$, one gets two manifolds with the common boundary $\Gamma = \partial\Omega' = \partial\Omega''$ which possess identical inverse data: $\Sigma' = \Sigma'', R'^{2T} = R''^{2T}$. Such manifolds are called equivalent: they are indistinguishable for the external observer extracting $\Sigma$ or $R^{2T}$ from the boundary measurements. Therefore, these data do not determine the manifold uniquely and both of the inverse problems need to be clarified. The precise formulation is given in the form of two questions:

1. Does the coincidence of the inverse data imply the equivalence of the manifolds?
2. Given the inverse data of an unknown manifold, how to construct a manifold possessing these data?

The BC method gives an affirmative answer to the first question and provides a procedure producing a representative of the class of equivalent manifolds from its inverse data. The method is based on the concepts of model and "coordinatization."

### Model

A pair consisting of an auxiliary Hilbert space $\tilde{\mathcal{H}}$ and an operator $\tilde{W}_{\text{bd}}^T : \mathcal{F}^T \to \tilde{\mathcal{H}}$ is said to be a model of the system $\alpha^T$, if $\tilde{W}_{\text{bd}}^T$ is determined by inverse data, and the map $U : W_{\text{bd}}^T f \mapsto \tilde{W}_{\text{bd}}^T f$ is an isometry from Ran $W_{\text{bd}}^T \subset \mathcal{H}$ onto Ran $\tilde{W}_{\text{bd}}^T \subset \tilde{\mathcal{H}}$. The model is an intermediate object in solving inverse problems. It plays the role of an auxiliary copy of the original dynamical system which an external observer can build from measurements on the boundary. While the genuine wave process inside $\Omega$, initiated by a boundary control, remains unaccessible for direct measurements, its $\tilde{\mathcal{H}}$-representation can be visualized by means of the model control operator $\tilde{W}_{\text{bd}}^T$. This is illustrated by the diagram on Figure 2, where the upper part is invisible for an external observer, whereas the lower part can be extracted from inverse data.

Each type of data determines a corresponding model. The spectral model is the pair

$$\tilde{\mathcal{H}} := l_2, \qquad \tilde{W}_{\text{bd}}^T := \{(\cdot, s_k^T)_{\mathcal{F}^T}\}_{k=1}^{\infty} \qquad [13]$$

(see [12]); the role of isometry $U$ is played by the Fourier transform $F : \mathcal{H} \to \tilde{\mathcal{H}}, Fy := \{(y, \varphi)_{\mathcal{H}}\}_{k=1}^{\infty}$. By virtue of [4], the data $\Sigma$ also determine the operator $\tilde{W}^r{}_{\text{vol}} : L_2([0, r]; \tilde{\mathcal{H}}) \to \tilde{\mathcal{H}}$,

$$\tilde{W}^r{}_{\text{vol}} = \int_0^r \tilde{L}^{-1/2} \sin\left[(r-t)(\tilde{L})^{1/2}\right](\cdot)(t)\, dt, \quad r \geq 0 \qquad [14]$$

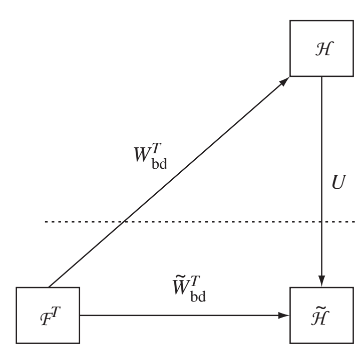

**Figure 2** Model of a system. (Data from Belishev (1997).)

where $\tilde{L} := ULU^* = \mathrm{diag}\{\lambda_k\}_{k=1}^{\infty}$. Thus, the spectral model allows one to see the Fourier images of invisible waves.

According to [5], the response operator $R^{2T}$ determines the modulus of the control operator

$$|W_{\mathrm{bd}}^T| = [(W_{\mathrm{bd}}^T)^* W_{\mathrm{bd}}^T]^{1/2} = (C^T)^{1/2}$$

which enters in the polar decomposition $W_{\mathrm{bd}}^T = \Phi |W_{\mathrm{bd}}^T|$. Along with it, the response operator determines the dynamical model

$$\tilde{\mathcal{H}} := \mathrm{cl}\ \mathrm{Ran}(C^T)^{1/2}, \qquad \tilde{W}_{\mathrm{bd}}^T := (C^T)^{1/2} \qquad [15]$$

The correspondence "system → model" is realized by the isometry $U = \Phi^* : W_{\mathrm{bd}}^T f \mapsto |W_{\mathrm{bd}}^T| f$. The operator $\tilde{L}^T := UL^T U^*$ dual to the Laplacian on waves, is determined by its graph

$$\mathrm{gr}\,\tilde{L}^T := \mathrm{cl}\left\{\{\tilde{W}_{\mathrm{bd}}^T f, -\tilde{W}_{\mathrm{bd}}^T f_{tt}\} | f \in C_0^{\infty}(\Gamma \times (0,T))\right\} \qquad [16]$$

(see [8]) and, therefore, $\tilde{L}^T$ is also determined by $R^{2T}$. In the case $T > T_*$, the operator $\tilde{W}_{\mathrm{vol}}^r : L_2([0,r]; \tilde{\mathcal{H}}) \to \tilde{\mathcal{H}}$ dual to $W_{\mathrm{vol}}^r$, is represented in the form

$$\tilde{W}_{\mathrm{vol}}^r = \int_0^r (\tilde{L}^T)^{-1/2} \sin\left[(r-t)(\tilde{L}^T)^{1/2}\right](\cdot)(t)\,\mathrm{d}t, \quad r \geq 0 \qquad [17]$$

in accordance with [9]. Thus, the dynamical model visualizes the $\Phi^*$-images of the waves propagating inside $\Omega$.

### Wave Coordinatization

In a general sense, a coordinatization is a correspondence between points $x$ of the studied set $\mathcal{A}$ and elements $\tilde{x}$ of another set $\tilde{\mathcal{A}}$ such that: (i) the elements of $\tilde{\mathcal{A}}$ are accessible and distinguishable; (ii) the map $x \mapsto \tilde{x}$ is a bijection; and (iii) relations between elements of $\tilde{\mathcal{A}}$ determine those between points of $\mathcal{A}$ which are studied (H Weyl). Coordinatization enables one to study $\mathcal{A}$ via operations with coordinates $\tilde{x} \in \tilde{\mathcal{A}}$.

The external observer investigating the manifold probes $\Omega$ with waves initiated by sources on $\Gamma$. The relevant coordinatization of $\Omega$ described below uses such waves and is implemented in three steps.

*Step 1* (*subdomains*) Let $x(\gamma, \tau)$ be the end point of the geodesic of the length $\tau > 0$ emanating from $\gamma \in \Gamma$ in the direction $-\nu(\gamma)$, and let $\sigma_\gamma^\varepsilon \subset \Gamma$ be a small neighborhood shrinking to $\gamma$ as $\varepsilon \to 0$. If $\tau \leq \tau_*(\gamma)$, then the family of subdomains

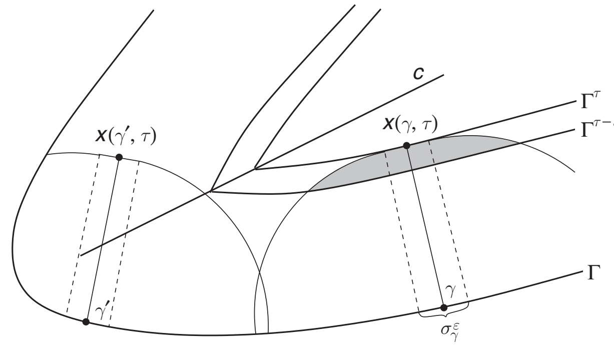

**Figure 3** The subdomains.

$$\omega^\varepsilon(\gamma, \tau) := [\langle\Gamma\rangle^\tau \setminus \langle\Gamma\rangle^{\tau-\varepsilon}] \cap \langle\sigma_\gamma^\varepsilon\rangle^\tau$$

(shaded domain on Figure 3) shrinks to $x(\gamma, \tau)$; if $\tau > \tau_*(\gamma)$, then the family terminates: $\omega^\varepsilon(\gamma, \tau) = \emptyset$ as $\varepsilon < \varepsilon_0(\gamma)$ (the case $\gamma = \gamma'$ in Figure 3). Such behavior of subdomains implies that

$$\lim_{\varepsilon \to 0} \left\langle [\langle\Gamma\rangle^\tau \setminus \langle\Gamma\rangle^{\tau-\varepsilon}] \cap \langle\sigma_\gamma^\varepsilon\rangle^\tau \right\rangle^r = \begin{cases} \langle x(\gamma,\tau)\rangle^r, & \tau \leq \tau_*(\gamma) \\ \emptyset, & \tau > \tau_*(\gamma) \end{cases} \qquad [18]$$

*Step 2* (*wave subspaces*) Pass from the subdomains to the corresponding subspaces $\mathcal{H}\langle\Gamma\rangle^\tau, \mathcal{H}\langle\sigma_\gamma^\varepsilon\rangle^\tau$, $\mathcal{H}\langle\omega^\varepsilon(\gamma,\tau)\rangle^r$, and represent them via reachable sets by [7]:

$$\mathcal{H}\langle\Gamma\rangle^\tau = \mathrm{cl}\ W_{\mathrm{bd}}^\tau \mathcal{F}^\tau, \qquad \mathcal{H}\langle\sigma_\gamma^\varepsilon\rangle^\tau = \mathrm{cl}\ W_{\mathrm{bd}}^\tau \mathcal{F}_{\sigma_\gamma^\varepsilon}^\tau$$

$$\begin{aligned}\mathcal{H}\langle\omega^\varepsilon(\gamma,\tau)\rangle^r &= \mathrm{cl}\ W_{\mathrm{vol}}^r L_2([0,r]; \mathcal{H}\omega^\varepsilon(\gamma,\tau)) \\ &= \mathrm{cl}\ W_{\mathrm{vol}}^r L_2\Big([0,r]; [\mathcal{H}\langle\Gamma\rangle^\tau \ominus \mathcal{H}\langle\Gamma\rangle^{\tau-\varepsilon}] \cap \mathcal{H}\langle\sigma_\gamma^\varepsilon\rangle^\tau\Big) \\ &= \mathrm{cl}\ W_{\mathrm{vol}}^r L_2\Big([0,r]; [\mathrm{cl}\ W_{\mathrm{bd}}^\tau \mathcal{F}^\tau \ominus \mathrm{cl}\ W_{\mathrm{bd}}^{\tau-\varepsilon} \mathcal{F}^{\tau-\varepsilon}] \cap \mathrm{cl}\ W_{\mathrm{bd}}^\tau \mathcal{F}_{\sigma_\gamma^\varepsilon}^\tau\Big)\end{aligned}$$

Define

$$\mathcal{W}_{(\gamma,\tau)}^r := \lim_{\varepsilon \to 0} \mathrm{cl}\ W_{\mathrm{vol}}^r L_2\Big([0,r]; [\mathrm{cl}\ W_{\mathrm{bd}}^\tau \mathcal{F}^\tau \ominus \mathrm{cl}\ W_{\mathrm{bd}}^{\tau-\varepsilon} \mathcal{F}^{\tau-\varepsilon}] \cap \mathrm{cl}\ W_{\mathrm{bd}}^\tau \mathcal{F}_{\sigma_\gamma^\varepsilon}^\tau\Big) \qquad [19]$$

$\mathcal{W}_{(\gamma,0)}^r := \mathcal{W}_{(\gamma,+0)}^r$, $r \geq 0$ (the limits in the sense of the strong operator convergence of the projections in $\mathcal{H}$ on the corresponding subspaces). By the definitions, one has $\mathcal{W}_{(\gamma,\tau)}^r = \lim_{\varepsilon \to 0} \mathcal{H}\langle\omega^\varepsilon(\gamma,\tau)\rangle^r$, whereas [18] leads to the equality

$$\mathcal{W}_{(\gamma,\tau)}^r = \begin{cases} \mathcal{H}\langle x(\gamma,\tau)\rangle^r, & \tau \leq \tau_*(\gamma) \\ \{0\}, & \tau > \tau_*(\gamma) \end{cases} \qquad [20]$$

for all $\gamma \in \Gamma$, $\tau \geq 0$, $r \geq 0$. As a result, since any $x \in \Omega$ can be represented as $x = x(\gamma, \tau)$, one attaches to every point of the manifold a family of expanding subspaces $\{\mathcal{W}^r_{(\gamma,\tau)} | r \geq 0\}$ built out of waves. As is seen from [20], the family is determined by the point $x$ (not dependent on the representation $x = x(\gamma,\tau)$); the subspaces which it consists of coincide with $\mathcal{H}\langle x\rangle^r$.

Expressing the distance as

$$d(x', x'') = 2\ \inf\{r > 0\,|\,\mathcal{H}\langle x'\rangle^r \cap \mathcal{H}\langle x''\rangle^r \neq \{0\}\}$$

in accordance with [20], one can represent

$$d(x', x'') = 2\ \inf\{r > 0\,|\,\mathcal{W}^r_{(\gamma',\tau')} \cap \mathcal{W}^r_{(\gamma'',\tau'')} \neq \{0\}\} \qquad [21]$$

where $x' = x(\gamma', \tau')$, $x'' = x(\gamma'', \tau'')$, and hence find the distance via the above families.

*Step 3* (*wave copy*) By varying $\gamma \in \Gamma, \tau \geq 0$, gather all nonzero families $\{\mathcal{W}^r_{(\gamma,\tau)} | r \geq 0\} =: \tilde{x}$ in the set $\tilde{\Omega} = \{\tilde{x}\}$. Redenoting $\mathcal{W}^r_{\tilde{x}} := \mathcal{W}^r_{(\gamma,\tau)} \in \tilde{x}$, endow the set with the distance

$$\tilde{d}(\tilde{x}', \tilde{x}'') := 2\ \inf\{r > 0\,|\,\mathcal{W}^r_{\tilde{x}'} \cap \mathcal{W}^r_{\tilde{x}''} \neq \{0\}\} \qquad [22]$$

In view of [21], one has $d(x', x'') = \tilde{d}(\tilde{x}', \tilde{x}'')$, so that the metric space $(\tilde{\Omega}, \tilde{d})$ is an isometric copy of $(\Omega, d)$ by construction. Thus, the correspondence $x \mapsto \tilde{x}$ ("point $\mapsto$ family") is an isometry and satisfies the general principles (i)–(iii) of coordinatization.

The manifold $(\tilde{\Omega}, \tilde{d})$ is the end product of the wave coordinatization. It represents the original manifold as a collection of infinitesimal sources interacting with each other via the waves which they produce.

### Solving Inverse Problems

The motivation for the above coordinatization is that the wave copy can be reproduced via any model. Namely, the external observer with the knowledge of $\Sigma$ or $R^{2T}(T > T_*)$ can recover $(\tilde{\Omega}, \tilde{d})$ up to isometry by the following procedure:

1. Construct the model corresponding to the given inverse data and determine the operators $\tilde{W}^\tau_{\text{bd}}$, $0 \leq \tau \leq T$ by [13], [15]; then determine $\tilde{L}, \tilde{L}^T$, and $\tilde{W}^r_{\text{vol}}$ by [14] or [16], [17].
2. Replace on the right-hand side of [19] all operators $W$ without tildes by the ones with tildes, and get the subspaces $\tilde{\mathcal{W}}^r_{(\gamma,\tau)} = U\mathcal{W}^r_{(\gamma,\tau)}$, $\gamma \in \Gamma$, $\tau \geq 0$, $r \geq 0$.
3. Gather all nonzero families $\{\tilde{\mathcal{W}}^r_{(\gamma,\tau)} | r \geq 0\} =: \hat{x}$ in the set $\hat{\Omega} = \{\hat{x}\}$ and redenote the subspaces as $\tilde{\mathcal{W}}^r_{\hat{x}} := \tilde{\mathcal{W}}^r_{(\gamma,\tau)} \in \hat{x}$; endow the set with the metric $\hat{d}(\hat{x}', \hat{x}'') := 2\ \inf\{r > 0\,|\,\tilde{\mathcal{W}}^r_{\hat{x}'} \cap \tilde{\mathcal{W}}^r_{\hat{x}''} \neq \{0\}\}$ (see [22]), and get a sample $(\hat{\Omega}, \hat{d})$ of the wave copy $(\tilde{\Omega}, \tilde{d})$.

This sample is isometric to the original $(\Omega, d)$ by construction. Identifying properly the boundaries $\partial\hat{\Omega}$ and $\Gamma$, one turns $(\hat{\Omega}, \hat{d})$ into a canonical representative of the class of equivalent manifolds possessing the given inverse data.

If the response operator $R^{2T}$ is given for a fixed $T < T_*$, the above procedure produces the wave copy of the submanifold $(\langle\Gamma\rangle^T, d)$. This locality in time is an intrinsic feature and advantage of the BC method: longer time of observation on $\Gamma$ increases the depth of penetration into $\Omega$.

### Amplitude Formula

Another variant of the BC method is based on geometrical optics formulas describing the propagation of singularities of the waves.

Let $y \in \mathcal{H}$, and let $\beta$ be the density of the volume in semigeodesic coordinates: $dx = \beta\, d\Gamma\, d\tau$; the function

$$\tilde{y}(\gamma, \tau) := \begin{cases} \beta^{1/2}(\gamma, \tau)\, y(x(\gamma, \tau)), & (\gamma, \tau) \in \Theta \\ 0, & \text{otherwise} \end{cases}$$

defined on $\Gamma \times [0, T_*]$ is called the image of $y$. The amplitude formula represents the images of waves initiated by boundary controls in the form

$$\widetilde{u^{f,0}(\cdot, T)}(\gamma, \tau) = \lim_{t \to T-\tau-0} [(W^T_{\text{bd}})^*(I - P^\tau)W^T_{\text{bd}} f](\gamma, t)$$
$$0 < \tau < T$$

where $I$ is the identity operator and $P^\tau$ is the projection in $\mathcal{H}$ onto $\text{cl}\, W^\tau_{\text{bd}}\mathcal{F}^\tau$. The formula is derived by the ray method going back to J Hadamard, the derivation uses the controllability [7].

Any model determines the right-hand side of the last relation by the isometry: $(W^T_{\text{bd}})^*(I - P^\tau) W^T_{\text{bd}} = (\tilde{W}^T_{\text{bd}})^*(\tilde{I} - \tilde{P}^\tau)\tilde{W}^T_{\text{bd}}$, where $\tilde{W}^T_{\text{bd}} = UW^T_{\text{bd}}, \tilde{I}$ is the identity operator, and $\tilde{P}^\tau = UP^\tau U^*$ is the projection in $\tilde{\mathcal{H}}$ onto $\text{cl}\, \tilde{W}^\tau_{\text{bd}}\mathcal{F}^\tau$. This leads to the representation

$$\widetilde{u^{f,0}(\cdot, T)}(\gamma, \tau) = \lim_{t \to T-\tau-0} [(\tilde{W}^T_{\text{bd}})^*(\tilde{I} - \tilde{P}^\tau)\tilde{W}^T_{\text{bd}} f](\gamma, t)$$
$$0 < \tau < T \qquad [23]$$

and makes the amplitude formula a useful tool for solving the inverse problems. The external observer can construct a model via inverse data and then visualize by [23] the wave images on the part $\Theta^T$ of the pattern (see **Figure 1**). The collection of images $\widetilde{u^{f,0}}$ corresponding to all possible controls $f$ is rich enough for recovering the tensor $g$ on $\Theta^T$ (i.e., the metric tensor in semigeodesic coordinates) and turning the pattern into an isometric copy of the submanifold $(\langle\Gamma\rangle^T, d)$. This variant of the method is

more appropriate if one needs to recover unknown coefficients of the wave equation in $\Omega$ – it can be realized in terms of numerical algorithms.

## Extensions of the Method

Electromagnetic waves are also well suited for coordinatization and for constructing the wave copy $(\tilde{\Omega}, \tilde{d})$. An appropriate version of the amplitude formula also exists for the system governed by the Maxwell equations (see Further Reading). At present (2004), the applicability of the BC method to three-dimensional inverse problems of elasticity theory is still an open question. The following hypothesis concerns the Lamé system: the wave coordinatization procedure (steps 1–3) using the elastic waves instead of the above $u^{f,0}$, gives rise to the copy of $\Omega \subset \mathbf{R}^3$ endowed with the metric $|dx|^2/c_p^2$ where $c_p = \sqrt{(\lambda + 2\mu)/\rho}$ is the speed of the pressure waves.

The concept of model is used for solving inverse problems for the heat and Schrödinger equations (Avdonin and Belishev, 1995–2004), as well as for the problem of boundary data continuation (Belishev 2001, Kurylev and Lassas 2002). A variant of the BC method allows one to recover not only the manifold but also the Schrödinger type operators on it and/or the dissipative term in the scalar wave equation (Kurylev and Lassas 1993–2003).

An appropriate version of the amplitude formula solves the inverse problem for one-dimensional two-velocity dynamical system which describes the waves consisting of two modes propagating with different speeds and interacting with each other (Belishev, Blagoveschenskii, Ivanov, 1997–2000).

One more variant of coordinatization going back to the first paper on the BC method, associates with points $x \in \Omega$ the Dirac measures $\delta_x$; then, their images $\tilde{\delta}_x$ are identified via suitable models. This variant solves inverse problems on graphs and the two-dimensional elliptic Calderon problem. The reader is referred to articles by the present author listed in Further Reading.

Within the scope of the method, one derives some natural analogs of the classical Gelfand–Levitan–Krein–Marchenko equations (Belishev, 1987–2001). Also, an appropriate analog solves the kinematic inverse problem for a class of two-dimensional manifolds (Pestov 2004).

There exists an abstract version of the approach, embedding the BC method into the framework of linear system theory (Belishev 2001). The method is also related to the problem of triangular factorization of operators (Belishev and Pushnitski 1996).

Numerical algorithms for solving two-dimensional spectral and dynamical inverse problems for the wave equation $\rho u_{tt} - \Delta u = 0$ which recover the variable density $\rho$ have been developed and tested (Filippov, Gotlib, Ivanov, 1994–1999).

# Boundary-Value Problems for Integrable Equations

**B Pelloni**, University of Reading, UK

## Introduction

Integrable equations are a special class of nonlinear equations arising in the modeling of a wide variety of physical phenomena. It has been argued that integrable PDEs are in a certain, specific sense "universal" models for physical phenomena involving weak nonlinearity. Indeed, integrable equations are obtained by a procedure involving rescaling and an asymptotic expansion from very large classes of nonlinear evolution equations, which preserves integrability while retaining in the limit weakly nonlinear effects. For this reason, integrable equations are a very important class of PDEs. Important examples are the nonlinear Schrödinger (NLS) equation

$$\mathrm{i}q_t + q_{xx} - 2\lambda|q|^2 q = 0, \quad \lambda = \pm 1 \qquad [1]$$

the Korteweg–deVries (KdV) equation

$$q_t + q_x \pm q_{xxx} + 6qq_x = 0 \qquad [2]$$

the modified KdV (mKdV) equation

$$q_t \pm q_{xxx} \mp 6\lambda q^2 q_x = 0, \quad \lambda = \pm 1 \qquad [3]$$

and the sine-Gordon (SG) equation in light-cone or laboratory coordinates

$$q_{xt} + \sin q = 0 \quad \text{or} \quad q_{tt} - q_{xx} + \sin q = 0 \qquad [4]$$

A general method for solving the initial-value problem for integrable equations in one space dimension was discovered in 1967, when in a pioneering and much celebrated work (Gardner *et al.* 1967), the initial-value problems for KdV with decaying initial condition was completely solved. Soon afterwards, it was understood that this method, now known as the "inverse scattering transform," is of more general applicability. Indeed, it can be applied to those nonlinear equations that can be written as the compatibility condition of a pair of linear eigenvalue equations. The method of solution for the Cauchy problem essentially relies on the possibility of expressing the equation through this pair, now called a Lax pair after the work of Lax (1968), who first clarified the connection. Zakharov and Shabat (1972) constructed such a pair for the NLS equation, and in subsequent years the Lax pairs associated with all important integrable equations in one and two spatial variables were constructed. These include the NLS, sG, mKdV, Davey–Stewartson I and II, and Kamdotsev–Petviashvili I and II equations.

There is no universally accepted definition of an integrable PDE, but on account of the above results, the existence of a Lax pair can be taken as the defining property of such equations. In the course of the 1970s, the inverse scattering transform was applied to solve the initial-value (Cauchy) problem for many integrable equations. In principle, there is no obstruction to solving analytically the initial-value problem by the inverse scattering transform as soon as a Lax pair is constructed for the equation, and appropriate decaying initial conditions are prescribed. The solution is then characterized in terms of a certain integral equation. This approach is equivalent to associating with the initial-value problem a classical problem in complex analysis, namely a matrix Riemann–Hilbert problem, defined in the complex spectral space. This point of view is currently taken by many authors as it provides a unifying and very flexible framework for the analysis.

After the success of the inverse scattering transform in solving the Cauchy problem, it was natural to attempt to generalize the approach to boundary-value problems. To describe the difficulties involved in this generalization, consider the case of evolution equations in one space and one time dimensions. The independent variables can be denoted by $(x, t)$, with $t > 0$ representing time. While the initial-value problem is posed on the full real line, hence for $x \in (-\infty, \infty)$, the simplest boundary-value problem is posed on a half-line, for $x \in (0, \infty)$. In addition to initial conditions for initial time $t = 0$, it is necessary to prescribe conditions at the boundary $x = 0$. The number of conditions that must be prescribed to obtain a problem which admits a unique solution depends on the particular equation, but for evolution equation it is roughly equal to half the number of $x$-derivatives involved in the equation. For example, for the NLS equation, a well-posed problem is defined as soon as one boundary condition at $x = 0$ is prescribed; hence a typical boundary-value problem for this equation is obtained, for example, when $q(x, 0) = q_0(x)$ and $q(0, t) = g_0(t)$ are prescribed and compatible, so that $q_0(0) = g_0(0)$. It follows that, while $q_{xx}(0, t)$ can be computed from the equation, $q_x(0, t)$ is not immediately known. An even more difficult situation arises for the KdV equation [2] (with the + sign), for which a well-posed problem is again defined as soon as one boundary condition is prescribed, so that there are two unknown boundary values.

Because of this simple fact, a straightforward application of the ideas of the inverse scattering transform immediately encounters one crucial difficulty. This transform method yields an integral representation of the solution which involves not only the given boundary conditions $f(t)$, but also the other "unknown" boundary values – in our example for the NLS equation, the function $q_x(0,t)$. The problem of characterizing these unknown boundary values has impeded progress in this direction for over thirty years.

On account of their physical significance, various boundary-value problems for the KdV equation have been considered, and classical PDE techniques (not specific to integrable models) have been used to establish existence and uniqueness results (Bona *et al.* 2001, Colin and Ghidaglia 2001, Colliander and Kenig 2001). These approaches, and in particular the approach of Colliander and Kenig, are quite general and possibly of wide applicability, and give global existence results in wide functional classes. However, they do not rely on integrability properties. Indeed, none of these results use the integrable structure of the equation in any fundamental or systematic way. However, the fact that these equations are integrable on the full line implies very special properties that should be exploited in the analysis and it is natural to try to generalize the inverse scattering transform approach.

Such a generalization is sometimes directly possible. For example, it has been used for studying the problem on the half-line for the hyperbolic version of the sG equation [4a] which does not involve unknown boundary values (Fokas 2000, Pelloni). It has also been used to study some specific boundary-value problems for the NLS equation, for example, for homogeneous Dirichlet or Neumann conditions, when it is possible to use even or odd extensions of the problem to the full line (Ablowitz and Segur 1974), or more recently in Degasperis *et al.* (2001). In the latter case, however, the unknown boundary values are characterized through an integral Fredholm equation, which does not admit a unique solution. Some special cases of boundary-value problems for the KdV equation (Adler *et al.* 1997, Habibullin 1999) and elliptic sG (Sklyanin 1987) have also been studied via the inverse scattering transform. However all the examples considered are nongeneric, and it has recently been shown (Fokas, in press) that the boundary conditions chosen fall in the special class of the so-called "linearizable" boundary conditions, for which the problem can be solved as if it were posed on the full line. One cannot hope to use similar methods to solve the problem with generic boundary conditions.

Recently, Fokas (2000) introduced a general methodology to extend the ideas of the inverse scattering transform to boundary-value problems. This methodology provides the tools to analyze boundary-value problems for integrable equations to a considerable degree of generality. We note as a side remark that linear PDEs are trivially integrable, in the sense of admitting a Lax pair (in this case the Lax pair can be found algorithmically, while the construction of the Lax pair associated with a nonlinear equation is by no means trivial). As a consequence of this remark, the extension of the inverse scattering transform also provides a method for solving boundary-value problems for a large variety of linear PDEs of mathematical physics.

What follows is a general description of the approach of Fokas, considering, for the sake of concreteness, the case of an integrable PDE in the two variables $(x,t)$ which vary in the domain $D$ (typically, for an evolution problem $D=(0,\infty)\times(0,T)$). We assume that $q(x,t)$ denotes the unique solution of a boundary-value problem posed for such an equation.

The method consists of the following steps.

1. Write the PDE as the compatibility condition of a Lax pair. This is a pair of linear ODEs for the function $\mu=\mu(x,t,k)$ involving the solution $q(x,t)$ of the PDE, the derivatives of this solution, and a complex parameter $k$, called the spectral parameter. This can be done algorithmically for linear PDEs, and in this case $\mu(x,t,k)$ is a scalar function. For nonlinear integrable PDEs, $\mu(x,t,k)$ is in general a matrix-valued function.

   The equivalence of the PDE with a Lax pair can be reformulated in the language of differential forms, and in this language it is easier to describe the methodology in general. Assume then that $\Omega(x,t,k)$ is a differential 1-form expressed in terms of a function $q(x,t)$ and its derivatives, and of a complex variable $k$, and one which is characterized by the property that $d\Omega=0$ if and only if $q(x,t)$ satisfies the given PDE. The closure of the form $\Omega$ yields the two important consequences 2(a) and 2(b) below.
2. (a) Since the domain $D$ under consideration is simply connected, the closed form $\Omega$ is also exact; hence, it is possible to find the particular, 0-form $\mu(x,t,k)$, solving $d\mu=\Omega$. In particular, $\mu(x,t,k)$ can be chosen to be sectionally bounded with respect to $k$ by solving either a Riemann–Hilbert problem or a $d$-bar problem in the complex spectral $k$ plane, and the solution $\mu(x,t,k)$ is then expressed in terms of certain "spectral functions" depending on all the boundary values

of the solution $q(x,t)$ of the PDE. The function $q(x,t)$ can then be expressed in terms of $\mu(x,t,k)$. (b) The integral of $\Omega$ along the boundary of the domain $D$ vanishes. This yields an integral constraint between all boundary values of the solution of the PDE, which becomes an algebraic constraint for the spectral functions. The resulting algebraic identity is called the "global relation."

3. The last step is the analysis the $k$-invariance properties of the global relation. This analysis yields the characterization of the spectral functions in terms only of the given boundary conditions.

The crucial and most difficult step in the solution process is the characterization described above. The analysis required depends on the type of problem under consideration. For nonlinear integrable evolution PDEs posed on the half-line $x > 0$, in general the characterization mentioned in step (3) involves solving a system of nonlinear Volterra integral equations. This is an important difference from the case of the Cauchy problem, where the solution is given by a single integral equation where all the terms are explicitly known.

The method outlined above has been applied successfully to solve a variety of boundary-value problems for linear and integrable nonlinear PDEs. For concreteness, here the focus is on the important case of integrable evolution PDEs in one space, which illustrates clearly the generalities of this method.

## Integrable Evolution Equations in One Space Dimension

The crucial property of integrable PDEs which is used in the inverse scattering transform approach to solve the initial-value problem is the fact that they can be written as the compatibility of a Lax pair. Many integrable evolution equations of physical significance (such as NLS, KdV, sG, and mKdV) admit a Lax pair of the form

$$\begin{aligned} \mu_x + \mathrm{i}f_1(k)\sigma_3\mu &= Q(x,t,k)\mu \\ \mu_t + \mathrm{i}f_2(k)\sigma_3\mu &= \tilde{Q}(x,t,k)\mu \end{aligned} \qquad [5]$$

where $\mu(x,t,k)$ is a $2 \times 2$ matrix, $\sigma_3 = \mathrm{diag}(1, -1)$, $f_i(k), i = 1, 2$, are analytic functions of the complex parameter $k$, and $Q$, $\tilde{Q}$ are analytic functions of $k$, of the function $q(x,t)$ (and of its complex conjugate $\overline{q(x,t)}$ for complex-valued problems) and of its derivatives. For example, the NLS equation [1] is equivalent to the compatibility condition of the pair

$$\begin{aligned} \mu_x + \mathrm{i}k\sigma_3\mu &= Q\mu, \quad Q = \begin{pmatrix} 0 & q \\ \lambda\bar{q} & 0 \end{pmatrix} \\ \mu_t + 2\mathrm{i}k^2\sigma_3\mu &= (2kQ - \mathrm{i}Q_x\sigma_3 - \mathrm{i}\lambda|q|^2\sigma_3)\mu \end{aligned} \qquad [6]$$

The first step towards a systematic new approach to solving boundary-value problem was the work of Fokas and Its, who associated the boundary-value problem for NLS on the half-line to a single Riemann–Hilbert problem determined by both equations in the Lax pair. The jump determining this Riemann–Hilbert problem has an explicit exponential dependence on both $x$ and $t$. This differs from the classical inverse scattering approach, in which the $x$-part of the Lax pair is used to determine an $x$-transform with $t$-dependent scattering data, and the $t$-part of the Lax pair is then exploited to find the time evolution of these data. The work of Fokas and Its led to the understanding that both equations in the Lax pair [6] must be considered in order to construct a spectral transform appropriate to solve boundary-value problems. Fokas (2000) reviews his systematic way to solve these problems by performing the simultaneous spectral analysis of both equations in the Lax pair. The transform thus obtained, which is a nonlinearization of the Fourier transform, precisely generalizes the inverse scattering transform.

This simultaneous analysis also leads naturally to the identification of the "global relation" which holds between initial and boundary data, and which plays an essential role in deriving an expression for the solution of the problem which does not involve unknown boundary values.

The Riemann–Hilbert problem with explicit $(x,t)$ dependence, the global relation, and the invariance properties of the latter with respect to the spectral parameter are the fundamental ingredients of this systematic approach to solve boundary-value problems for integrable equations.

The steps involved in this method are summarized in the introduction. While steps (1) and (2) can be described generally, and, once the Lax pair is identified, can be performed algorithmically (at least under the assumption that the solution of the PDE exists), the last step is the most difficult part of the analysis, and it needs to be considered separately for each given problem. However, it is this step that yields the effective characterization of the solution.

The results obtained for the particular case of eqn [1] are reviewed in detail in the next section, as they provide an important example, which can be generalized without any conceptual difficulty to eqns [2]–[4].

### The NLS Equation

As already mentioned, the initial-value problem for NLS was solved, for decaying initial condition, by Zakharov and Shabat, and studied in depth by many others. However, by the mid-1990s only a handful of papers had been written on the solution of the boundary-value problem posed on the half-line, all on a specific example or aspect of the problem, or attempts at solving the problem using general PDE techniques.

For this equation, the approach of Fokas yields the following results. Let the complex-valued function $q(x,t)$ satisfy the NLS equation [1], for $x>0$ and $t>0$, for prescribed one initial and one boundary conditions. For the sake of concreteness, we select the specific initial and boundary conditions

$$\begin{aligned} q(x,0) &= q_0(x) \in \mathcal{S}(\mathbb{R}^+) \\ q(0,t) &= g_0(t) \in \mathcal{S}(\mathbb{R}^+) \\ q_0(0) &= g_0(0) \end{aligned} \qquad [7]$$

where $\mathcal{S}$ denotes the space of Schwartz functions (similar results hold for different choices of boundary conditions, and less restrictive function classes).

The solution of this initial boundary-value (IBV) problem can be constructed as follows (Fokas 2000, 2002; in press):

- Given $q_0(x)$ construct the spectral functions $\{a(k), b(k)\}$. These functions are defined by

  $$a(k) = \phi_2(0,k), \quad b(k) = \phi_1(0,k)$$

  where the vector $\phi(x,k)$ with components $\phi_1(x,k)$ and $\phi_2(x,k)$ is the following solution of the $x$-problem of the associated Lax pair evaluated at $t=0$:

  $$\begin{aligned} \phi_x + \mathrm{i}k\sigma_3\phi &= Q(x,0,k)\phi, \quad 0<x<\infty,\ \mathrm{Im}\,k\geq 0 \\ \phi(x,k) &= \mathrm{e}^{\mathrm{i}kx}\left(\begin{pmatrix}0\\1\end{pmatrix}+o(1)\right) \text{ as } x\to\infty \\ Q(x,0,k) &= \begin{pmatrix} 0 & q_0(x) \\ \lambda\bar{q}_0(x) & 0\end{pmatrix}\end{aligned}$$

  ($\sigma_3$ and $Q(x,t,k)$ are defined after eqns [5] and [6], respectively).
- Given $q_0(x)$ and $g_0(t)$ characterize $g_1(t)$ by the requirement that the spectral functions $\{A(t,k), B(t,k)\}$ satisfy the global relation

  $$\begin{aligned} B(t,k) - R(k)A(t,k) &= \mathrm{e}^{4\mathrm{i}k^2t}\frac{c(t,k)}{a(k)} \\ R(k) &= \frac{b(k)}{a(k)},\ t\in[0,T],\ k\in\bar{D}\end{aligned} \qquad [8]$$

  where $D$ denotes the first quadrant of the complex $k$-plane:

  $$D = \{k|\mathrm{Re}\,k>0, \mathrm{Im}\,k>0\}$$

  $\bar{D}$ denotes the closure of $D$, and $c(t,k)$ is a function of $k$ analytic in $D$ and of order $\mathrm{O}(1/k)$ as $k\to\infty$. The spectral functions are defined by

  $$\begin{aligned} A(t,k) &= \mathrm{e}^{2\mathrm{i}k^2t}\overline{\Phi_2(t,\bar{k})}, \\ B(t,k) &= -\mathrm{e}^{2\mathrm{i}k^2t}\Phi_1(t,k)\end{aligned} \qquad [9]$$

  where the vector $\Phi(t,k)$ with components $\Phi_1$ and $\Phi_2$ is the following solution of the $t$-problem of the associated Lax pair evaluated at $x=0$:

  $$\begin{aligned} &\Phi_t + 2\mathrm{i}k^2\sigma_3\Phi = \tilde{Q}(0,t,k)\Phi \\ &\quad 0<t<T, \quad k\in\mathbb{C} \\ &\quad \Phi(0,k) = \begin{pmatrix}0\\1\end{pmatrix} \\ &\quad \tilde{Q}(0,t,k) = \\ &\begin{pmatrix} -|g_0(t)|^2 & 2kg_0(t) + \mathrm{i}\lambda\lambda g_1(t) \\ 2k\bar{g}_0(t) - \mathrm{i}\lambda\bar{g}_1(t) & |g_0(t)|^2\end{pmatrix}\end{aligned} \qquad [10]$$

- Given $a(k), b(k)$ and $A(k), B(k)$, define a $2\times 2$ matrix Riemann–Hilbert problem. This problem has the distinctive feature that its jump has explicit $(x,t)$ dependence in the exponential form of $\exp\{\mathrm{i}kx+2\mathrm{i}k^2t\}$. Determine $q(x,t)$ in terms of the solution of this Riemann–Hilbert problem by using the fact that these functions are related by the Lax pair. Then the function $q(x,t)$ solves the IBV problem [1]–[7] with $q(x,0)=q_0(x), q(0,t)=g_0(t)$, and $q'_x(0,t)=g_1(t)$.

The above construction can be summarized in the following theorem (Fokas 2002):

**Theorem 1** *Consider the boundary-value problem for the NLS equation [1] determined by the conditions [7]. Let $a(k), b(k)$ be given by [8], and suppose that there exists a function $g_1(t)$ such that if $A(k), B(k)$ are defined by [9], then the global relation [8] holds.*

*Let $M(x,t,k)$ be the solution of the $2\times 2$ Riemann–Hilbert problem with jump on the real and imaginary axes given by*

- *$M_-(x,t,k)=M_+(x,t,k)J(x,t,k)$ with $M=M_-$ in the second and fourth quadrants of $\mathbb{C}$, $M=M_+$ in the first and third quadrants of $\mathbb{C}$, and $J(x,t,k)$ is defined in terms of a, b, A, B and the exponential $\mathrm{e}^{\mathrm{i}kx-2\mathrm{i}k^2t}$.*
- *$M=I+\mathrm{O}(1/k)$ as $k\to\infty$ and has appropriate residue conditions if there are poles*

  *Then M(x,t,k) exists and is unique, and*

  $$q(x,t) = 2\mathrm{i}\lim_{k\to\infty}(kM(x,t,k))_{12}$$

The result above relies on characterizing the unknown boundary value $g_1(t)$ *a priori* by requiring that the global relation hold. Recently, substantial progress has been made in this direction in the case of integrable nonlinear evolution equations, in particular of NLS. Namely Fokas (in press) contains an effective description of the map assigning to each given $q(x,0)=q_0(x)$ and $g_0(t)=q(0,t)$ a unique value for $q_x(0,t)$ (called the Dirichlet to Neumann map) for the NLS, as well as for a version of the Korteweg–deVries and sG equations. We state below the relevant theorem for the case of the NLS equation.

**Theorem 2** *Let $q(x,t)$ satisfy the NLS equation on the half-line $0<x<\infty, t>0$ with the initial and boundary conditions [7]. Then $g_1(t) := q_x(0,t)$ is given by*

$$\begin{aligned} g_1(t) = {} & \frac{g_0(t)}{\pi}\int_{\partial D} \mathrm{e}^{-2ik^2t}(\Phi_2(t,k)-\Phi_2(t,-k))\mathrm{d}k \\ & + \frac{4i}{\pi}\int_{\partial D} \mathrm{e}^{-2ik^2t} kR(k)\overline{\Phi_2(t,\bar{k})}\mathrm{d}k \\ & + \frac{2i}{\pi}\int_{\partial D} \mathrm{e}^{-2ik^2t}(k[\Phi_1(t,k)-\Phi_1(t,-k)]+\mathrm{i}g_0(t))\mathrm{d}k \end{aligned}$$

*with $\Phi=(\Phi_1,\Phi_2)^\tau$ given by the solution of [10]. The Neumann datum $g_1(t)$ is unique and exists globally in $t$.*

This result yields a rigorous proof of the global existence of the solution of boundary-value problems on the half-line for the NLS equation. Therefore, the assumption in Theorem 1 that a suitable function $g_1(t)$ exists can be dropped.

## Generalizations and Summary of Results

Results analogous to the ones presented in the previous section can be phrased exclusively in terms of integral equations rather than in terms of Riemann–Hilbert problems, as done for example in Khruslov and Kotlyarov (2003). This is the point of view of the school of Gelfand and Marchenko, and in this setting the functions $\Phi$ are given in the so-called Gelfand–Levitan–Marchenko representation. Results on boundary-value problems for the NLS equation using this representation have been obtained only under additional assumptions on the unknown part of the boundary values. It was only after the idea that the $x$- and $t$-parts of the spectral equations should be treated simultaneously that this approach yielded complete results. However, the Gelfand–Levitan–Marchenko representation yields a crucial simplification for deriving the explicit form of the Dirichlet to Neumann map and proving Theorem 2. This representation has now been derived for all equations [1]–[3], see Fokas (in press).

The analysis of the invariance properties of the global relation with respect to $k$ also yields the characterization of all the boundary conditions for which the transform obtained to represent the solution linearizes. For these boundary conditions, called linearizable, the solution can be represented as effectively as for the Cauchy problem. For example, the linearizable boundary conditions for the NLS equation are given by any boundary values that satisfy

$$g_0(t)\overline{g_1(t)} - \overline{g_0(t)}g_1(t) = 0$$

An example of boundary condition satisfying this constraint, encompassing also Dirichlet and Neumann homogeneous conditions, is $q(0,t) - \chi q_x(0,t) = 0$, with $\chi$ a non-negative constant.

As mentioned at the beginning of the previous section, the approach described in general can be used to obtain results similar to those given for the NLS equation for many other integrable evolution equations, in particular, mKdV (Boutet de Monvel *et al.* 2004), sG, and KdV (Fokas 2002). The results obtained are essentially the same as for NLS, starting from the general form [5] of the Lax pair, and include the derivation of the solution representation, the complete characterization of linearizable boundary conditions, and the analysis of the Dirichlet to Neumann map.

The approach above can also be used for studying boundary-value problems posed on finite domains, for $x \in [0,1]$. This has been done for a model for transient simulated Raman scattering (Fokas and Menyuk 1999), for the sG equation in light-cone coordinates (Pelloni, in press), and for the NLS equation (Fokas and Its 2004). In this case also the method yields a representation of the solution which is suitable for asymptotic analysis. In this respect, the question of soliton generation from boundary data is of some importance, and has been recently considered by various authors (Fokas and Menyuk 1999, Boutet de Monvel and Kotlyarov 2003, Pelloni in press, Boutet de Monvel *et al.* 2004). The results are however still considered case by case, and there is no general framework for this problem identified yet. For problem on the half-line, solitons may be generated but not necessarily in correspondence to the singularities that generate soliton for the full line problem, even when the same singularities are present. For problems posed on finite domains, in some specific cases at least for the simulated Raman scattering, and the sG equations, it appears that the dominant asymptotic behavior is given by a similarity solution.

In conclusion, the extension of the inverse scattering transform given by Fokas provides the tool for analyzing boundary-value problems specific to nonlinear integrable equations. This tool relies, in an essential way, on the integrability structure of the problem, and yields a full characterization of the solution as well as uniqueness and existence results. The solution representation thus obtained is not always fully explicit, but it is always suitable for asymptotic analysis using standard techniques such as the recent nonlinearization of the classical steepest descent method.

# Braided and Modular Tensor Categories

**V Lyubashenko**, Institute of Mathematics, Kyiv, Ukraine

## Introduction

Tensor or monoidal categories are encountered in various branches of modern mathematical physics. First examples came without mentioning the name of a monoidal category as categories of modules over a group or a Lie algebra. The operation of a monoidal product in this case is the usual tensor product $X \otimes_{\mathbb{C}} Y$ of modules (representations) $X$ and $Y$. These categories are symmetric: the modules $X \otimes Y$ and $Y \otimes X$ are isomorphic; moreover, the permutation isomorphism (the twist) $\boldsymbol{c}: X \otimes Y \mapsto Y \otimes X$, $x \otimes y \to y \otimes x$, is involutive, $\boldsymbol{c}^2 = \mathrm{id}_{X \otimes Y}$. Next examples of monoidal categories were given by categories of representations of supergroups or Lie superalgebras. They are also symmetric: now the symmetry (Koszul's rule) $\boldsymbol{c}: X \otimes Y \to Y \otimes X$, $x \otimes y \mapsto (-1)^{\deg x \cdot \deg y} y \otimes x$, is the twist with a sign, which depends on the degree (or parity) $\deg x$ of elements $x \in X$.

The development of the theory of exactly solvable models in statistical mechanics led Drinfeld (1987) to the notion of quantum groups – Hopf algebras $H$ with additional structures (quasitriangular Hopf algebras). $H$-Modules also form a monoidal category; however, it is not symmetric, but only braided.

It means that a canonical braiding isomorphism $\boldsymbol{c}: X \otimes Y \to Y \otimes X$ still exists, but it is not involutive any more, $\boldsymbol{c}^2 \neq \mathrm{id}$. The braiding $\boldsymbol{c}$ satisfies the Yang–Baxter equation

$$(\boldsymbol{c} \otimes 1)(1 \otimes \boldsymbol{c})(\boldsymbol{c} \otimes 1) = (1 \otimes \boldsymbol{c})(\boldsymbol{c} \otimes 1)(1 \otimes \boldsymbol{c}) : X \otimes Y \otimes Z \to Z \otimes Y \otimes X$$

for any three $H$-modules $X$, $Y$, $Z$.

In the above examples, we also have an obvious isomorphism of associativity $\boldsymbol{a}: X \otimes (Y \otimes Z) \to (X \otimes Y) \otimes Z$ of the iterated tensor product. There are, however, monoidal categories of modules, where such an isomorphism is nontrivial, namely, modules over quasi-Hopf algebras. These were introduced by Drinfeld (1989a, b) in connection with the Knizhnik–Zamolodchikov equations. These nontrivial associativity isomorphisms $\boldsymbol{a}: X \otimes (Y \otimes Z) \to (X \otimes Y) \otimes Z$ are required to satisfy the pentagon equation of Mac Lane and Stasheff.

Braided monoidal categories also arise in rational conformal field theories (RCFTs), integrable models of statistical mechanics and topological quantum field theories (TQFTs). The common feature of these categories is that they are semisimple abelian with finite number of simple modules. In other words, such a category $\mathcal{C}$ is equivalent to the category of finite-dimensional $\mathbb{C}^n = \mathbb{C} \times \cdots \times \mathbb{C}$-modules for some $n$. However, not monoidally equivalent, the monoidal structure can be rather involved. For instance, from the Ising model one can obtain the monoidal category with two simple objects $I$ and $X$, which obey the monoidal law $\mathbb{1} \otimes \mathbb{1} = \mathbb{1}, \mathbb{1} \otimes X = X \otimes \mathbb{1} = X, X \otimes X = \mathbb{1} \oplus X$. Clearly, such relations cannot be satisfied by finite-dimensional $\mathbb{C}$-vector spaces $\mathbb{1}$ and $X$, if $\otimes$ would mean the usual tensor product $\otimes_{\mathbb{C}}$ of $\mathbb{C}$-vector spaces. However, here $\otimes$ means simply a functor $\otimes: \mathcal{C} \times \mathcal{C} \to \mathcal{C}$ with certain properties. Categories which come from RCFT, integrable models or TQFT often enjoy additional properties. They are *rigid* – for each object $X$, there exists a dual object $X^\vee$. They are *ribbon* (balanced) – there is a canonical endomorphism $\upsilon_X : X \to X$ for each object $X$, which is related to the braiding. They are *modular*, which is defined as nondegeneracy of a certain matrix. The meaning of modularity is that the ribbon category is suitable for producing a TQFT out of it.

For categories equivalent to the category of $\mathbb{C} \times \cdots \times \mathbb{C}$-modules, the ribbon (braided) monoidal structure can be specified by a finite number of complex matrices. For instance, $6j$-symbols or $q$-$6j$-symbols encode the associativity isomorphism. In this form, modular categories appeared in the work of Moore and Seiberg (1989) on RCFTs. Such categories can be realized as categories of modules over *weak Hopf algebras*, but we stress again that the monoidal product for such modules does not coincide with the tensor product of vector spaces. So, general features are better seen at the level of category theory, and we now start with precise definitions.

## Rigid Monoidal Categories

We recall here the basic definitions of monoidal categories, monoidal functors, and dual objects.

**Definition 1** A monoidal category $(\mathcal{C}, \otimes, \boldsymbol{a}, \mathbb{1}, \boldsymbol{l}, \boldsymbol{r})$ is a category $\mathcal{C}$, a functor $\otimes: \mathcal{C} \times \mathcal{C} \to \mathcal{C}$ (called the tensor product), a functorial isomorphism $\boldsymbol{a}: X \otimes (Y \otimes Z) \to (X \otimes Y) \otimes Z$, the associativity isomorphism, a unit object $\mathbb{1}$, and two functorial isomorphisms $\boldsymbol{l}: \mathbb{1} \otimes X \to X, \boldsymbol{r}: X \otimes \mathbb{1} \to X$ such that

$$\begin{array}{ccc} X \otimes (Y \otimes (Z \otimes W)) \xrightarrow{a} (X \otimes Y) \otimes (Z \otimes W) & \xrightarrow{a} & ((X \otimes Y) \otimes Z) \otimes W \\ {\scriptstyle X \otimes a}\downarrow & & \uparrow{\scriptstyle a \otimes W} \\ X \otimes ((Y \otimes Z) \otimes W) & \xrightarrow{\quad a \quad} & (X \otimes (Y \otimes Z)) \otimes W \end{array}$$

commutes (the pentagon equation) and

$$\boldsymbol{a}_{X,\mathbb{1},Y} = \left( X \otimes (\mathbb{1} \otimes Y) \xrightarrow{X \otimes l_Y} X \otimes Y \xrightarrow{r_X^{-1} \otimes Y} (X \otimes \mathbb{1}) \otimes Y \right)$$

**Definition 2** A monoidal functor $(F, \phi, \boldsymbol{f}): (\mathcal{C}, \otimes) \to (\mathcal{D}, \otimes)$ is a functor $F: \mathcal{C} \to \mathcal{D}$, a functorial isomorphism $\phi = \phi_{X,Y} : F(X) \otimes F(Y) \to F(X \otimes Y) \in \mathcal{D}$, and an isomorphism $\boldsymbol{f}: \mathbb{1} \to F\mathbb{1} \in \mathcal{D}$ such that

$$\begin{array}{ccc} FX \otimes (FY \otimes FZ) \xrightarrow{1 \otimes \phi} FX \otimes F(Y \otimes Z) & \xrightarrow{\phi} & F(X \otimes (Y \otimes Z)) \\ \boldsymbol{a}\downarrow & & \downarrow F\boldsymbol{a} \\ (FX \otimes FY) \otimes FZ \xrightarrow{\phi \otimes 1} F(X \otimes Y) \otimes Z & \xrightarrow{\phi} & F((X \otimes Y) \otimes Z) \end{array}$$

$$\begin{array}{ccc} F\mathbb{1} \otimes FX \xrightarrow{\phi} F(\mathbb{1} \otimes X) & & FX \otimes F\mathbb{1} \xrightarrow{\phi} F(X \otimes \mathbb{1}) \\ {\scriptstyle f \otimes 1}\uparrow \qquad \downarrow{\scriptstyle Fl,} & & {\scriptstyle 1 \otimes f}\uparrow \qquad \downarrow{\scriptstyle Fr} \\ \mathbb{1} \otimes FX \xrightarrow{\ l\ } FX & & FX \otimes \mathbb{1} \xrightarrow{\ r\ } FX \end{array}$$

commute. A morphism of monoidal functors $\lambda: (F, \phi, \boldsymbol{f}) \to (G, \psi, \boldsymbol{g})$ is a functorial morphism $\lambda: F \to G$ such that

$$\begin{array}{ccc} FX \otimes FY & \xrightarrow{\phi} & F(X \otimes Y) \\ {\scriptstyle \lambda \otimes \lambda}\downarrow & & \downarrow{\scriptstyle \lambda} \\ GX \otimes GY & \xrightarrow{\psi} & G(X \otimes Y) \end{array}$$

$$g = (\mathbb{1} \xrightarrow{f} F\mathbb{1} \xrightarrow{\lambda} G\mathbb{1})$$

The $f$ datum of a monoidal functor $(F, \phi, f)$ is uniquely determined by the $(F, \phi)$ data, so we can denote a monoidal functor as $(F, \phi)$ or even $F$.

The coherence theorem of Mac Lane (1963) states that any monoidal category $\mathcal{C}$ is equivalent to a strictly monoidal category, in which $X \otimes (Y \otimes Z) = (X \otimes Y) \otimes Z, \mathbb{1} \otimes X = X = X \otimes \mathbb{1}$, and the isomorphisms $\boldsymbol{a}, \boldsymbol{l}, \boldsymbol{r}$ are identity isomorphisms. Thus, in theoretical constructions, one may ignore the associativity isomorphism. It is not always so in practice. For instance, working with quasi-Hopf algebras related with the Knizhnik–Zamolodchikov equation one prefers to keep the original category, which is (a deformation of) the category of modules over a Lie algebra, rather than to replace it with a strict monoidal category, that is not a category of modules any more.

**Definition 3** A rigid category $\mathcal{C}$ is a monoidal category in which, to every object $X \in \mathcal{C}$, dual objects $X^\vee$ and ${}^\vee X \in \mathcal{C}$ are assigned together with morphisms of evaluation and coevaluation

$$\mathrm{ev}_X : X \otimes X^\vee \to \mathbb{1} = X \bigcup X^\vee$$

$$\mathrm{ev}'_X : {}^\vee X \otimes X \to \mathbb{1} = {}^\vee X \bigcup X$$

$$\mathrm{coev}_X : \mathbb{1} \to X^\vee \otimes X = X^\vee \bigcap X$$

$$\mathrm{coev}'_X : \mathbb{1} \to X \otimes {}^\vee X = X \bigcap {}^\vee X$$

The evaluations and coevaluations are chosen such that the compositions

$$X \xrightarrow{r^{-1}} X \otimes \mathbb{1} \xrightarrow{1\otimes\mathrm{coev}} X \otimes (X^\vee \otimes X) \xrightarrow{a} (X \otimes X^\vee) \otimes X \xrightarrow{\mathrm{ev}\otimes 1} \mathbb{1} \otimes X \xrightarrow{1} X$$

$$X \xrightarrow{1^{-1}} \mathbb{1} \otimes X \xrightarrow{\mathrm{coev}'\otimes 1} (X \otimes {}^\vee X) \otimes X \xrightarrow{a^{-1}} X \otimes ({}^\vee X \otimes X) \xrightarrow{1\otimes\mathrm{ev}'} X \otimes \mathbb{1} \xrightarrow{r} X$$

$$X^\vee \xrightarrow{1^{-1}} \mathbb{1} \otimes X^\vee \xrightarrow{\mathrm{coev}\otimes 1} (X^\vee \otimes X) \otimes X^\vee \xrightarrow{a^{-1}} X^\vee \otimes (X \otimes X^\vee) \xrightarrow{1\otimes\mathrm{ev}} X^\vee \otimes \mathbb{1} \xrightarrow{r} X^\vee$$

$${}^\vee X \xrightarrow{r^{-1}} {}^\vee X \otimes \mathbb{1} \xrightarrow{1\otimes\mathrm{coev}'} {}^\vee X \otimes (X \otimes {}^\vee X) \xrightarrow{a} ({}^\vee X \otimes X) \otimes {}^\vee X \xrightarrow{\mathrm{ev}'\otimes 1} \mathbb{1} \otimes {}^\vee X \xrightarrow{1} {}^\vee X$$

are all identity morphisms.

In a rigid monoidal category $\mathcal{C}$, there is a pairing

$$(X \otimes Y) \otimes (Y^\vee \otimes X^\vee) \xrightarrow{\sim} (X \otimes (Y \otimes Y^\vee)) \otimes X^\vee \xrightarrow{X\otimes\mathrm{ev}\otimes X^\vee} (X \otimes \mathbb{1}) \otimes X^\vee \xrightarrow{r\otimes X^\vee} X \otimes X^\vee \xrightarrow{\mathrm{ev}} \mathbb{1}$$

which induces an isomorphism $j_{+X,Y} : Y^\vee \otimes X^\vee \to (X \otimes Y)^\vee$, such that the above pairing coincides with

$$(X \otimes Y) \otimes (Y^\vee \otimes X^\vee) \xrightarrow{1\otimes j_+} (X \otimes Y) \otimes (X \otimes Y)^\vee \xrightarrow{\mathrm{ev}} \mathbb{1}$$

The equation

$$\mathrm{coev}_{X\otimes Y} = \Big(\mathbb{1} \xrightarrow{\mathrm{coev}_Y} Y^\vee \otimes Y \simeq Y^\vee \otimes \mathbb{1} \otimes Y \xrightarrow{1\otimes\mathrm{coev}_X\otimes 1} Y^\vee \otimes X^\vee \otimes X \otimes Y \xrightarrow{j_+\otimes 1} (X \otimes Y)^\vee \otimes (X \otimes Y)\Big)$$

also holds. Similarly, there is an isomorphism $j_{-X,Y} : {}^\vee Y \otimes {}^\vee X \to {}^\vee(X \otimes Y)$.

Morphisms constructed from braidings and (co)-evaluations are often described by tangles. The conventions are listed in Figure 1. The suggested assignment of morphisms in $\mathcal{C}$ to elementary pictures extends to a unique functor $\Phi$ from the category of $\mathcal{C}$-colored tangles to the category $\mathcal{C}$ itself. With the above interpretation, these tangles need not be oriented. We shall use the same notation for framed tangles, and the framing will be within the plane.

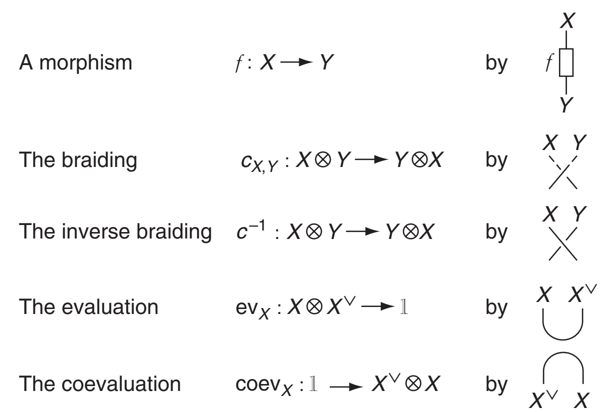

**Figure 1** Conventions for notation of morphisms from tangles.

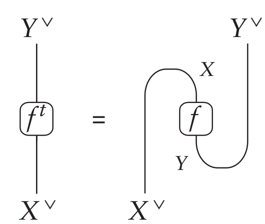
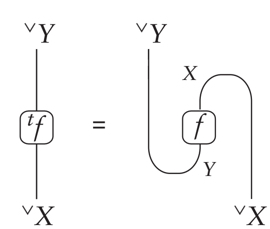
The maps $\mathrm{Ob}\,\mathcal{C} \to \mathrm{Ob}\,\mathcal{C}, X \mapsto X^\vee$, and $X \mapsto {}^\vee X$ extend to contravariant self-equivalences $\mathcal{C} \to \mathcal{C}$, $f \mapsto f^{\mathrm{t}}$, and $f \mapsto {}^{\mathrm{t}}f$. For given $f$, the morphisms $f^{\mathrm{t}}$ and ${}^{\mathrm{t}}f$ can be defined, respectively, by the following pictures using the assignment from Figure 1:





We have a monoidal self-equivalence of $\mathcal{C}$,

$$(-^{\vee\vee}, j_2) : (\mathcal{C}, \otimes, \mathbb{1}) \to (\mathcal{C}, \otimes, \mathbb{1}),\ X \mapsto X^{\vee\vee},\ f \mapsto f^{\mathrm{tt}}$$

$$j_{2X,Y} = \left(X^{\vee\vee} \otimes Y^{\vee\vee} \xrightarrow{j_+} (Y^\vee \otimes X^\vee)^\vee \xrightarrow{j_+^{-1\mathrm{t}}} (X \otimes Y)^{\vee\vee}\right) \qquad [1]$$

It is not always true that the two duals $X^\vee$ and ${}^\vee X$ are isomorphic. However, there are canonical isomorphisms

$$X \to {}^\vee(X^\vee), \qquad X \to ({}^\vee X)^\vee$$

We may replace the category $\mathcal{C}$ with an equivalent one, such that the above isomorphisms become identity morphisms, and the functors $-^\vee$ and ${}^\vee-$ are inverse to each other. We shall assume this to simplify notations. Finally, we denote the iterated duals by $X^{(n\vee)} = X^{\vee\cdots\vee}$ ($n$ times) and $X^{(-n\vee)} = {}^{\vee\cdots\vee}X$ ($n$ times) for $n \geq 0$.

## Braided Categories

Here we review the definitions of the braiding isomorphism and further derived isomorphisms. Several basic relations between them are listed. Two important classes of examples of braided categories are given by the categories of modules over quasitriangular Hopf algebras and the categories of tangles.

**Definition 4** A braided category $(\mathcal{C}, c)$ is a monoidal category $\mathcal{C}$ equipped with a functorial isomorphism $c = c_{X,Y} : X \otimes Y \to Y \otimes X$ – the braiding, or the commutativity isomorphism – such that the two hexagons commute,

$$\begin{array}{ccccc} X\otimes(Y\otimes Z) & \xrightarrow{1\otimes c^{\pm1}} & X\otimes(Z\otimes Y) & \xrightarrow{a} & (X\otimes Z)\otimes Y \\ a\downarrow & & & & \downarrow c^{\pm1}\otimes 1 \\ (X\otimes Y)\otimes Z & \xrightarrow{c^{\pm1}} & Z\otimes(X\otimes Y) & \xrightarrow{a} & (Z\otimes X)\otimes Y \end{array}$$

(one for $c$ and one for $c^{-1}$).

The graphical notation for the braiding and its inverse is

$c = (c_{X,Y} : X \otimes Y \to Y \otimes X) =$ 

$c =$ 

In a rigid braided category, we can define functorial isomorphisms using again the conventions from Figure 1:

$u_1^2 =$ 
, $u_{-1}^2 =$ 

$u_{-1}^{-2} =$ 
, $u_{-1}^{-2} =$ 

These are isomorphisms of monoidal functors (see [1])

$$u_1^2 : (\mathrm{Id}, c^{-2}) \longrightarrow (-^{\vee\vee}, j_2)$$
$$u_{-1}^2 : (\mathrm{Id}, c^2) \longrightarrow (-^{\vee\vee}, j_2)$$

In particular, this implies the commutativity of the diagram

$$\begin{array}{ccc} X\otimes Y & \xrightarrow{c^{-2}} & X\otimes Y \\ u_1^2\otimes u_1^2\downarrow & & \downarrow u_1^2 \\ X^{\vee\vee}\otimes Y^{\vee\vee} & \xrightarrow{j_2} & (X\otimes Y)^{\vee\vee} \end{array}$$

The square of the monoidal functor $(-^{\vee\vee}, j_2)$ is

$$(-^{\vee\vee\vee\vee}, j_4) : (\mathcal{C}, \otimes, \mathbb{1}) \longrightarrow (\mathcal{C}, \otimes, \mathbb{1}),$$
$$X \mapsto X^{\vee\vee\vee\vee}, \quad f \mapsto f^{\mathrm{tttt}}$$

where

$$j_{4X,Y} = \left( X^{\vee\vee\vee\vee} \otimes Y^{\vee\vee\vee\vee} \xrightarrow{j_2} (X^{\vee\vee} \otimes Y^{\vee\vee})^{\vee\vee} \xrightarrow{j_2^{\mathrm{tt}}} (X \otimes Y)^{\vee\vee\vee\vee} \right)$$

The natural isomorphism $u_0^4 = u_{-1}^2 \circ u_1^2$ is, in fact, an isomorphism of monoidal functors $u_0^4 : (\mathrm{Id}, \mathrm{id}) \to (-^{\vee\vee\vee\vee}, j_4)$.

## Ribbon Categories

Now we define balancing and recall some properties of balanced (ribbon) categories.

**Definition 5** Let $\mathcal{C}$ be a rigid braided category. A balancing $\beta_X : X \to X^{\vee\vee}$ is an isomorphism of monoidal functors $\beta : (\mathrm{Id}, \mathrm{id}, \mathrm{id}) \to (-^{\vee\vee}, j_2, d_2)$ such that $\beta^2 = u_0^4$ and $\beta_X^{\mathrm{t}} = \beta_{X^\vee}^{-1} : X^{\vee\vee\vee} \to X^\vee$. The category $\mathcal{C}$ equipped with a balancing is called balanced.

We also use the notation $u_0^2 = \beta$. In any balanced category, there exists a canonical ribbon twist $v$. A *ribbon twist* $v = v_X : X \to X, v : \mathrm{Id} \to \mathrm{Id}$ is a self-adjoint $(v_{X^\vee} = v_X^{\mathrm{t}})$ automorphism of the identity functor such that $c^2 = (v_X^{-1} \otimes v_Y^{-1}) \circ v_{X\otimes Y}$. It can be determined from the equations

$$u_0^2 = u_1^2 \circ v^{-1} = u_{-1}^2 \circ v : X \to X^{\vee\vee}$$
$$\beta^{-1} = u_0^{-2} = u_1^{-2} \circ v^{-1} = u_{-1}^{-2} \circ v : X \to {}^{\vee\vee}X$$

In particular, its square is given by the canonical isomorphism $v^2 = u_1^{-2} \circ u_1^2$. Conversely, in any rigid braided category with a ribbon twist (called *ribbon category*) there exists a canonical balancing $u_0^2$ given by the above formulas. Thus, ribbon categories and balanced categories are synonyms.

In the case of $X = \mathbb{1}$, we have $v_{\mathbb{1}} = \mathrm{id}_{\mathbb{1}}$.

The following result can be used to simplify notations:

**Proposition 1** *For any ribbon category $\mathcal{C}$ there exists a ribbon category $\mathcal{D}$ equivalent to $\mathcal{C}$ such that in it*

(i) $\mathbb{1}^\vee = \mathbb{1}$;
(ii) *for any object $X$ we have* ${}^\vee X = X^\vee, X^{\vee\vee} = X$, *and* $\beta_X = \mathrm{id}_X : X \to X^{\vee\vee} = X$.
(iii) *for any object $X$ we have* $\mathrm{ev}_X = \mathrm{ev}'_{X^\vee} : X \otimes X^\vee \to \mathbb{1}$, *and* $\mathrm{coev}_X = \mathrm{coev}'_{X^\vee} : \mathbb{1} \to X^\vee \otimes X$.

In the category $\mathcal{C} = H$-mod, where $H$ is a ribbon Hopf algebra, the equation $X^\vee = {}^\vee X$ is not necessarily satisfied. Nevertheless, $X^\vee$ is canonically isomorphic to ${}^\vee X$. The same holds in any ribbon category. We identify these objects via $\beta = \boldsymbol{u}_0^2$: ${}^\vee X \to X^\vee$. This allows us to use the right dual objects in place of the left ones. In that role, the right duals are equipped with the left evaluation and coevaluation, called flipped evaluation and coevaluation, respectively:

$$\widetilde{\mathrm{ev}} : X^\vee \otimes X \xrightarrow{X^\vee \otimes \beta} X^\vee \otimes X^{\vee\vee} \xrightarrow{\mathrm{ev}} \mathbb{1}$$

$$\widetilde{\mathrm{coev}} : \mathbb{1} \xrightarrow{\mathrm{coev}} X^{\vee\vee} \otimes X^\vee \xrightarrow{\beta^{-1} \otimes X^\vee} X \otimes X^\vee$$

They are often denoted simply ev and coev and should be replaced by $\widetilde{\mathrm{ev}}$ and $\widetilde{\mathrm{coev}}$ in applications. In the context of Hopf algebra, $\beta$ is given by the action of a group-like element introduced by Drinfeld.

## Hopf Algebras in Braided Categories

Let $\mathcal{C}$ be a braided monoidal category. A Hopf algebra $H$ in $\mathcal{C}$ is an object $H \in \mathrm{Ob}\,\mathcal{C}$ together with an associative multiplication $m : H \otimes H \to H$ and an associative comultiplication $\Delta : H \to H \otimes H$, obeying the bialgebra axiom

$$\left(H \otimes H \xrightarrow{m} H \xrightarrow{\Delta} H \otimes H\right)$$
$$= \left(H \otimes H \xrightarrow{\Delta \otimes \Delta} H \otimes H \otimes H \otimes H \xrightarrow{H \otimes c \otimes H} H \otimes H \otimes H \otimes H \xrightarrow{m \otimes m} H \otimes H\right)$$

Moreover, $H$ has a unit $\eta : \mathbb{1} \to H$, a counit $\varepsilon : H \to \mathbb{1}$, an antipode $\gamma : H \to H$, and the inverse antipode $\gamma^{-1} : H \to H$. The defining relations for these are the same as in the classical case. Notice, in particular, that the unit is also a morphism. Associativity of multiplication, as well as coassociativity of comultiplication, is formulated with the use of associativity isomorphism (in the nonstrict case).

Hopf algebras in braided categories have also been called braided groups. Their basic properties are very similar to those of usual Hopf algebras, for example, the antipode is antimultiplicative with respect to the braiding (see, e.g., Majid (1993)). For Hopf algebras in rigid braided categories, there exist integrals in a sense very much similar to the case of ordinary finite-dimensional Hopf algebras, as shown by Bespalov *et al.* (2000).

## Modular Categories

Assume that a braided rigid monoidal category $\mathcal{C}$ is equivalent as a category (with monoidal structure ignored) to the category of finite-dimensional modules over a finite-dimensional algebra. In particular, $\mathcal{C}$ is abelian. Then there exists an object $F$ in $\mathcal{C}$, equipped with a morphism $i_X : X \otimes X^\vee \to F$ for each $X \in \mathrm{Ob}\,\mathcal{C}$, such that the diagram

$$\begin{array}{ccc} X \otimes Y^\vee & \xrightarrow{f \otimes Y^\vee} & Y \otimes Y^\vee \\ {\scriptstyle X \otimes f^t}\downarrow & & \downarrow{\scriptstyle i_Y} \\ X \otimes X^\vee & \xrightarrow{i_X} & F \end{array}$$

is commutative for all morphisms $f : X \to Y$ of $\mathcal{C}$, and, moreover, $F$ is universal between objects with such properties. Here $f^t : Y^\vee \to X^\vee$ is the transpose of a morphism $f : X \to Y$. In other words, $F$ is a direct limit, called the coend and denoted as $F = \int^{Z \in \mathcal{C}} Z \otimes Z^\vee$. It can also be defined via an exact sequence

$$\bigoplus_{f : X \to Y \in \mathcal{C}} X \otimes Y^\vee \xrightarrow{f \otimes Y^\vee - X \otimes f^t} \bigoplus_{Z \in \mathcal{C}} Z \otimes Z^\vee \xrightarrow{\oplus i_Z} F \to 0$$

It turns out that the coend $F$ is a Hopf algebra in the braided category $\mathcal{C}$, when it is equipped with the following operations. The comultiplication in $F$ is uniquely determined by the equation

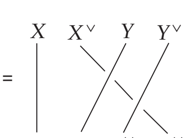
$$\left(X \otimes X^\vee \xrightarrow{i_X} F \xrightarrow{\Delta} F \otimes F\right)$$
$$= \left(X \otimes X^\vee = X \otimes \mathbb{1} \otimes X^\vee \xrightarrow{X \otimes \mathrm{coev} \otimes X^\vee} X \otimes X^\vee \otimes X \otimes X^\vee \xrightarrow{i_X \otimes i_X} F \otimes F\right)$$

The counit in $F$ is determined by the equation

$$\left(X \otimes X^\vee \xrightarrow{i_X} F \xrightarrow{\varepsilon} \mathbb{1}\right) = \left(X \otimes X^\vee \xrightarrow{\mathrm{ev}} \mathbb{1}\right)$$

The multiplication $m : F \otimes F \to F$ is defined by the following diagram:

$m$ =



and

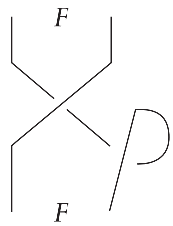
$$\begin{array}{ccc} X \otimes X^\vee \otimes (Y \otimes Y^\vee) & \xrightarrow{i_X \otimes i_Y} & F \otimes F \\ {\scriptstyle X \otimes c}\downarrow & & \exists\downarrow{\scriptstyle m} \\ X \otimes Y \otimes (X \otimes Y)^\vee & \xrightarrow{i_{X \otimes Y}} & F \end{array}$$

The unit is given by the morphism

$$\eta : \mathbb{1} = \mathbb{1} \otimes \mathbb{1}^{\vee} \xrightarrow{i_{\mathbb{1}}} F$$

The diagram corresponding to the antipode $\gamma_F : F \to F$ is given by

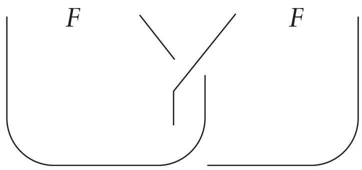
$\gamma_F =$



The structure of the coend $F$ as a Hopf algebra can also be found directly from its universal property, as in Majid (1993).

There is a pairing of Hopf algebras $\omega : F \otimes F \to \mathbb{1}$ in $\mathcal{C}$:

$\omega =$



It induces a homomorphism of Hopf algebras $F \to F^{\vee}$.

**Definition 6** A ribbon category $\mathcal{C}$, equivalent as a category to the category of finite-dimensional modules over a finite-dimensional algebra, is called modular if the pairing $\omega$ is nondegenerate, that is, the induced morphism $F \to F^{\vee}$ is invertible.

Examples of nonsemisimple modular categories include $\mathcal{C} = H$-mod, where $H = u_q(\mathfrak{g})$ is a finite-dimensional algebra, quotient of the quantum universal enveloping algebra $U_q(\mathfrak{g})$, and $q$ is a root of unity of odd degree. In these examples, the coalgebra $F$ identifies with the dual Hopf algebra $H^*$, but the multiplication in $F$ differs from that of $H^*$. Explicit formula for the multiplication in $F$ uses the $R$-matrix for $H$ (see, e.g., Majid (1993)). A definition of modularity for another type of categories (not necessarily abelian) was given by Turaev (1994).

When the category $\mathcal{C}$ is modular, the integrals for the Hopf algebra $F$ have especially simple properties. The integral element in $F$ is two sided. It is a morphism $\mu : \mathbb{1} \to F$ such that

$$\left(F = F \otimes \mathbb{1} \xrightarrow{1 \otimes \mu} F \otimes F \xrightarrow{m} F\right)$$
$$= \left(F \xrightarrow{\varepsilon} \mathbb{1} \xrightarrow{\mu} F\right)$$
$$= \left(F = \mathbb{1} \otimes F \xrightarrow{\mu \otimes 1} F \otimes F \xrightarrow{m} F\right)$$

and $\mu$ is universal between morphisms with such property. By duality, the integral functional $\lambda : F \to \mathbb{1}$ is also two sided. It satisfies

$$\left(F \xrightarrow{\Delta} F \otimes F \xrightarrow{1 \otimes \lambda} F \otimes \mathbb{1} = F\right)$$
$$= \left(F \xrightarrow{\lambda} \mathbb{1} \xrightarrow{\eta} F\right)$$
$$= \left(F \xrightarrow{\Delta} F \otimes F \xrightarrow{\lambda \otimes 1} \mathbb{1} \otimes F = F\right)$$

and is universal between morphisms with such property. The integral element and the integral functional are unique up to a multiplication by an element of $\mathrm{Aut}_{\mathcal{C}}\, \mathbb{1}$.

## Semisimple Abelian Modular Categories

Reshetikhin and Turaev proposed to construct invariants of 3-manifolds via quantum groups. More precisely, they use certain abelian semisimple ribbon categories obtained from quantum groups at roots of unity as trace quotients. One can forget about the origin of these categories and work simply with semisimple modular categories. We shall describe them as input data for the modular functor construction.

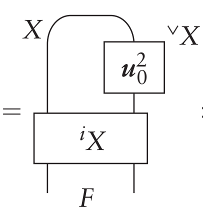
Let $\mathcal{C}$ be a $\mathbb{C}$-linear abelian semisimple modular ribbon category. Assume that the number of isomorphism classes of simple objects is finite. Assume also that $\mathbb{1}$ is simple and for each simple object $X$ the endomorphism algebra End $X = \mathbb{C}$. We denote by $\mathcal{S} = \{X_i\}_i$ the list of (representatives of isomorphism classes of) all simple objects.

Under these assumptions, many formulas simplify. The coend $F \in \mathcal{C}$ takes the form

$$F = \bigoplus_{X \in \mathcal{S}} X \otimes X^{\vee} \in \mathcal{C}$$

Any morphism $\mathbb{1} \to F$ is a $\mathbb{C}$-linear combination of the standard morphisms for $X \in \mathcal{S}$,

$\phi_X =$



$$: \mathbb{1} \xrightarrow{\mathrm{coev}} X \otimes {}^{\vee}X \xrightarrow{1 \otimes u_0^2} X \otimes X^{\vee} \xrightarrow{i} F$$

The morphisms $\phi_X$ form a basis of the commutative algebra $\mathrm{Inv}\, F = \mathrm{Hom}_{\mathcal{C}}(\mathbb{1}, F)$. The Grothendieck ring of the category $\mathcal{C}$ determines the multiplication law in $\mathrm{Inv}\, F$ via the algebra isomorphism $\mathbb{C} \otimes_{\mathbb{Z}} K_0(\mathcal{C}) \to \mathrm{Inv}\, F, [X] \mapsto \phi_X$.

Any morphism $F \to \mathbb{1}$ can be represented as a linear combination of the morphisms

$$\psi_X : F \xrightarrow{\mathrm{pr}_X} X \otimes X^{\vee} \xrightarrow{\mathrm{ev}_X} \mathbb{1}$$

where $X \in \mathcal{S}$. The functional $\psi_1 : F \to \mathbb{1}$ satisfies the properties of a two-sided integral $\lambda$ of the braided Hopf algebra $F$.

### The Verlinde Formula

The number

$\dim_q(X) =$ 

$$: \mathbb{1} \xrightarrow{\text{coev}} X^\vee \otimes X \xrightarrow{1\otimes u_0^2} X^\vee \otimes X^{\vee\vee} \xrightarrow{\text{ev}} \mathbb{1}$$

is called the dimension of an object $X \in \mathrm{Ob}\,\mathcal{C}$. (The index $q$ reminds us that this number coincides with the $q$-dimension in the case $\mathcal{C} = U_q(\mathfrak{g})$-mod.) We have $\dim_q(X^\vee) = \dim_q(X)$.

**Definition 7** Introduce a biadditive function of two variables $\mathsf{s} : \mathrm{Ob}\,\mathcal{C} \times \mathrm{Ob}\,\mathcal{C} \to \mathbb{C}$ on the class of objects of $\mathcal{C}$:

$\mathsf{s}_{XY} =$ 

In particular, its restriction to $\mathcal{S}$ is a matrix $\mathsf{s}|_{\mathcal{S}} : \mathcal{S} \times \mathcal{S} \to \mathbb{C}$, denoted again by $\mathsf{s} = (\mathsf{s}_{XY})_{X,Y\in\mathcal{S}}$ by abuse of notation; here $X$ and $Y$ run over simple objects.

Notice that $\mathsf{s}_{XY} = \mathsf{s}_{YX}$, so the matrix $\mathsf{s}$ is symmetric. Let us consider the $\mathbb{C}$-algebra $\mathrm{Inv}\,F = \mathrm{Hom}_{\mathcal{C}}(\mathbb{1}, F)$. It has the basis $\phi_X, X \in \mathcal{S}$; hence, it is $n$-dimensional, where $n = \mathrm{Card}\,\mathcal{S}$. The form $\omega$ on $F$ induces a bilinear form

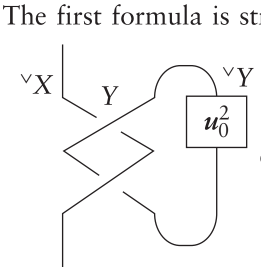
$$\omega' : \mathrm{Inv}\,F \times \mathrm{Inv}\,F \xrightarrow{\otimes} \mathrm{Hom}(\mathbb{1}, F \otimes F) \xrightarrow{\mathrm{Hom}(1,\omega)} \mathbb{1}$$

The matrix $(\mathsf{s}_{XY})$ is the matrix of the form $\omega'$ in the basis $(\phi_X)$.

**Lemma 1** (The Verlinde formula) *For any simple $X \in \mathcal{S}$ and any objects $Y$ and $Z$ of $\mathcal{C}$, we have*

$$\mathsf{s}_{X1} = \dim_q(X), \qquad \mathsf{s}_{X1}\mathsf{s}_{X,Y\otimes Z} = \mathsf{s}_{XY}\mathsf{s}_{XZ} \qquad [2]$$

**Proof** The first formula is straightforward. Since



$\in \mathrm{End}\,^\vee X \simeq \mathbb{C}$

is a number, we can move it from the second factor to the first in the following computation:

$\mathsf{s}_{X1}\mathsf{s}_{X,Y\otimes Z}$

$=$ 

$=$ 

$= \mathsf{s}_{XY}\mathsf{s}_{XZ}$

This proves the second formula. □

**Proposition 2** (Criterion of modularity) *In the above assumption of semisimplicity, the following conditions are equivalent:*

(i) *$\mathcal{C}$ is modular ($\omega$ is nondegenerate);*
(ii) *the matrix $(\mathsf{s}_{XY})_{X,Y\in\mathcal{S}}$ is nondegenerate;*
(iii) *for any $X \in \mathcal{S}$ its dimension $\dim_q X$ does not vanish, and there exist numbers $\mu'_Y, Y \in \mathcal{S}$, such that for all $X \in \mathcal{S}$ we have $\sum_{Y\in\mathcal{S}} \mathsf{s}_{XY}\mu'_Y = \delta_{X1}$; and*
(iv) *for each simple $X \not\simeq \mathbb{1}$ we have $\sum_{Y\in\mathcal{S}} \mathsf{s}_{XY} \dim_q Y = 0$ and $\dim_q X \neq 0$.*

The easy implication (ii) $\Longrightarrow$ (iii) can be deduced from the Verlinde formula. If the dimension $\dim_q(X) = \mathsf{s}_{X1}$ of a simple object $X$ vanishes, then $\mathsf{s}_{XY}^2 = 0$ for all $Y \in \mathrm{Ob}\,\mathcal{C}$. This contradicts to the assumption of nondegeneracy of $(\mathsf{s}_{XY})$.

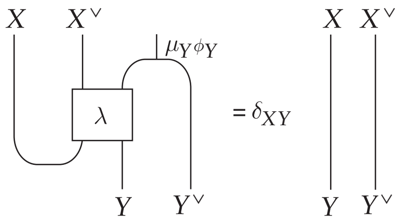
Let us determine the coefficients $\mu_Y$ of the integral element

$$\mu = \sum_{Y\in\mathcal{S}} \mu_Y \phi_Y : \mathbb{1} \to F$$

of the Hopf algebra $F$. It also has a two-sided integral-functional $\lambda : F \to \mathbb{1}$. The corresponding endomorphism is

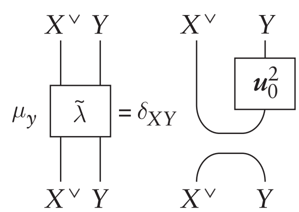
$$\tilde{\lambda}_Z = \left(Z \xrightarrow{\delta_Z} F \otimes Z \xrightarrow{\lambda\otimes Z} \mathbb{1} \otimes Z =\!= Z\right)$$

for an arbitrary object $Z$ of $\mathcal{C}$, where $\delta_Z$ is the natural coaction. The equation



[3]

follows from the properties of the two-sided integral $\lambda$ of the Hopf algebra $F$. Due to uniqueness of integrals, $\lambda$ is proportional to $\psi_1$. In eqn [3], $X$ and $Y$ vary over $\mathcal{S}$. The right-hand side is the identity morphism if $X = Y$, and vanishes otherwise. Substituting the definition of $\phi_Y$, we rewrite the equation as follows:



[4]

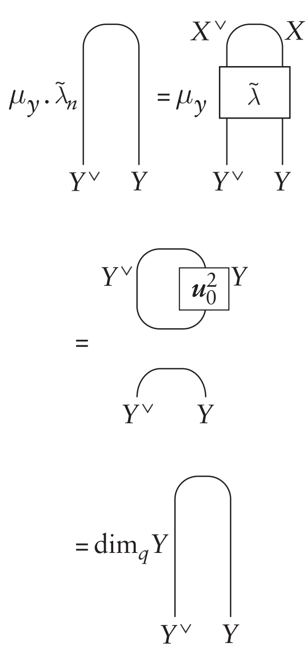
For $X = 1$, we get

$$\mu_Y \cdot \tilde{\lambda}_Y = \delta_{1Y} \cdot \mathrm{id}_Y : Y \to Y \qquad [5]$$

If $Y \not\cong \mathbb{1}$, then $\tilde{\lambda}_Y = 0$. So [5] tells essentially that

$$\mu_1 \cdot \tilde{\lambda}_1 = \mathrm{id}_1 : \mathbb{1} \to \mathbb{1} \qquad [6]$$

Now return to [4] with $X = Y$. If we compose that equation with $\mathrm{coev} : \mathbb{1} \to Y^\vee \otimes Y$, we obtain

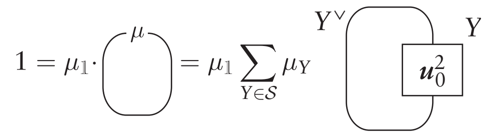


[7]

Multiplying both sides of [7] with $\mu_1$, we find

$$\mu_Y = \mu_1 \cdot \dim_q(Y)$$

The normalization is fixed by eqn [6], which we can write as



$$= \mu_1^2 \sum_{Y \in \mathcal{S}} (\dim_q(Y))^2$$

Hence,

$$(\mu_1)^2 = \left( \sum_{Y \in \mathcal{S}} (\dim_q(Y))^2 \right)^{-1} \qquad [8]$$

So, we find $\mu_1$, unique up to a sign.

## Conjugation Properties

From the Verlinde formula [2], we conclude that the commutative $\mathbb{C}$-algebra $\mathrm{Inv}\, F$ possesses homomorphisms

$$\chi_X : \mathrm{Inv}\, F \to \mathbb{C}$$
$$\phi_Y \mapsto (\dim_q(X))^{-1} s_{XY} = s_{XY}/s_{X1}$$

The matrix $s$ is invertible, so that its columns cannot be proportional. Hence, all $\chi_X$ are different characters. Their number is $n = \mathrm{Card}\, \mathcal{S} = \dim_{\mathbb{C}} F$; hence, there is an isomorphism of $\mathbb{C}$-algebras

$$\chi : \mathrm{Inv}\ F \to \mathbb{C} \times \cdots \times \mathbb{C} = \mathbb{C}^n$$
$$\phi \mapsto (\chi_1(\phi), \ldots, \chi_n(\phi))$$

Now we show that the dimensions $\dim_q(Y)$ are real numbers, so that $\mu_1$ is also a real number. One can introduce in $\mathrm{Inv}\ F$ an antilinear involution,

$$-^* : \mathrm{Inv}\, F \to \mathrm{Inv}\, F, \quad (\phi_X)^* = \phi_{X^\vee}$$

and a scalar (Hermitian) product

$$(\phi_X | \phi_Y) = \delta_{XY}, \quad X, Y \in \mathcal{S}$$

Then $\mathrm{Inv}\ F$ becomes a finite-dimensional commutative Hilbert algebra. Indeed,

$$\begin{aligned}(\phi_X \phi_Y | \phi_Z) &= \dim \mathrm{Hom}(X \otimes Y, Z)\\ &= \dim \mathrm{Hom}(X, Y^\vee \otimes Z) = (\phi_X | \phi_Y^* \phi_Z)\end{aligned}$$

From the theory of finite-dimensional commutative Hilbert algebras, we know that idempotents in the algebra $\mathrm{Inv}\ F$ are self-adjoint (only in that case the scalar product can be positive definite). Hence, $\chi$ is a $*$-morphism, that is, $\chi_X(\phi^*) = \overline{\chi_X(\phi)}$. Therefore,

$s_{XY^\vee}/s_{X\mathbb{1}} = \overline{s_{XY}}/\overline{s_{X\mathbb{1}}}$. In the particular case of $X = \mathbb{1}$, we obtain

$$\dim_q(Y) = \dim_q(Y^\vee) = s_{\mathbb{1}Y^\vee} = \overline{s_{\mathbb{1}Y}} = \overline{\dim_q(Y)}$$

since $s_{\mathbb{1}\mathbb{1}} = 1$. This proves that for any $Y \in \mathcal{C}$ its dimension $\dim_q(Y)$ is a real number.

It is natural to take for $\mu_1$ the positive root of the right-hand side of [8]. Positiveness fixes $\mu_1$ uniquely.

### Examples of Semisimple Modular Categories

In their original paper, Reshetikhin and Turaev (1991) use as algebraic input data the representation theory of the quantum deformation $U = U_q(\mathrm{sl}_2)$ of the Lie algebra $\mathrm{sl}(2, \mathbb{C})$, where $q$ is a root of unity. They construct the invariant as a trace over $U$-equivariant morphisms, and prove the necessary modularity condition concerning the nondegeneracy of the braided pairing.

The general picture is drawn by Turaev (1994), where 3-manifold invariants and TQFTs are constructed from semisimple modular categories. He shows how to obtain the latter as quotients of certain subcategories of representations of a modular Hopf algebra by the ideal of trace-negligible morphisms.

Finkelberg (1996), based on results of Gelfand and Kazhdan, establishes (via the theory of Kazhdan and Lusztig) an equivalence between two modular categories. The first is the semisimple category $\mathcal{C}$ of integrable modules over an affine Lie algebra $\hat{\mathfrak{g}}$ of positive integer level $k$. The second is a certain subquotient of the category of $U_q(\mathfrak{g})$-modules for $q = \exp(\pi i m^{-1}/(k + h^\vee))$, where $m \in \{1, 2, 3\}$ and $h^\vee$ is the dual Coxeter number of $\mathfrak{g}$. Huang and Lepowsky (1999) describe the rigid braided structure of $\mathcal{C}$ using vertex operators. Bakalov and Kirillov (2001) use geometrical constructions to make $\mathcal{C}$ into a modular category, associated with the Wess–Zumino–Witten (WZW) model. They construct the corresponding WZW modular functor.

## Modular Functor and TQFT

Modular categories give rise to a modular functor and a TQFT. The meanings of those differ from author to author, but the common features are the following. Such a TQFT is a functor from the category whose objects are smooth surfaces with additional structures and morphisms are three-dimensional manifolds with additional structures to the category of vector spaces. A modular functor is the restriction of such TQFT to the subcategory whose morphisms are homeomorphisms of surfaces. One of the constructions due to Kerler and Lyubashenko (2001) takes a nonsemisimple modular category as an input and assigns to it a double TQFT functor, that is, a functor between double categories. The target is the 2-category of abelian categories.

# Brane Construction of Gauge Theories

**S L Cacciatori**, Università di Milano, Milan, Italy

## Introduction

Branes appear in string theories and M-theory as extended objects which contain some nonperturbative information about the theory, and, apart from gravity, they can couple with gauge fields.

At low energies, M-theory can be approximated with an 11-dimensional $N=1$ supergravity, which in fact is unique and contains a graviton field (the metric $g_{\mu\nu}$), a spin 3/2 field $\psi$ (the gravitino) and a gauge field consisting of a 3-form potential field $c$. The gauge field, whose field strength is a 4-form $G=\mathrm{d}c$, can then couple electrically with two-dimensional extended objects, called M2 membranes. Moving in spacetime, an M2 membrane describes a three-dimensional world volume $W3$ so that its coupling to the gauge field is

$$S_2 = k\int_{W3} c \qquad [1]$$

$k$ representing the charge.

With $c$ we can associate a dual field $\tilde{c}$ such that $\mathrm{d}\tilde{c} = {}^*G$. It is a 6-form and can then electrically couple with a five-dimensional object, the M5 membrane. However, as $c$ is the true field, we say that M5 couples magnetically with $c$.

In superstring theories, which however are related to M-theory by a dualities web, there are many more objects to be considered. In particular, we will consider type II strings, which at low energies are described by ten-dimensional $N=2$ supergravity theories. They contain a Neveu–Schwarz sector consisting of a graviton $g_{\mu\nu}$, a 2-form potential $B_{\mu\nu}$, and a scalar field $\phi$, the dilaton. The content of the Ramond–Ramond fields depends on the chirality of the supercharges.

Type IIA strings are nonchiral (their left and right supercharges having opposite chiralities) and contain only odd-dimensional $p$-form potentials $A^{(p)}$, with $p=1,3,5,7,9$.

Type IIB strings are chiral and contain only even-dimensional $p$-form potentials $A^{(p)}$, with $p=0,2,4,6,8$.

Proceeding as before, we see that a $(p+1)$-form potential can couple electrically with a $p$-dimensional object and magnetically with a $(6-p)$-dimensional object. Such objects in fact exist in type II strings: the D$p$ branes are $p$-dimensional extended objects, with $p=0,2,4,6,8$ for IIA strings and $p=-1,1,3,5,7,9$ for IIB strings. In particular, D0 and D1 branes are called D-particles and D-strings respectively, whereas D$(-1)$ branes are instantons, that is, points in spacetime. Concretely, D-branes are extended regions in spacetime where the endpoints of open strings are constrained to live. Mathematically, they are defined imposing Dirichlet conditions (whence the "D" of D-brane) on the ends of the string, along certain spatial directions. Excitation of these string states gives rise to the dynamic of the brane. They correspond to a ten-dimensional U(1) gauge field, whose components, which are tangent to the brane world volume, give rise to a gauge field in $p+1$ dimensions, whereas the orthogonal components generate deformations of the brane shape. Moreover, if $n$ parallel $p$-branes overlap, the gauge theory on the world volume is enhanced to a U($n$) gauge theory. Closed strings can generate gravitational interactions responsible for wrappings of the brane. However, in the cases when gravitational interaction is negligible, we can use this mechanism to construct $(p+1)$-dimensional gauge theories, as we will see.

Before explaining how the construction works let us remember that there are two other interesting objects which often appear. In fact, we have not yet considered the Neveu–Schwarz $B$-field: this field can couple electrically with a one-dimensional object and magnetically with a five-dimensional object. These are the usual string (also called a fundamental or F-string) and a five-dimensional membrane called NS5 brane.

We will see how supersymmetric gauge theory configurations can be realized geometrically, considering more or less simple configurations of branes. We will also show that quantum corrections, be they exact or perturbative, can be described in this geometrical fashion. To be explicit, we will work with four-dimensional gauge theories, but it is clear that similar constructions can be done in different dimensions.

## Gauge Groups on the Branes

A deeper understanding of how D-branes and related world-volume gauge theories work requires the introduction of dualities, but a quite simple heuristic argument can be given, giving up some rigor in favor of intuition.

To set our ideas, let us think of an open string moving in a nearly flat (but ten-dimensional) spacetime. Its trajectory will describe a two-dimensional surface having a boundary traced by the ends of the string (Figure 1). The string can then be described by a map from a two-dimensional surface $\Sigma$, having a

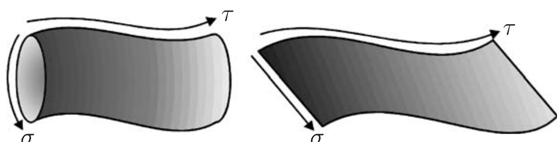

**Figure 1** Strings moving in spacetime.

boundary $\gamma = \partial\Sigma$, to spacetime, say $X^\mu(\sigma, \tau)$ with $\mu = 0, 1, \ldots, 9$. Here we chose on $\Sigma$ local coordinates $\sigma^\alpha = (\sigma, \tau)$, where $\sigma \in [0, \pi]$ is a spacelike coordinate and $\tau$ is a timelike one. Then $\sigma = 0, \pi$ individuate the ends of the string and are identified for the closed string. Now, on a given background, the string evolution is usually described as a two-dimensional (supersymmetric) conformal field theory for the fields $X^\mu(\sigma, \tau)$. The action for the bosonic part is the same for both type IIA and IIB strings, and reads

$$S[X] = \frac{1}{4\pi\alpha'} \int_\Sigma \mathrm{d}^\sigma \sqrt{h} h^{\alpha\beta} g_{\mu\nu}(X) \frac{\partial X^\mu}{\partial \sigma^\alpha} \frac{\partial X^\nu}{\partial \sigma^\beta} + \frac{1}{4\pi\alpha'} \int_\Sigma B_{\mu\nu}(X) \frac{\partial X^\mu}{\partial \sigma^\alpha} \frac{\partial X^\nu}{\partial \sigma^\beta} \mathrm{d}\sigma^\alpha \wedge \mathrm{d}\sigma^\beta \qquad [2]$$

where $g_{\mu\nu}$ and $B$ are the metric and a 2-form potential field for the given spacetime background, and $h_{\alpha\beta}$ is a metric for $\Sigma$. In general, we must also add a scalar field $\phi(X)$, but it will not play any role here. Using conformal invariance, we can reduce $h_{\alpha\beta}$ to the flat metric. Also consider a flat background $g_{\mu\nu}(X) = \eta_{\mu\nu}$ and concentrate for a moment on the $B$-field.

Conceived as a 2-form field over the spacetime, the potential field $B$ is a gauge field: its field strength 3-form $H = \mathrm{d}B$ is unchanged under a shift

$$B \longrightarrow B + \mathrm{d}A \qquad [3]$$

generated by the 1-form field $A(X)$. Here $A$ should be a totally unphysical field. However, note that if one considers open strings, the action for the $B$-field, and then the full action is shifted by a boundary term

$$S[X] \longrightarrow S[X] + \frac{1}{4\pi\alpha'} \int_\gamma A_\mu(X) \frac{\partial X^\mu}{\partial \sigma^\alpha} \mathrm{d}\sigma^\alpha \qquad [4]$$

The boundary $\gamma$ just describes the timelike world lines of the ends of the string. Thus, the ends of the string carry a U(1) charge and, even though the $B$-field vanishes, we can have the open-string action

$$S[X] = \frac{1}{4\pi\alpha'} \int_\Sigma \partial_\alpha X^\mu \partial^\alpha X_\mu \mathrm{d}^2\sigma + \int_\gamma A_\mu(X) \partial_\alpha X^\mu \mathrm{d}\sigma^\alpha \qquad [5]$$

Here we conventionally rescaled the $A$ field to normalize the action. To define the equation of motion, however, we must also specify boundary conditions for $X^\mu(\sigma, \tau)$ on $\gamma$. Let us choose Neumann conditions for $\mu = 0, 1, \ldots, p$ and Dirichlet conditions for the remaining directions

$$\partial_\sigma X^a(\gamma) = 0, \quad a = 0, \ldots, p \qquad [6]$$

$$\partial_\sigma X^i(\gamma) = 0, \quad i = p + 1, \ldots, 9 \qquad [7]$$

This means that the extrema of the string are bound on a $(p + 1)$-dimensional region (including time): the D$p$ brane. If for $\Sigma$ we consider the full strip $(\sigma, \tau) = [0, \pi] \times \mathbb{R}$ then the U(1) action reduces to

$$S_A[X] = \int_{-\infty}^{\infty} A_a \partial_\tau X^a(\pi, \tau) - \int_{-\infty}^{\infty} A_a \partial_\tau X^a(0, \tau) \qquad [8]$$

Thus, only the components of $A_a$ tangent to the brane interact with the ends of the strings. What about the normal components $A_i$?

To understand its meaning, let us proceed to compute the mean momentum transferred by the string, as it would be rigid. Imitating the Hamilton–Jacobi procedures for particles, let us consider the action up to a fixed time, say $\tau = 0$, so that $\Sigma = [0, \pi] \times [-\infty, 0]$. It is then a function of the position $X^\mu(\sigma, 0)$ of the string at the instant $\tau = 0$. To compute the momentum, we must vary the action by changing the position by a constant shift $\delta X^\mu(\sigma) = \Delta_0^\mu$. The variation will then contain some boundary terms which, for reasons of consistency, we must make vanish.

Before doing such a computation, let us make some further comments. It is plausible to assume that the two ends of the string could be charged for different U(1) fields. To the states of the open string we can in fact add two discrete labels $I, J = 1, \ldots, n$, for some integer $n$, called Chan–Paton factors, and referring, respectively, to the two ends of the string. We will indicate the ends of the string as $X^\mu(0, \tau; I)$ and $X^\mu(\pi, \tau; J)$ when we need to specify the states. If the string is in the excited state $(I, J)$, then $X(0, \tau; I)$ can couple with the field $A^I$ and $X(\pi, \tau; J)$ with $A^{(J)}$. For simplicity, we will now assume that these fields are constant. Note however that $A^{(I)}$ must be intended as a function of $X(0, \tau)$ only, and similarly for $A^{(J)}$. Also to realize the variation we can vary $X^\mu(\sigma, \tau)$ by a function $\delta X^\mu(\sigma, \tau) = \Delta^\mu(\tau)$ strictly picked to $\Delta_0^\mu$ at $\tau = 0$ so that essentially

$$\partial_\tau \Delta^\mu(\tau) = \Delta_0^\mu \delta(\tau) \qquad [9]$$

where $\delta(\tau)$ is the Dirac delta function.

Using the chosen boundary conditions, the variation of the full action contains the boundary terms

$$\begin{aligned}\delta S_{\text{bound}} &= \left(A_i^{(J)} - A_i^{(I)}\right)\int_{-\infty}^{0} \partial_\tau \Delta^i(\tau)\mathrm{d}\tau \\ &\quad + \frac{1}{2\pi\alpha'}\int_0^\pi \Delta^i \partial_\sigma X_i(\sigma,0)\mathrm{d}\sigma \\ &= \frac{\Delta^i}{2\pi\alpha'}\Big[X_i(\pi,0) - X_i(0,0) \\ &\quad + 2\pi\alpha'\left(A_i^{(J)} - A_i^{(I)}\right)\Big]\end{aligned} \quad [10]$$

Imposing the condition of its vanishing gives the physical interpretation for the normal components of the U(1) fields

$$X_i(\pi,0) - X_i(0,0) = -2\pi\alpha'\left(A_i^{(J)} - A_i^{(I)}\right) \quad [11]$$

This means that, up to a constant shift, the fields $A_i^{(K)}$ measure the positions of the ends of the strings in the transverse directions! (Figure 2). Equivalently, we can say that the string ends on two different D$p$ branes, parallel but displaced in the transverse directions by a quantity $-2\pi\alpha'\left(A_i^{(J)} - A_i^{(I)}\right)$. We are thus also able to interpret the Chan–Paton factors. They mean that the string is living in a background of $n$ parallel branes, stretched between the $I$th and the $J$th brane. On every brane, a U(1) gauge group lives so that the full gauge group is $\mathrm{U}(1)^n$. However, when $k$ of the branes overlap, the corresponding set of states become indistinguishable, so that the gauge group can be enhanced to a U($k$) group. In conclusion, $n$ overlapping parallel D$p$ branes carry a $(p+1)$-dimensional U($n$) gauge theory which breaks in U($k_i$) block factors if the branes separate in stacks of $k_i$ overlapping branes.

We can say a little bit more about this. If the string excited states represent gauge degree of freedom, they must become massive to break gauge symmetry when the branes separate. To see this, let us conclude by computing the mean momentum carried by the string. After elimination of the boundary terms, the total variation of the action due to the shift $\delta X^\mu(\sigma,0) = \Delta^\mu$ becomes

$$\begin{aligned}\delta S &= \frac{1}{2\pi\alpha'}\int_\Sigma \partial_\tau \Delta^\mu \partial_\tau X_\mu \mathrm{d}\sigma^2 \\ &= \frac{\Delta^\mu}{2\pi\alpha'}\int_0^\pi \partial_\tau X_\mu(\sigma,0)\mathrm{d}\sigma\end{aligned} \quad [12]$$

The resulting momentum is

$$P_\mu = \frac{1}{2\pi\alpha'}\int_0^\pi \partial_\tau X_\mu(\sigma,0)\mathrm{d}\sigma$$

On the bulk, the fields $X^\mu$ satisfy the standard wave equation in two dimensions, so that the general solution is the sum of a left-moving and a right-moving part, $X^\mu(\sigma,\tau) = X_\mathrm{L}^\mu(\tau+\sigma) + X_\mathrm{R}^\mu(\tau-\sigma)$. Imposing the boundary conditions, one finds

$$\begin{aligned}X^a(\sigma,\tau) &= X_\mathrm{L}^a(\tau+\sigma) + X_\mathrm{L}^a(\tau-\sigma) \\ &\quad + 2\pi\alpha' p^a \tau + X_0^a\end{aligned} \quad [13]$$

$$\begin{aligned}X^i(\sigma,\tau) &= X_\mathrm{L}^i(\tau+\sigma) - X_\mathrm{L}^i(\tau-\sigma) \\ &\quad + 2\alpha'\left(A^{(J)i} - A^{(I)i}\right)\sigma + X_0^i\end{aligned} \quad [14]$$

Here $X_0^\mu$ and $p^a$ are integration constants and $X_\mathrm{L}^i(\tau+\pi) - X_\mathrm{L}^i(\tau-\pi) = 0$. A direct computation then shows that $P^a = p^a$ and $P^i = 0$, which is also what intuition suggests: the string can freely move along the branes but is fixed between them in the orthogonal directions. However, if it is stretched between two separated branes (i.e., if $I \neq J$), there is another contribution to the energy. In fact the factor $T := 1/(2\pi\alpha')$ represents the string tension, so that if $\Delta$ is its minimal length, its minimal contribution to the energy will be $\delta E = T\Delta$. This energy must equally contribute to the spectrum of the excited modes, the gauge field bosons. Here in fact, is where $T$-duality comes into play, but we will not discuss it.

The conclusion is that the spectrum corresponding to the stretched string must satisfy the condition $E \geq T\Delta$, which is as if the string states acquired a mass $T\Delta$, that is,

$$m^2 = \sum_{i=p+1}^{9}\left(A^{(J)i} - A^{(I)i}\right)^2 \quad [15]$$

This gives us a geometric tool to construct $(p+1)$-dimensional gauge theories: on $n$ coincident D$p$ branes there exists a U($n$) gauge theory which can be broken separating the branes and thus giving a mass to the gauge bosons. Such a mass is proportional to the distance between the branes (Figure 3).

Before continuing with some examples, let us make two comments. First, the theory obtained in this way is a supersymmetric one, because the

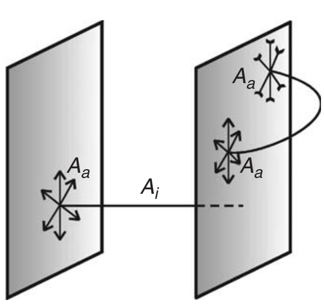

**Figure 2** Tangential components of $A_a$ appear as gauge modes. Normal components $A_i$ appear as shift modes.

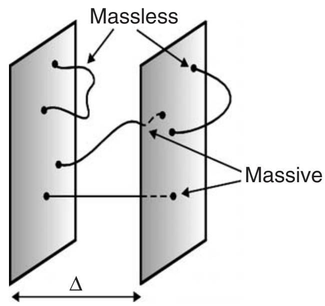

**Figure 3** Stretched strings acquire a mass.

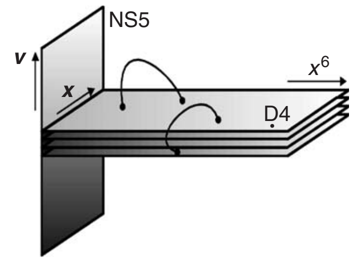

**Figure 4** D4 branes ending on an NS5 brane. Gauge degrees of freedom are frozen in four dimensions.

Dirichlet conditions allow the action of supersymmetric transformations of the form $\epsilon_L Q_L + \epsilon_R Q_R$, where $Q_L$ and $Q_R$ are the fermionic left and right supercharge operators and $\epsilon_L$, $\epsilon_R$ are spinors satisfying the brane projection condition $\epsilon_L = \pm\Gamma^0\Gamma^1 \cdot \ldots \cdot \Gamma^p \epsilon_R$. Here $\Gamma^\mu$ are the ten-dimensional Dirac matrices and one refers to "antibranes" for the negative sign.

Second, the gauge group can be converted into an SO($n$) or an Sp($n/2$) (for even $n$), adding an orientifold plane parallel to the branes. The orientifold plane acts on the orthogonal spacetime directions with a $\mathbb{Z}_2$-action

$$X^i \sim -X^i \qquad [16]$$

if $X^i = 0$ is the position of the orientifold. It further acts on the string world sheet as $\sigma \sim \pi - \sigma$ making it an unoriented string. The effect is to project out some states from the spectra, thus reducing the gauge group.

## Geometric Engineering of Gauge Theories from Branes

To illustrate how brane construction of gauge theories works, we will consider a particular configuration of branes (Witten 1997).

We would like to obtain a four-dimensional U($n$) gauge theory. A possibility could be to take $n$ D3 branes in a type IIB string background. However, such a model would contain too many supersymmetries: in ten dimensions, supersymmetries are generated by two 16-dimensional chiral spinors $\epsilon_L$, $\epsilon_R$ ($\Gamma^0 \cdot \ldots \cdot \Gamma^9 \epsilon_{L,R} = \epsilon_{L,R}$). From the four-dimensional point of view, each of them represents four four-dimensional spinors giving an $N = 8$ supersymmetric theory. The projection condition, due to the branes, reduces the number of supersymmetries to four. Supersymmetry not being manifest in nature, it is desirable to have fewer supersymmetric gauge theories at hand. Because different brane projection conditions can further reduce supersymmetry, we can try to consider the coexistence of more kinds of branes.

One way to do this is to consider $n$ parallel 4-branes ending on an NS5 brane in type IIA string theory (Figure 4), and then analyze the gauge theory restricted to the four-dimensional intersection (here the theory is nonchiral as $\Gamma^0 \cdot \ldots \cdot \Gamma^9 \epsilon_{L/R} = \pm\epsilon_{L/R}$). What kind of branes can end on other kind of branes can be established, starting from the fact that strings can end on a brane, and using the dualities tool (Giveon and Kutasov 1999).

Let us fix some conventions. We will indicate with $\boldsymbol{x} = (x^0, x^1, x^2, x^3) \in \mathbb{R}^4$ the coordinates on the intersection, so that $(\boldsymbol{x}; \boldsymbol{v}) = (\boldsymbol{x}; x^4, x^5) \in \mathbb{R}^6$ define the NS5 brane, and $(\boldsymbol{x}, x^6)$, with $x^6 \in [0, \infty)$, the 4-branes. Also $\boldsymbol{v}_I$ will indicate the position of the $I$th 4-brane on the 5-brane, and $\boldsymbol{y} = (x^7, x^8, x^9)$ will collect the remaining coordinates. Finally, we will indicate the product of Γ-matrices, corresponding to given directions, indicizing a simple Γ with the respective coordinates. For example $\Gamma^{\boldsymbol{v}} = \Gamma^4\Gamma^5$. With these conventions, the brane projection conditions for D4 and NS5 branes, respectively, read

$$\epsilon_L = \Gamma^{\boldsymbol{x}}\Gamma^6 \epsilon_R \qquad [17]$$

$$\epsilon_L = \Gamma^{\boldsymbol{x}}\Gamma^{\boldsymbol{v}} \epsilon_L, \qquad \epsilon_R = \Gamma^{\boldsymbol{x}}\Gamma^{\boldsymbol{v}} \epsilon_R \qquad [18]$$

These projections reduce supersymmetry to $N = 2$. After a short manipulation and using for example antichirality of $\epsilon_R$, it is easy to see that the first condition can be substituted by

$$\epsilon_L = \Gamma^{\boldsymbol{x}}\Gamma^{\boldsymbol{y}} \epsilon_R \qquad [19]$$

In other words, we could add a number of 6-branes in the $(\boldsymbol{x}, \boldsymbol{y})$ directions, without further reducing supersymmetry. We will consider this possibility later.

On the D4 branes there is an eventually broken U($n$) gauge theory. Here the vector fields $A_\mu$, $\mu = 0, 1, 2, 3, 6$, and the scalar fields $\boldsymbol{v}_I$ and $\boldsymbol{y}$ live. The last ones are set to zero by the Dirichlet conditions, whereas $\boldsymbol{v}_I$ measure the fluctuations of the D3 brane positions over NS5. The O(2) group

of rotations of the $(x^4, x^5)$ coordinates acts on them, which can be broken by an expectation value $\langle v_I \rangle \neq 0$. The SO(3) rotations of $(x^6, x^7, x^8)$ (under which $v_I$ are singulets) do not influence the projection conditions and can then be identified with the R-symmetry group $SU(2)_R$. It could be broken by a nonvanishing expectation value $\langle y \rangle \neq 0$, but as we said it cannot happen in the actual configuration. This highlights an unbroken supersymmetric Coulomb branch.

What is the physics as seen by an observer living on the four-dimensional spacetime $x$? The components $A_\alpha$, $\alpha = 0, 1, 2, 3$, of the vector fields transform as vectors with respect to the four-dimensional Lorentz group SO(1, 3). They satisfy Neumann boundary conditions on $x^6 = 0$ and then survive as $U(n)$ gauge vector fields. The $A_6$ component behaves as a scalar with respect to SO(1, 3) but is eliminated by a Dirichlet condition in $x^6 = 0$. The $v$ scalar field will be responsible for the eventual breaking of the gauge group.

This seems to be quite a good scenario but actually the situation is unsatisfactory. If a 4-brane extends to the interval $[0, L]$ in the $x^6$ direction, the effective action for the gauge fields goes like this:

$$\frac{1}{g_{D_4}^2}\int_0^L \mathrm{d}x^6 \int_{\mathbb{R}^4} \mathrm{d}^4 x \mathrm{tr} F_{\mu\nu}F^{\mu\nu} \approx \frac{L}{g_{D_4}^2}\int_{\mathbb{R}^4} \mathrm{d}^4 x \mathrm{tr} F_{\alpha\beta}F^{\alpha\beta} \qquad [20]$$

where $\alpha, \beta = 0, 1, 2, 3$. Thus, the gauge coupling in four dimensions appears to be $g_4 = (g_{D_4})/\sqrt{L}$. In our case, where $L$ goes to infinity, the gauge coupling vanishes and the gauge degrees of freedom are frozen. Moreover, an argument similar to the one made for the stretched strings shows that the energy of the D4 brane is very high and makes the mechanism of gauge group breaking difficult. The same is true for the NS5 brane, which also turns out to be extremely massive and does not participate in the dynamics. But this is what we want.

To solve the problem and restore gauge dynamics in four dimensions, one must consider a stack of 4-branes of finite length in the $x^6$ direction. This can be achieved placing in $x^6 = L$ a second NS5 brane parallel to the first one and in the same point in $y$ (Figure 5). In this way, the D4 branes can stretch between the NS5 branes. If $L$ is little enough, the gauge dynamics is restored also requiring a small value for $g_{D_4}$, to ensure the gravitational coupling (and the couplings with the Kaluza–Klein and NS5 modes) to be negligible. However, $L$ must be bigger then the $\delta X^6$ fluctuations in order to avoid quantum corrections.

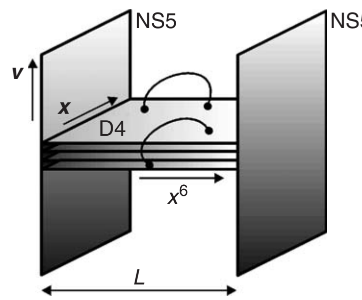

**Figure 5** $N = 2$ four-dimensional super Yang–Mills theory, with $U(n)$ gauge group.

What we just obtained is an $N = 2$ supersymmetric classical $U(n)$ gauge theory in four dimensions, without matter, and in the Coulomb branch. Before considering quantization, let us briefly discuss some possible generalizations. For example, matter can be realized attaching to the left-hand side NS5 brane, new D4 branes parallel to the previous ones, but extended in the $x^6$ direction from $-\infty$ to 0 (Figure 6). Considering strings stretched between long and short branes, we obtain states whose half-gauge action, associated with the end connected to the long brane, is frozen. The corresponding states thus appear in the fundamental representation and can be interpreted as matter states.

To consider the Higgs branch, one should be able to break supersymmetry giving an expectation value to $y$. As mentioned above, in the actual configuration this cannot happen because $y$ is set to 0 by Dirichlet conditions. Fortunately, as we said, one can add 6-branes in the $(x, y)$ directions. If we insert such branes to stop the long D4 branes in a large but finite value of $x^6$, say $x^6 = -M$ with $M \gg L$, then long branes have Neumann conditions in the $y$ directions. Thus, fluctuations of the long branes can give an expectation value to $y$, breaking supersymmetry and subsequently the Higgs branch can be tuned, shifting 4-branes stretched between 6-branes (Figure 7).

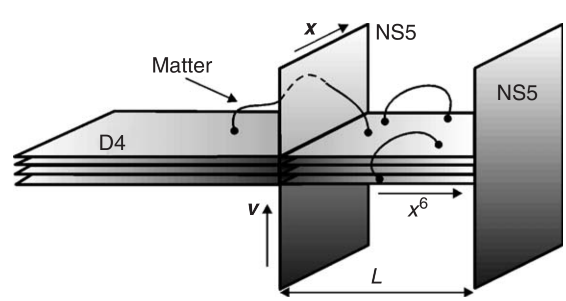

**Figure 6** Adding matter.

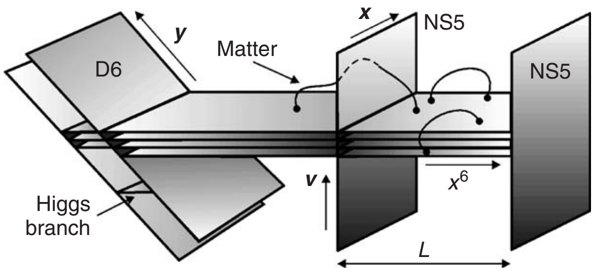

**Figure 7** Permitting Higgs phases.

The details require some careful inspection, but we shall stop our analysis here (Giveon and Kutasov 1999).

More general gauge configurations can be realized by adding more parallel NS5 branes, and thus obtaining product groups. Adding orientifold planes, one can change gauge groups as explained in the previous section (Figure 8).

Finally, we can take a further step towards more physical models, constructing $N = 1$ gauge theories. For example, this can be achieved from the previous $N = 2$ model, rotating the second NS5 brane from the $(\boldsymbol{x}, \boldsymbol{v})$ position, to the $(\boldsymbol{x}, \boldsymbol{w})$ position, where $\boldsymbol{w} = (x^8, x^9)$ (Figure 9). Then a new brane projection condition appears ($\epsilon_{\mathrm{L}} = \Gamma^x \Gamma^w \epsilon_{\mathrm{R}}$), breaking supersymmetry down to $N = 1$.

In this case, one could also obtain chiral matter, adding, for example, orientifold planes.

## Quantum Corrections from M-Theory

Up to this point we have considered classical gauge configurations. Quantum corrections could be computed switching on brane fluctuations. However, it is an amusing fact that working with $M$-theory one can obtain exact quantum results. As an example, let us sketch how the exact Seiberg–Witten solution can be obtained for the $N = 2$ model described in the previous section, in the simplest case without matter.

The full web of dualities suggests the existence of a unique unifying theory called M-theory. At low energies, M-theory appears as the strong-coupling limit of type IIA strings. In such a limit, D0 branes become the dominant objects and the corresponding states can be interpreted as Kaluza–Klein modes coming from an eleventh dimension $x^{10}$ compactified on a circle $S^1$ (Figure 10).

Thus, M-theory manifests itself as an 11-dimensional supergravity. In particular, it can be shown that there can be only a unique 11-dimensional supergravity. As said, here the nonperturbative objects are two- or five-dimensional membranes.

From the M-theory point of view, the D4 branes considered in our model appear as M5 membranes wrapped on the eleventh direction $S^1$ (Figure 11). Because quantum corrections are no longer negligible, we can no longer think of these branes as stretched in the $x^6$ direction, but $\boldsymbol{v}$ must also be considered. Thus, the M5 membranes will describe, in $\mathbb{R}^{10} \times S^1$, a region $\mathbb{R}^4 \times S$, where $\mathbb{R}^4$ are the $\boldsymbol{x}$ coordinates, and $S$ is a Riemann surface immersed in $Q \times S^1, Q$ being spanned by the $(\boldsymbol{v}, x^6)$ coordinates. In fact, supersymmetry constrains the surface to be a holomorphic curve, so that to describe it, it is convenient to collect $\boldsymbol{v} = (x^4, x^5)$ and $(x^6, x^{10})$ into complex coordinates $v = x^4 + \mathrm{i}x^5$ and $s = x^6 + \mathrm{i}x^{10}$.

To compute quantum fluctuations, let us note that the end of a D4 brane over an NS5 brane is free to move along the $v$ directions. A fully free end of a brane would satisfy a free wave equation. However, as $x^6$ is constrained in all directions but the $v$ ones, it will simply satisfy a Laplace equation in two dimensions: $\Delta_v X^6 = 0$. Let us solve it, for a fixed NS5 brane. It will be (at least for large values of $v$)

$$x^6(v) = k \sum_{i=1}^{n_{\mathrm{L}}} \log |v - v_{\mathrm{L}i}^{(\alpha)}| - k \sum_{i=1}^{n_{\mathrm{R}}} \log |v - v_{\mathrm{R}i}^{(\alpha)}| \quad [21]$$

where $n_{\mathrm{L}}$ is the number of D4 branes ending on the left-hand side of the NS5 brane, in the positions $v_{\mathrm{L}i}^{(\alpha)}$, and similar for the R index, which refers to

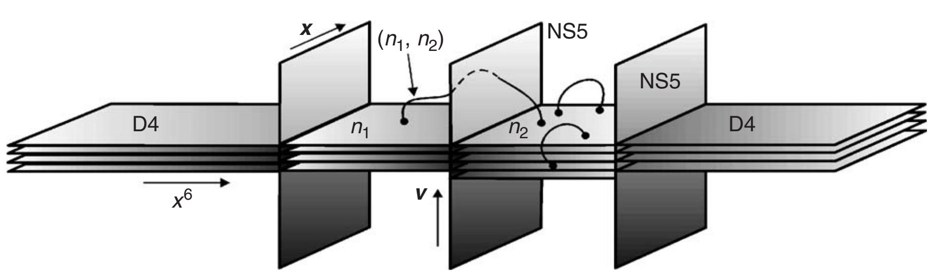

**Figure 8** $N = 2$ four-dimensional super Yang–Mills theory with $\mathrm{U}(n_1) \times \mathrm{U}(n_2)$ gauge group and matter. Strings crossing the central NS5 brane give matter in the $(n_1, n_2)$ representation.

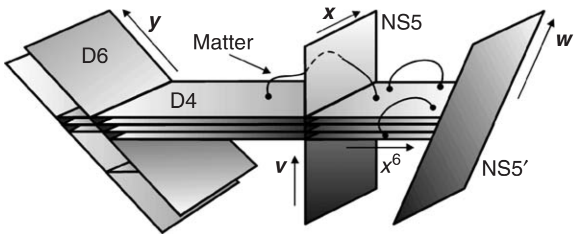

**Figure 9** Going down to $N=1$ supersymmetry.

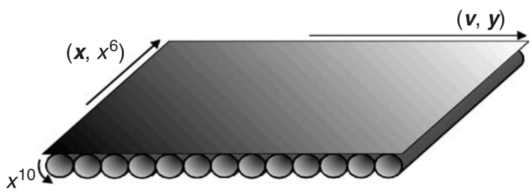

**Figure 10** In M-theory one can think as if at any ten-dimensional spacetime point, there is attached an $S^1$ circle of ray $R_{10}$.

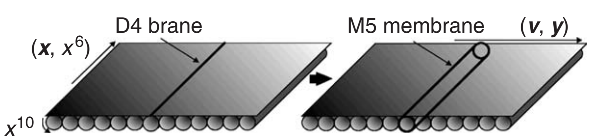

**Figure 11** D4 branes become M5 membranes in M-theory.

the right-hand side. Here $(\alpha)$ refers to the $\alpha$th NS5 brane, and $k$ is an integration constant.

Because $x^6$ is the real part of a holomorphic field, whose imaginary part is compactified on a circle of ray $R_{10}$, we then find

$$s(v) = R_{10} \sum_{i=1}^{n_{\mathrm{L}}} \log\left(v - v_{\mathrm{L}i}^{(\alpha)}\right) - R_{10} \sum_{i=1}^{n_{\mathrm{R}}} \log\left(v - v_{\mathrm{R}i}^{(\alpha)}\right) \qquad [22]$$

This describes the quantum fluctuations of the NS5 brane as seen in M-theory. In particular, because of the imaginary part of $s$, the ends of the D4 branes appear as vortices on the NS5 brane. In place of $s$, it is now convenient to introduce a new field $t := \exp(-s/R_{10})$ so that

$$t(v) = \frac{\prod_{i=1}^{n_{\mathrm{R}}} \left(v - v_{\mathrm{R}i}^{(\alpha)}\right)}{\prod_{i=1}^{n_{\mathrm{L}}} \left(v - v_{\mathrm{L}i}^{(\alpha)}\right)} \qquad [23]$$

Before continuing, let us look a bit again at the classical limit. In this case, a fixed value of $v$ will correspond to the position of a D4 brane, whereas a fixed value of $s$ will correspond to the fixed position of an NS5 brane. The classical configuration is then

$$\left(s - s^{(1)}\right)\left(s - s^{(2)}\right) \prod_{i=1}^{n} (v - v_i) = 0 \qquad [24]$$

Here $s^{(\alpha)}$ are the positions of the NS5 branes, and the positions $v_i$ of the D4 branes coincide for both the NS5 branes. Also, for large values of $v$, one has $t^{(1)} \approx v^n$ and $t^{(2)} \approx v^{-n}$.

Quantum mechanically, the configuration is determined in terms of $v$ and $t$ by the holomorphic curve $S$, which can be described as an algebraic curve $F(v,t) = 0$, generalizing the classical configuration. As there are two NS5 branes and $n$ D4 branes, $F$ must be a polynomial of degree 2 in $t$,

$$F(v,t) = A_2(v)t^2 + A_1(v)t + A_0(v) \qquad [25]$$

where $A_a$, $a = 1,2,3$, are all polynomials of degree $n$. Note that values of $v$ such that $A_1$ vanishes give the solution $t = 0$, which corresponds to sending the right-hand side NS5 brane to $\infty$. Similarly, $A_2 = 0$ sends the other NS5 brane to $-\infty$. To avoid these undesirable configurations, we can set $A_0 = A_2 = 1$. For $A_1$, we can take the most general choice, up to an eventual shift in $v$, giving the quantum configuration

$$t^2 + \left[v^n + a_{n-2}v^{n-2} + \cdots + a_1 v + a_0\right]t + 1 = 0 \qquad [26]$$

This realizes a quantum-mechanical correspondence between the M5 membrane configurations described by the given polynomials, and the $N=2$ super Yang–Mills vacua. But this is also the claimed Seiberg–Witten curve. In particular, M-theory gives a concrete physical meaning for the support Riemann surfaces of the Seiberg–Witten solutions.

To conclude, let us make some further comments. It is clear how the construction can be extended for involving more configurations, for example, with more NS5 branes, or adding matter.

Also, we have seen that the geometrical picture which branes give of gauge theories extends at the quantum level.

A similar construction can be made for the $N=1$ model, which also permits a full geometrical proof of the Seiberg duality at both classical and quantum levels.

Finally, we should note that there are also other methods, which work in spacetimes where extra dimensions are compactified. There, the branes wrap around certain singular loci which contain information about gauge symmetries (Lerche 1997).

## Introduction

At high enough energies, Einstein's classical theory of general relativity breaks down, and will be superseded by a quantum gravity theory. The singularities predicted by general relativity in gravitational collapse and in the hot big bang origin of the universe are thought to be artifacts of the classical nature of Einstein's theory, which will be removed by a quantum theory of gravity. Developing a quantum theory of gravity and a unified theory of all the forces and particles of nature are the two main goals of current work in fundamental physics. The problem is that general relativity and quantum field theory cannot simply be molded together. There is as yet no generally accepted (pre-)quantum gravity theory.

The quest for a quantum gravity theory has a long and thus far not very successful history. Many different lines of attack have been developed, each having a different way of dealing with the classical singularities that arise from point particles and smooth spacetime geometry. String theory does away with zero-dimensional point particles, and particles are modeled as different states of new fundamental objects, the one-dimensional strings. It turns out, however, that there is a price to pay – the number of spacetime dimensions must be greater than four for a consistent theory. When fermions are included, which leads to superstring theory, the required number of dimensions is ten – one time and nine space dimensions.

There are in fact five distinct (1+9)-dimensional superstring theories. In the mid-1990s, duality transformations were discovered that relate these superstring theories to each other and to the (1+10)-dimensional supergravity theory. This led to the conjecture that all of these theories arise as different limits of a single theory, which has come to be known as M theory. It was also discovered that extended objects of higher dimension than strings play a fundamental role in the theory. These objects are known as "branes" (from membranes), and the relation between them and strings leads to a new picture of how gravity and matter may be connected in the universe. Roughly speaking, open strings describe the particles of the nongravitational sector, and their ends are attached to branes, while closed strings, which describe the graviton and associated particles of the gravitational sector, can move freely in all dimensions.

Thus, the observable universe could be a $(1+3)$-surface – a "brane," embedded in a $(1+3+d)$-dimensional spacetime – the "bulk," with standard-model particles and fields trapped on the brane, while gravity is free to access the bulk. Brane-world models offer a phenomenological way to test some of the novel predictions and corrections to general relativity that are implied by M theory.

## Higher-Dimensional Gravity

Brane worlds can be seen as reviving the original higher-dimensional ideas of Kaluza and Klein in the 1920s, but in a new context of quantum gravity. An important consequence of extra dimensions is that the four-dimensional Planck scale $M_{\rm p} \equiv M_{(4)} = 1.2 \times 10^{19}$ GeV is no longer the fundamental energy scale of gravity. The fundamental scale is instead $M_{(4+d)}$. This can be seen from the modification of the gravitational potential. For an Einstein–Hilbert gravitational action,

$$S_{\rm gravity} = \frac{1}{2\kappa^2_{(4+d)}} \int {\rm d}^4x\, {\rm d}^dy \sqrt{-{}^{(4+d)}g} \times \left[ {}^{(4+d)}R - 2\Lambda_{(4+d)} \right] \quad [1]$$

we have the higher-dimensional Einstein field equations,

$$\begin{aligned} {}^{(4+d)}G_{AB} &\equiv {}^{(4+d)}R_{AB} - \tfrac{1}{2}{}^{(4+d)}R\,{}^{(4+d)}g_{AB} \\ &= -\Lambda_{(4+d)}{}^{(4+d)}g_{AB} + \kappa^2_{(4+d)}{}^{(4+d)}T_{AB} \quad [2] \end{aligned}$$

where $x^A = (x^a, y^1, \ldots, y^d)$ and $\kappa^2_{(4+d)}$ is the gravitational coupling constant given by

$$\kappa^2_{(4+d)} = 8\pi G_{(4+d)} = \frac{8\pi}{M^{2+d}_{(4+d)}} \qquad [3]$$

The static weak field limit of the field equations leads to the $(4+d)$-dimensional Poisson equation, whose solution is the gravitational potential

$$V(r) \propto \frac{\kappa^2_{(4+d)}}{r^{1+d}} \qquad [4]$$

In the simplest scenario, we can assume a toroidal configuration for the $d$ extra dimensions, with each compactified on the same length scale $L$. Then on scales $r \lesssim L$, the potential is $(4+d)$-dimensional, $V \sim r^{-(1+d)}$. By contrast, on scales large relative to $L$, where the extra dimensions do not contribute to variations in the potential, $V$ behaves like a four-dimensional potential, $V \sim L^{-d} r^{-1}$. This means that the usual Planck scale becomes an effective coupling constant, describing gravity on scales much larger than the extra dimensions, and related to the fundamental scale via the volume of the extra dimensions:

$$M_{\rm p}^2 \sim M^{2+d}_{(4+d)} L^d \qquad [5]$$

## Large Extra Dimensions

If the extra-dimensional volume is significantly above the Planck scale, then the true fundamental scale $M_{(4+d)}$ can be much less than the effective scale $M_{\rm p}$,

$$L^d \gg M_{\rm p}^{-d} \;\Rightarrow\; M_{(4+d)} \ll M_{\rm p} \qquad [6]$$

In this case, we understand the weakness of gravity as due to the fact that it "spreads" into extra dimensions, and only a part of it is felt in four dimensions.

A lower limit on $M_{(4+d)}$ is given by null results in table-top experiments to test for deviations from Newton's law in four dimensions, $V \propto r^{-1}$. These experiments currently probe submillimeter scales, and find no detectable deviation, so that

$$L \lesssim 10^{-1}\,\text{mm} \sim (10^{-15}\,\text{TeV})^{-1} \\ \Rightarrow\; M_{(4+d)} \gtrsim 10^{(32-15d)/(d+2)}\,\text{TeV} \qquad [7]$$

Stronger bounds can be derived from null results in particle accelerators in some brane-world models, or from constraints imposed by observations of supernovae or of light-element abundance.

Brane worlds, arising in the framework of string theory, thus incorporate the possibility that the fundamental scale is much less than the Planck scale felt in four dimensions. This emerges by virtue of the large size of the extra dimensions. It is not necessary for all extra dimensions to be of equal size for this mechanism to operate. There are string theory solutions (Horava–Witten solutions) with two $(1+9)$-branes located at the boundaries of the bulk, at the endpoints of an $S^1/Z_2$ orbifold, that is, a circle folded on itself across a diameter. The orbifold extra dimension is the large one, whereas the other six extra dimensions on the branes are compactified on a very small scale, close to the fundamental scale, and their effect on the dynamics is felt through "moduli" fields, that is, five-dimensional scalar fields.

These solutions can be thought of as effectively five dimensional, with an extra dimension that can be large relative to the fundamental scale. They provide the basis for the Randall–Sundrum 1 (RS1) phenomenological models of five-dimensional gravity. The single-brane Randall–Sundrum 2 (RS2) models with infinite extra dimension arise when the orbifold radius tends to infinity. The RS models are not the only phenomenological realizations of M theory ideas. They were preceded by the brane-world models of Arkani-Hamed, Dimopoulos, and Dvali (ADD), which put forward the idea that a large volume for the compact extra dimensions would lower the effective Planck scale $M_{(4+d)}$. If $M_{(4+d)}$ is close to the electroweak scale, $M_{\rm ew}$, then this would address the long-standing "hierarchy" problem, that is, why there is such a large gap between $M_{\rm ew} \sim 1\,\text{TeV}$ and $M_{\rm p} \sim 10^{16}\,\text{TeV}$.

In the ADD models, more than one extra dimension is required for agreement with experiments, and there is "democracy" among the equivalent extra dimensions, which, in addition, are flat. By contrast, the RS models have a "preferred" extra dimension, with other extra dimensions treated as ignorable (i.e., stabilized except at energies near the fundamental scale). Furthermore, this extra dimension is curved or "warped" rather than flat: the bulk is a portion of anti-de Sitter ($\text{AdS}_5$) spacetime. The RS branes are $Z_2$-symmetric (mirror symmetry), and have a tension, which serves to counter the influence on the brane of the negative bulk cosmological constant. This also means that the self-gravity of the branes is incorporated in the RS models. The novel feature of the RS models compared to previous higher-dimensional models is that the observable three dimensions are protected from the large extra dimension (at low energies) by curvature (warping), rather than straightforward compactification.

The RS brane worlds provide phenomenological models that reflect at least some of the features of

M theory, and that bring exciting new geometric and particle physics ideas into play. The RS2 models also provide a framework for exploring holographic ideas that have emerged in M theory. Roughly speaking, holography suggests that higher-dimensional dynamics may be determined from a knowledge of the fields on a lower-dimensional boundary. The AdS/CFT correspondence is an example in which the classical dynamics of the higher-dimensional AdS gravitational field are equivalent to the quantum dynamics of a conformal field theory (CFT) on the boundary.

## Kaluza–Klein Modes

The dilution of gravity via extra dimensions not only weakens gravity, it also broadens the range of graviton modes felt on the brane. The graviton is more than just the four-dimensional massless mode of four-dimensional gravity – other modes, with an effective mass on the brane, arise from the fact that the graviton is a (4+d)-dimensional massless particle. These extra modes on the brane are known as Kaluza–Klein (KK) modes of the graviton.

For simplicity, consider a flat brane with one flat extra dimension, compactified through the identification $y \leftrightarrow y + 2\pi nL$, where $n = 0, 1, 2, \ldots$ . The perturbative five-dimensional graviton is defined via

$$^{(5)}\eta_{AB} \rightarrow {}^{(5)}\eta_{AB} + h_{AB} \qquad [8]$$

where $^{(5)}\eta_{AB}$ is the five-dimensional Minkowski metric and $h_{AB}$ is a small transverse traceless perturbation. Its amplitude can be Fourier expanded as

$$h(x^a, y) = \sum_n \mathrm{e}^{iny/L}\, h_n(x^a) \qquad [9]$$

where $h_n$ are the amplitudes of the KK modes, that is, the effective four-dimensional modes of the five-dimensional graviton. To see that these KK modes are massive from the brane viewpoint, we start from the five-dimensional wave equation that the massless five-dimensional field $h$ satisfies (in a suitable gauge):

$$^{(5)}\Box h = 0 \;\Rightarrow\; \Box h + \partial_y^2 h = 0 \qquad [10]$$

It follows that the KK modes satisfy a four-dimensional Klein–Gordon equation with an effective four-dimensional mass, $m_n$:

$$\Box h_n = m_n^2 h_n, \quad m_n = \frac{n}{L} \qquad [11]$$

The massless mode, $h_0$, is the usual four-dimensional graviton mode. But there is a tower of massive modes, $L^{-1}, 2L^{-1}, \ldots,$ which imprint the effect of the five-dimensional gravitational field on the four-dimensional brane. Compactness of the extra dimension leads to discreteness of the spectrum. For an infinite extra dimension, $L \to \infty$, the separation between the modes disappears and the tower forms a continuous spectrum.

## Randall–Sundrum Brane Worlds

RS brane worlds do not rely on compactification to localize gravity at the brane, but on the curvature of the bulk. What prevents gravity from "leaking" into the extra dimension at low energies is a negative bulk cosmological constant,

$$\Lambda_{(5)} = -\frac{6}{\ell^2} = -6\mu^2 \qquad [12]$$

where $\ell$ is the curvature radius of $AdS_5$ and $\mu$ is the corresponding energy scale. The bulk cosmological constant with its repulsive gravity effect acts to "squeeze" the gravitational potential closer to the brane. We can see this clearly in Gaussian normal coordinates $x^A = (x^\mu, y)$ based on the brane at $y = 0$, for which the metric takes the form

$$^{(5)}\mathrm{d}s^2 = \mathrm{d}y^2 + \mathrm{e}^{-2|y|/\ell}\eta_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu \qquad [13]$$

with $\eta_{\mu\nu}$ the Minkowski metric. The exponential warp factor reflects the confining role of the bulk cosmological constant. The $Z_2$-symmetry about the brane at $y = 0$ is incorporated via the $|y|$ term. In the bulk, this metric is a solution of the five-dimensional Einstein equations,

$$^{(5)}G_{AB} = -\Lambda_{(5)}{}^{(5)}g_{AB} \qquad [14]$$

that is, $^{(5)}T_{AB} = 0$ in eqn [2]. The brane is a flat Minkowski spacetime, $g_{AB}(x^\mu, 0) = \eta_{\mu\nu}\delta^\mu{}_A\delta^\nu{}_B$, with self-gravity in the form of brane tension.

The two RS models are distinguished as follows:

**RS1** There are two branes in RS1, at $y = 0$ and $y = L$, with $Z_2$-symmetry identifications

$$y \leftrightarrow -y, \qquad y + L \leftrightarrow L - y \qquad [15]$$

The branes have equal and opposite tensions, $\pm\lambda$, where

$$\lambda = \frac{3}{4\pi}\,\frac{M_{\mathrm{p}}^2}{\ell^2} \qquad [16]$$

The positive-tension "TeV" brane has fundamental scale $M_{(5)} \sim 1$ TeV. Because of the exponential

warping factor, the effective scale on the negative tension "Planck" brane at $y = L$ is $M_p$. On the positive tension brane,

$$M_p^2 = M_{(5)}^3 \ell \left[1 - e^{-2L/\ell}\right] \quad [17]$$

So RS1 gives a new approach to the hierarchy problem. Because of the finite separation between the branes, the KK spectrum is discrete.

**RS2** In RS2, there is only one, positive-tension, brane. This may be thought of as arising from sending the negative tension brane off to infinity, $L \to \infty$. Then the energy scales are related via

$$M_{(5)}^3 = \frac{M_p^2}{\ell} \quad [18]$$

On the RS2 brane, the negative $\Lambda_{(5)}$ is offset by the positive brane tension $\lambda$. The fine-tuning in eqn [16] ensures that there is zero effective cosmological constant on the brane, so that the brane has the induced geometry of Minkowski spacetime. To see how gravity is localized at low energies, we consider the five-dimensional graviton perturbations of the metric:

$$\begin{gathered} {}^{(5)}g_{AB} \to {}^{(5)}g_{AB} + h_{AB} \\ h_{Ay} = 0 = h^\mu{}_\mu = \partial_\nu h^{\mu\nu} \end{gathered} \quad [19]$$

We split the amplitude $h$ into three-dimensional Fourier modes, and the linearized five-dimensional Einstein equations lead to the wave equation ($y > 0$)

$$e^{2y/\ell}\left[\ddot{h} + k^2 h\right] = h'' - \frac{4}{\ell} h' \quad [20]$$

Separability means we can write

$$h(t, y) = \sum_m \varphi_m(t)\, h_m(y) \quad [21]$$

and the wave equation reduces to

$$\ddot{\varphi}_m + (m^2 + k^2)\varphi_m = 0 \quad [22]$$

$$h''_m - \frac{4}{\ell} h'_m + e^{2y/\ell} h_m = 0 \quad [23]$$

The zero-mode solution is

$$\varphi_0(t) = A_{0+}\, e^{+ikt} + A_{0-}\, e^{-ikt} \quad [24]$$

$$h_0(y) = B_0 + C_0 e^{4y/\ell} \quad [25]$$

and the massive KK mode ($m > 0$) solutions are

$$\begin{aligned} \varphi_m(t) = {} & A_{m+} \exp\left(+i\sqrt{m^2 + k^2}\, t\right) \\ & + A_{m-} \exp\left(-i\sqrt{m^2 + k^2} t\right) \end{aligned} \quad [26]$$

$$\begin{aligned} h_m(y) = {} & e^{2y/\ell}\Big[B_m J_2\left(ml e^{y/\ell}\right) \\ & + C_m Y_2\left(ml e^{y/\ell}\right)\Big] \end{aligned} \quad [27]$$

where $J_2, Y_2$ are Bessel functions.

The boundary condition for the perturbations is $h'(t, 0) = 0$, which implies

$$C_0 = 0, \qquad C_m = -\frac{J_1(m\ell)}{Y_1(m\ell)} B_m \quad [28]$$

In the RS1 model, we have a further boundary condition, $h'(t, L) = 0$, which leads to a discrete eigenspectrum, namely the masses $m$ that satisfy

$$J_1\left(m\ell e^{L/\ell}\right) Y_1(m\ell) - Y_1\left(m\ell e^{L/\ell}\right) J_1(m\ell) = 0 \quad [29]$$

The zero mode is normalizable, since

$$\left| \int_0^\infty B_0 e^{-2y/\ell} dy \right| < \infty \quad [30]$$

Its contribution to the gravitational potential $V = (1/2)h_{00}$ gives the four-dimensional result, $V \propto r^{-1}$. The contribution of the massive KK modes sums to a correction of the four-dimensional potential. For $r \ll \ell$, one obtains

$$V(r) \approx \frac{GM}{r}\left(1 + \frac{\ell}{r}\right) \approx \frac{GM\ell}{r^2} \quad [31]$$

which simply reflects the fact that the potential becomes truly five dimensional on small scales. For $r \gg \ell$,

$$V(r) \approx \frac{GM}{r}\left(1 + \frac{2\ell^2}{3r^2}\right) \quad [32]$$

which gives the small correction to four-dimensional gravity at low energies from extra-dimensional effects.

## Cosmological Brane Worlds

The RS models contain vacuum (Minkowski) branes. In order to pursue brane-world ideas in cosmology, we need to generalize the RS models to incorporate cosmological branes with matter and radiation on them. The effective field equations on the brane are the vehicle for brane-bound observers to interpret cosmological dynamics. They arise from projecting the five-dimensional field equations onto the brane, via the Gauss–Codazzi equations. These equations involve also the extrinsic curvature $K_{\mu\nu}$ of the brane, which determines how the brane is imbedded in the bulk.

The stress-energy on the brane (tension, matter, radiation) means that there is a jump in $K_{\mu\nu}$ across

the brane. More precisely, the junction conditions across the brane are

$$g^{+}_{\mu\nu} - g^{-}_{\mu\nu} = 0 \quad [33]$$

$$K^{+}_{\mu\nu} - K^{-}_{\mu\nu} = -\kappa^2_{(5)}\left[T^{\text{brane}}_{\mu\nu} - \tfrac{1}{3}T^{\text{brane}}\, g_{\mu\nu}\right] \quad [34]$$

where

$$T^{\text{brane}}_{\mu\nu} = T_{\mu\nu} - \lambda g_{\mu\nu} \quad [35]$$

is the total energy–momentum tensor on the brane and $T^{\text{brane}} = g^{\mu\nu}T^{\text{brane}}_{\mu\nu}$. The $Z_2$-symmetry means that when approaching the brane from one side and going through it, one emerges into a bulk that looks the same, but with the normal reversed. This implies that

$$K^{-}_{\mu\nu} = -K^{+}_{\mu\nu} \quad [36]$$

so that we can use the junction condition (eqn [34]) to determine the extrinsic curvature:

$$K_{\mu\nu} = -\tfrac{1}{2}\kappa^2_{(5)}\left[T_{\mu\nu} + \tfrac{1}{3}(\lambda - T)g_{\mu\nu}\right] \quad [37]$$

where $T = T^{\mu}{}_{\mu}$, we have dropped the (+) and we evaluate quantities on the brane by taking the limit $y \to +0$.

Together with the Gauss–Codazzi equations, eqn [37] leads to the induced field equations on the brane:

$$G_{\mu\nu} = -\Lambda g_{\mu\nu} + \kappa^2 T_{\mu\nu} + 6\frac{\kappa^2}{z\lambda}\mathcal{S}_{\mu\nu} - \mathcal{E}_{\mu\nu} \quad [38]$$

where

$$\kappa^2 \equiv \kappa^2_{(4)} = \tfrac{1}{6}\lambda\kappa^4_{(5)} \quad [39]$$

$$\Lambda \equiv \Lambda_{(4)} = \tfrac{1}{2}\left[\Lambda_{(5)} + \kappa^2\lambda\right] \quad [40]$$

$$\mathcal{S}_{\mu\nu} = \tfrac{1}{12}TT_{\mu\nu} - \tfrac{1}{4}T_{\mu\alpha}T^{\alpha}{}_{\nu} + \tfrac{1}{24}g_{\mu\nu}\left[3T_{\alpha\beta}T^{\alpha\beta} - T^2\right] \quad [41]$$

and

$$\mathcal{E}_{\mu\nu} = {}^{(5)}C_{ACBD}n^C n^D g_{\mu}{}^{A} g_{\nu}{}^{B} \quad [42]$$

where $n^A$ is the unit normal to the brane and ${}^{(5)}C_{ACBD}$ is the Weyl tensor in the bulk.

The induced field equations [38] show two key modifications to the standard four-dimensional Einstein field equations arising from extra-dimensional effects.

- $\mathcal{S}_{\mu\nu} \sim (T_{\mu\nu})^2$ is the high-energy correction term, which is negligible for $\rho \ll \lambda$, but dominant for $\rho \gg \lambda$ (where $\rho$ is the energy density):

$$\frac{|\kappa^2\mathcal{S}_{\mu\nu}/\lambda|}{|\kappa^2 T_{\mu\nu}|} \sim \frac{|T_{\mu\nu}|}{\lambda} \sim \frac{\rho}{\lambda} \quad [43]$$

- $\mathcal{E}_{\mu\nu}$, the projection of the bulk Weyl tensor on the brane, encodes corrections from KK or five-dimensional graviton effects. From the brane-observer viewpoint, the energy–momentum corrections in $\mathcal{S}_{\mu\nu}$ are local, whereas the KK corrections in $\mathcal{E}_{\mu\nu}$ are nonlocal, since they incorporate five-dimensional gravity wave modes. These nonlocal corrections cannot be determined purely from data on the brane. In the perturbative analysis of RS2 which leads to the corrections in the gravitational potential, eqn [32], the KK modes that generate this correction are responsible for a nonzero $\mathcal{E}_{\mu\nu}$; this term is what carries the modification to the weak-field field equations.

The effective field equations are not a closed system. One needs to supplement them by five-dimensional equations governing $\mathcal{E}_{\mu\nu}$, which are obtained from the five-dimensional Einstein equations.

## Cosmological Dynamics

A (1+4)-dimensional spacetime with spatial 4-isotropy (four-dimensional spherical/ plane/ hyperbolic symmetry) has a natural splitting into hypersurfaces of symmetry, which are (1+3)-dimensional surfaces with 3-isotropy and 3-homogeneity, that is, Friedmann–Robertson–Walker (FRW) surfaces. In particular, the $AdS_5$ bulk of the RS2 brane world, which admits a foliation into Minkowski surfaces, also admits an FRW foliation since it is 4-isotropic. The generalization of $AdS_5$ that preserves 4-isotropy and solves the five-dimensional Einstein equation is Schwarzschild $AdS_5$, and this bulk therefore admits an FRW foliation. It follows that an FRW cosmological brane world can be embedded in Schwarzschild $AdS_5$ spacetime.

The black hole in the bulk is felt on the brane via the $\mathcal{E}_{\mu\nu}$ term. The bulk black hole gives rise to "dark radiation" on the brane via its Coulomb effect. The FRW brane can be thought of as moving radially along the fifth dimension, with the junction conditions determining the velocity via the Friedmann equation. Thus, one can interpret the expansion of the universe as motion of the brane through the static bulk. In the special case of no black hole and no brane motion, the brane is empty and has Minkowski geometry, that is, the original RS2 brane world is recovered, in different coordinates.

An intriguing aspect of the cosmological metric is that five-dimensional gravitational wave signals can take "shortcuts" through the bulk in traveling

between points A and B on the brane. The travel time for such a graviton signal is less than the time taken for a photon signal (which is stuck to the brane) from A to B.

Cosmological dynamics on the brane are governed by the modified Friedmann equation:

$$H^2 = \frac{\kappa^2}{3}\rho\left(1+\frac{\rho}{2\lambda}\right)+\frac{m}{a^4}+\frac{1}{3}\Lambda-\frac{K}{a^2} \qquad [44]$$

where $H = \dot{a}/a$ is the Hubble expansion rate, $a(t)$ is the scale factor, $K$ is the curvature index, and $m$ is the mass of the bulk black hole.

The $\rho^2/\lambda$ term is the high-energy term. When $\rho \gg \lambda$, in the early universe, then $H^2 \propto \rho^2$. This means that a given energy density produces a greater rate of expansion that it would in standard four-dimensional gravity. As a consequence, inflation in the early universe is modified in interesting ways, some of which may leave a signature in cosmological observations.

The $m/a^4$ term in eqn [44] is the "dark radiation," so called because it redshifts with expansion like ordinary radiation. But, unlike ordinary radiation, it is not a form of detectable matter, but the imprint on the brane of the gravitational field in the bulk (the Coulomb effect of the bulk black hole). This additional effective relativistic degree of freedom is constrained by nucleosynthesis in the early universe. Any extra radiative energy not thermally coupled to radiation affects the rate of production of light elements, and observed abundances place tight constraints on such extra energy. The dark radiation can be no more than ~3% of the radiation energy density at nucleosynthesis:

$$\frac{3m}{\kappa^2\rho_{\rm nuc}} \lesssim 0.03 \qquad [45]$$

The other modification to the Hubble rate is via the high-energy correction $\rho/\lambda$. In order to recover the observational successes of general relativity, the high-energy regime where significant deviations occur must take place before nucleosynthesis, that is, cosmological observations impose the lower limit

$$\lambda > (1\,\mathrm{MeV})^4 \;\Rightarrow\; M_{(5)} > 10^4\,\mathrm{GeV} \qquad [46]$$

This is much weaker than the limit imposed by table-top experiments, which limit the curvature radius to $\ell \lesssim 0.2\,\mathrm{mm}$, leading to

$$\lambda > (100\,\mathrm{GeV})^4 \Rightarrow M_{(5)} > 10^8\,\mathrm{GeV} \qquad [47]$$

The high-energy regime during radiation domination is short-lived. Since $\rho^2/\lambda$ decays as $a^{-8}$ during the radiation era, it will rapidly drop below one, and the universe will enter the low-energy four-dimensional regime. However, traces of the high-energy era may be left in the perturbation spectra that leave an imprint in the cosmic microwave background radiation.

In conclusion, simple brane-world models of RS2 type provide a rich phenomenology for exploring some of the ideas that are emerging from M theory. The higher-dimensional degrees of freedom for the gravitational field, and the confinement of standard model fields to the visible brane, lead to a complex but fascinating interplay between gravity, particle physics, and geometry, which enlarges and enriches general relativity in the direction of a quantum gravity theory. High-precision astronomical data mean that cosmology is a potential laboratory for testing and constraining these brane worlds. The models predict extra-dimensional signatures in the cosmic microwave background and other observations, and these predictions can in principle be tested against data.

# Branes and Black Hole Statistical Mechanics

**S R Das**, University of Kentucky, Lexington, KY, USA

## Introduction

In classical general relativity, a black hole is a solution of Einstein's equations with a region of spacetime which is causally disconnected from the asymptotic region at infinity. The boundary of such a region is called the "event horizon." The spacetime around the simplest black hole in three space dimensions is described by the Schwarzschild metric

$$ds^2 = -\left(1 - \frac{2GM}{rc^2}\right) dt^2 + \left(1 - \frac{2GM}{rc^2}\right)^{-1} dr^2 + r^2\, d\Omega^2 \qquad [1]$$

where $G$ is Newton's gravitational constant, $c$ is the velocity of light, and we have used spherical coordinates with $d\Omega$ the line element on an $S^2$. A nonrotating, uncharged star which is too massive to form a neutron star will eventually collapse, and at late times the metric will be given by [1]. The horizon is a null surface $S^2 \times t$ and the radius of the $S^2$ is $r_{\text{horizon}} = 2GM/c^2$. The Schwarzschild solution has generalizations to black holes with charge and angular momentum and no-hair theorems guarantee that a black hole has no other characteristic property. All these solutions can be generalized to other theories like supergravity in various dimensions.

In 1974, Hawking showed that due to pair production of particles near the horizon, black holes radiate thermally. Hawking's calculation is valid for black holes whose masses are much larger than the Planck mass: for such black holes, the curvature at the horizon is weak and normal semiclassical quantization is valid. Remarkably, the properties of Hawking radiation are quite universal. A black hole can be characterized by an entropy called the Bekenstein–Hawking entropy. The leading result for the entropy $S_{\text{BH}}$ for all black holes in any theory with the standard Einstein–Hilbert action is given by

$$S_{\text{BH}} = \frac{A_{\text{H}}}{4G} \qquad [2]$$

where $A_{\text{H}}$ denotes the area of the horizon. The temperature $T_{\text{H}}$ is given by

$$T_{\text{H}} = \frac{\kappa}{2\pi} \qquad [3]$$

where $\kappa$ is the surface gravity at the horizon. The principle of detailed balance further ensures that the radiation rate of some species of particle $i$, $\Gamma_i(k)$, in some given momentum range $(\boldsymbol{k}, \boldsymbol{k} + d\boldsymbol{k})$ is related to the corresponding absorption cross section $\sigma_i(k)$ by

$$\Gamma(k) = \frac{\sigma_i(k)}{e^{\omega/T_{\text{H}}} \pm 1} \frac{d^d k}{(2\pi)^d} \qquad [4]$$

where $\omega$ is the energy and $d$ denotes the number of spatial dimensions. The $\pm$ sign refers to fermions (bosons), respectively. A nontrivial $k$ dependence of $\sigma_i$ signifies a departure from black-body behavior. Consequently, $\sigma_i(k)$ is often called a grey-body factor. Equations [2] and [3] may be derived by combining Hawking's calculation of the radiation with standard thermodynamic relations. Alternatively, they follow from the leading semiclassical approximations of path-integral formulations of Euclidean gravity based on the standard Einstein–Hilbert action. For an account of black-hole thermodynamics, see Wald (1994).

Unlike usual thermodynamic systems, black holes appear to pose a deep puzzle. In usual systems, thermodynamics is a coarse-grained description of a system which is in a highly degenerate state. Typically, such systems are described in terms of a few macroscopic parameters such as the total energy, the total volume, the total charge. For each set of values of these macroscopic parameters, there are a large number of microscopic states which can be described in terms of the constituents such as atoms or molecules. This degeneracy manifests itself as an entropy $S$ which is related to the number of microscopic states for a given set of values of the macroscopic parameters, $\Omega$ by Boltzmann's relation

$$S = \log(\Omega) \qquad [5]$$

where units have been chosen such that the Boltzmann constant is unity. For a black hole, the macrostates are specified by its mass, charge, and angular momentum. No-hair theorems, however, seem to suggest that there are no other properties and hence no obvious candidate for microstates. In the absence of such a statistical basis, one would be inevitably led to the conclusion that there is loss of information in processes involving black holes.

In a consistent quantum theory of gravity, there would be such a statistical basis since quantum mechanics is unitary. String theory is a strong candidate for a unified theory which contains gravity. Indeed, string theory provides a microscopic description for a class of black holes.

## Black Hole Solutions in String Theory

Perturbatively, the basic excitations of string theory are fundamental closed and open strings characterized by a string tension $T_s$ and hence a length scale, the string length $l_s = 1/\sqrt{2\pi T_s}$. Consistency requires that the string should be able to propagate in ten spacetime dimensions and should be supersymmetric at the fundamental level. Formulated in this fashion, there are several consistent string theories: type IIA, type IIB, and heterotic string theory (which contain only closed strings perturbatively) and type I theory (which contains both open and closed strings).

At energies much smaller than $1/l_s$, only the massless modes of the string can be excited. For all these string theories, the massless spectrum of closed strings contains the graviton and the low-energy dynamics is given by the appropriate supersymmetric generalization of general relativity, supergravity. In addition, the closed-string spectrum contains a neutral scalar field, the dilaton $\phi$, whose expectation value gives rise to a dimensionless parameter governing interactions, called the string coupling $g_s$:

$$g_s = e^{<\phi>} \qquad [6]$$

The ten-dimensional gravitational constant is given by

$$G_{10} = 8\pi^6 g_s^2 l_s^8 \qquad [7]$$

Ten-dimensional supergravity has a wide variety of black hole solutions, the simplest of which is the straightforward generalization of the Schwarzschild solution.

### Black $p$-Brane Solutions

More significantly, there are solutions which are charged with respect to the various gauge fields that appear in the supergravity spectrum. Generically, these charged solutions represent extended objects. For accounts of such solutions, see Maldacena (1996).

Consider, for example, the supergravity which follows from type IIB string theory. This theory has a pair of 2-form gauge fields $B_{MN}$ and $B'_{MN}$ and a 4-form gauge field $A_{MNPQ}$ with a self-dual field strength. Just as an ordinary point electric charge produces a 1-form gauge field, a $(p+1)$-form gauge field may be sourced by an electrically charged $p$-dimensional extended object. The corresponding field strength is a $(p+2)$-form, whose Hodge dual in $d$ spacetime dimensions is a $(d-p-2)$ form. This shows that there should be magnetically charged $(d-p-4)$-dimensional extended objects as well. These extended objects are called "branes."

In the type IIB example, there should be two kinds of one-dimensional extended objects which carry electric charge under $B_{MN}, B'_{MN}$, called the F-string and the D-string, respectively. There are also two kinds of five-dimensional branes which carry magnetic charges under $B_{MN}, B'_{MN}$, called the NS 5-brane and D5 brane, respectively. Finally, there should be a 3-brane, since the corresponding 5-form field strength is self-dual as well as a D7 brane. A similar catalog can be prepared for other string theories, as well as for 11-dimensional supergravity, which is the low-energy limit of M-theory.

The classical solutions for a set of $p$-branes of the same kind generally have inner and outer horizons which have the topology $t \times S^{8-p} \times R^p$. The outer horizon is then associated with a Hawking temperature and a Bekenstein–Hawking entropy. Of particular interest are extremal limits. In this limit, the inner and outer horizons coincide and the mass density is simply proportional to the charge. Given some charge, the extremal solution has the lowest energy. Extremal limits are interesting because in supergravity these correspond to solutions in which some of the supersymmetries (in this case, half of the supersymmetries) are retained – such solutions are called Bogomolny–Prasad–Sommerfeld (BPS) saturated solutions. The charge in question appears as a central charge in the extended supersymmetry algebra. This fact may be used to show that such BPS solutions are absolutely stable. Indeed, for the particular solution considered here, the Hawking temperature $T_H \to 0$, so that there is no Hawking radiation, as required by stability. Furthermore, the entropy $S_{BH} \to 0$. The horizon shrinks to a point which appears as a naked null singularity.

All the ten dimensions of string theory need not be noncompact. In fact, to describe the real world, one must have a solution of string theory in which six of the dimensions are wrapped up and form a compact space. In principle, however, one can compactify any number of dimensions. In the above example of a $p$-brane, it is trivial to compactify the directions along which the brane is extended to a $p$-dimensional torus, $T^p$, which can be chosen to be a product of $p$ circles each of radius $R$. At length scales much smaller than $R$, the theory then becomes a $(10-p)$-dimensional theory. The $p$-brane appears as a black hole with a spherical horizon and, since the original $p$-form gauge field now behaves as an ordinary 1-form gauge field with a nonzero time component, this is an electrically charged black hole.

### D1–D5–*N* System and Five-Dimensional Black Holes

For reasons which will become clear in the next section, it is useful to get extremal black holes with large horizon areas, so that Hawking's semiclassical formulas are valid. It turns out that such solutions involve branes of various types which intersect each other and are suitably wrapped on compact internal spaces. Such black holes then have necessarily different kinds of charges. It turns out that the simplest case is a five-dimensional black hole with three kinds of charges, which is obtained by brane systems wrapped on a compact five-dimensional space. An example is a type IIB solution which has D5 branes which are wrapped on either $T^4 \times S^1$ or $K3 \times S^1$, together with D1 branes wrapped on the $S^1$ as well as some momentum along the $S^1$. From the noncompact five-dimensional point of view, this is a black hole with three kinds of gauge charges: the D5 charge $Q_5$, the D1 charge $Q_1$, and a Kaluza–Klein charge $N$ coming from the momentum $P = N/R$ along the circle of radius $R$.

When the internal space is $T^4 \times S^1$ the five-dimensional Einstein frame metric is given by

$$ds^2 = -[f(r)]^{-2/3}\left(1 - \frac{r_0^2}{r^2}\right)dt^2 + [f(r)]^{1/3}\left[\frac{dr^2}{(1 - r_0^2/r^2)} + r^2\, d\Omega_3^2\right] \qquad [8]$$

where

$$f(r) = \left(1 + \frac{r_0^2 \sinh^2 \alpha_1}{r^2}\right)\left(1 + \frac{r_0^2 \sinh^2 \alpha_5}{r^2}\right) \times \left(1 + \frac{r_0^2 \sinh^2 \sigma}{r^2}\right) \qquad [9]$$

and the three charges are

$$Q_1 = \frac{V r_0^2 \sinh 2\alpha_1}{32\pi^4 g_s l_s^6}, \qquad Q_5 = \frac{r_0^2 \sinh 2\alpha_5}{2 g_s l_s^2}$$
$$N = \frac{V R^2}{32\pi^4 l_s^8 g_s^2} r_0^2 \sinh 2\sigma \qquad [10]$$

where $V$ is the volume of the $T^4$ and $R$ is the radius of the circle $S^1$.

The ADM mass of the black hole is

$$M_{\text{ADM}} = \frac{R V r_0^2}{32\pi^4 g_s^2 l_s^8} \times [\cosh 2\alpha_1 + \cosh 2\alpha_5 + \cosh 2\alpha] \qquad [11]$$

The Bekenstein–Hawking entropy is given by

$$S_{\text{BH}} = \frac{R V r_0^3}{8\pi^3 l_s^8 g_s^2} \cosh \alpha_1 \cosh \alpha_5 \cosh \sigma \qquad [12]$$

while the Hawking temperature is

$$T_{\text{H}} = \frac{1}{2\pi r_0 \cosh \alpha_1 \cosh \alpha_5 \cosh \sigma} \qquad [13]$$

The extremal limit of this solution is given by

$$r_0 \to 0, \quad \alpha_1, \alpha_5, \sigma \to \infty$$
$$Q_1,\, Q_5,\, N = \text{fixed} \qquad [14]$$

The extremal solution is a BPS saturated state and retains four of the original supersymmetries. In this limit, the inner and outer horizons coincide. However, the horizon is now a smooth $S^3$ with a finite area in the Einstein frame metric. Consequently, the extremal Bekenstein–Hawking entropy is also finite and may be seen to be

$$S_{\text{BH}}^{\text{3-charge extremal}} = 2\pi\sqrt{Q_1 Q_5 N} \qquad [15]$$

The temperature, however, is zero in this limit, which is consistent with the stability of a BPS saturated state.

The above five-dimensional black hole is in fact a generalization of the Reissner–Nordtsrom black hole. Similar solutions with large horizon areas in the extremal limit can be constructed in four dimensions. One such construction is in the IIB theory wrapped on $T^6$ in which there are four sets of D3 branes which wrap four different $T^3$'s contained in the $T^6$. Black holes with lower supersymmetry may be obtained by replacing the $T^6$ by a Calabi–Yau space.

### Duality and Branes

String theory has a rich set of symmetries called duality symmetries which relate different kinds of string theories that are suitably compactified. These symmetries relate different classical solutions. For example, application of these symmetries relate the five-dimensional black holes above with other five-dimensional black holes with different kinds of charges. Furthermore, at the level of supergravity, these various theories may be derived from a yet unknown 11-dimensional theory called the M-theory whose low-energy limit is 11-dimensional supergravity.

## Branes in String Theory

For a given string theory, the perturbative spectrum consists of strings. However, at the nonperturbative

level, there are, in addition, extended objects of other dimensionalities. Duality symmetries imply that these extended objects are as "fundamental" as the strings themselves. Such extended objects are also called branes. For an exhaustive account of branes in string theory, see Johnson (2003).

Like their counterparts in supergravity, branes in string theory are typically charged with respect to some gauge fields. While supergravity solutions are possible with any value of the charge, in string theory the brane charges have to be quantized. Multiple units of the minimum quantum of charge can appear as collections of branes each with unit charge or, alternatively, branes which wrap around compact cycles in space a multiple number of times.

### D-Branes

The extended objects in string theory are described in terms of their collective excitations. These are best understood for the class of branes called D-branes in the type II theory, discovered by Polchinski. These are D1, D3, D5, and D7 branes in type IIB and D0, D2, D4, and D6 branes in type IIA theory. D$p$ branes are characterized by the fact that they couple to, and act as sources for, $(p+1)$-form gauge fields which belong to the Ramond–Ramond sector of the theory. Collective excitations of a $p$-dimensional extended object in field theory are expected to be described by waves on its $(p+1)$-dimensional world volume. The collective coordinate action would be a quantum field theory which has vectors, corresponding to longitudinal oscillations of the brane, and scalars which correspond to transverse oscillations. For D-branes in string theory, the theory of collective excitations is a string field theory of open strings whose endpoints lie on the brane. (This is the origin of the nomenclature D-brane: an open string whose ends are constrained to lie on the brane has a world-sheet description in which the bosonic fields corresponding to transverse target space coordinates have Dirichlet boundary conditions.) The lowest-energy states of open superstrings are ordinary massless gauge fields and their supersymmetric partners so that the low-energy limit of the string field theory is a supersymmetric gauge theory.

The fact that the underlying theory is a string theory has an important consequence. For a system of $N$ parallel D-branes of the same type, one would have open strings which join different branes as well as the same brane. The low-energy theory then becomes a supersymmetric nonabelian gauge theory with gauge group U($N$). In a suitable gauge, the off-diagonal gauge fields and their supersymmetric partners (which include scalar fields in the adjoint representation) are the low-energy degrees of freedom of open strings which connect different branes.

The mass density or tension $T_p$ of a single D$p$ brane is given by

$$T_p = \frac{1}{g_s (2\pi)^p l_s^{p+1}} \qquad [16]$$

This couples to the $(p+1)$-form gauge field with a charge

$$\mu_p = g_s T_p \qquad [17]$$

and the Yang–Mills coupling constant for the collective theory on the brane world volume is given by

$$g^2_{\mathrm{YM-D}p} = (2\pi)^{p-2} g_s l_s^{p-3} \qquad [18]$$

The ground state of a single D$p$ brane is a BPS state which preserves 16 of the 32 supersymmetries of the original theory. One consequence of this is that two or more parallel D$p$ branes of the same type form a threshold bound state preserving the same supersymmetries, with no net force between them. As a result, the tension of $N$ parallel D$p$ branes is simply $NT_p$.

Branes of different dimensionalities can also form bound states. Of particular interest are configurations which can form threshold bound states which preserve some supersymmetries. For example, a set of $N_1$ parallel D$p$ branes can form a threshold bound state with a set of $N_2$ parallel D$(4+p)$ branes with all the $p$ branes lying entirely along the $(4+p)$-branes. This configuration is also a BPS saturated state preserving eight of the original supersymmetries and would have charges under both $(p+1)$-form and $(p+5)$-form gauge potentials. The BPS nature ensures that the total mass density is the sum of the individual mass densities.

### NS Branes

The other extended objects in string theory are called NS branes since they couple to $p$-form gauge fields which arise from the Neveu–Schwarz/Neveu–Schwarz sector of the world-sheet theory. These are present in all the five string theories and appear in two types. The first is a macroscopic fundamental string which may be wound around a compact direction. The second is called a solitonic 5-brane. While the collective dynamics of a fundamental string is the standard world-sheet description of string theory, the description for the NS 5-brane is rather complicated and not known in full detail. The rest of this article deals exclusively with D-branes.

## D-Branes and Black Branes

The idea that black holes correspond to highly degenerate states in string theory is quite old and dates back to 't Hooft (1990) and Susskind (1993). In the following two sections we discuss such black holes which are described by D-branes. For reviews see Maldacena (1996), Das and Mathur (2001), and David *et al.* (2002).

We have so far discussed the string-theoretic branes in two different ways. In the first description, branes are solutions of the low-energy equations of motion – this is the setting in which branes provide conventional descriptions of black holes. In the second description, branes are certain states in the quantum theory of superstrings. More specifically, D-branes are described in terms of states of the open-string field theory which lives on the branes. The first description is necessarily approximate. On the other hand, the second description is exact in principle, although in practice one might not know how to write down and analyze the string-field theory in an exact fashion.

The description in terms of open-string field theory should reduce to the description in terms of a classical solution when the charges and masses become large. If black-hole thermodynamics has a microscopic origin, D-branes should be highly degenerate states in this limit and the entropy should be given by the Boltzmann formula. Furthermore, Hawking radiation should be understood as an ordinary decay process.

For a system of $Q_p$ parallel D$p$ branes, the mass is $Q_p/g_s$, while Newton's gravitational constant $G \sim g_s^2$. Gravitational effects are controlled by $GM \sim g_s Q_p$. A semiclassical limit in closed-string theory requires $g_s \to 0$, while a nontrivial gravitational effect in this limit requires $g_s Q_p$ finite, which implies one must have $Q_p \gg 1$. Furthermore, when $g_s Q_p \gg 1$ the typical curvatures are small compared to the string scale and the semiclassical string theory reduces to classical supergravity. This is the limit in which branes are well described as classical solutions.

Similar considerations apply for brane systems with multiple charges. For example, in the D1–D5–$N$ system the classical solution becomes a good description when all the quantities $g_s Q_1$, $g_s Q_5$, and $g_s^2 N$ become large. (The relevant quantity which comes with the momentum has $g_s^2$ rather than $g_s$ because the mass contribution from the momentum is simply $N/R$ without any inverse power of $g_s$.) However, $g_s$ is the square of the coupling constant of the open-string theory living on the brane – in fact, eqn [18] shows this relation in the low-energy limit. It is well known that in a U($Q_p$) gauge theory the real coupling constant is $g_{\mathrm{YM}}\sqrt{Q_P} \sim \sqrt{g_s Q_p}$. This means that the semiclassical limit corresponds to a strongly coupled string-field theory which reduces to strongly coupled gauge theory in the low-energy limit and the picture of D-branes as a collection of open strings is not very useful. In fact, known calculational methods in gauge theory or open-string theory are not valid in this regime.

### Microscopic Entropy for Two-Charge Systems

The prospects are much better for extremal black holes, which appear as BPS states in string theory. This is because the spectra of BPS states do not depend on the coupling. The degeneracy of such states may therefore be calculated at weak coupling, where techniques are well known and the result can be extrapolated to strong coupling without change.

The simplest BPS state is the ground state of a set of parallel D-branes of the same type. This state is indeed 128-fold degenerate, which would imply a microscopic entropy. This entropy, however, is small and therefore invisible in the corresponding classical solution. Indeed, the classical solution shows that in the extremal limit the horizon area is zero, leading to a vanishing Bekenstein–Hawking entropy.

The next interesting class of states consists of threshold bound states with two kinds of charges. Consider, for example, the D1–D5 system on $T^4 \times S^1$ considered above with no momentum along the D1's. By known duality transformations, this is equivalent to a fundamental IIB string which is wound $Q_5$ times around the $S^1$ and with a net momentum $P = Q_1/2\pi Q_5 R$ (where $R$ is the radius of the $S^1$), with four of the transverse directions compactified on a $T^4$. For this system, it is easy to count the number of states for given values of $Q_1$ and $Q_5$ at weak string coupling by simply enumerating the perturbative oscillator states of the string. For large values of $Q_1$ and $Q_5$, we can alternatively calculate this entropy by using a canonical ensemble of eight massless bosons corresponding to the eight transverse polarizations and their supersymmetric partners – eight massless fermions – moving on the string with some temperature $T$ and a chemical potential $\alpha$ for the total momentum.

Consider a noninteracting gas of $f$ massless bosons and $f$ fermions living on a circle with circumference $L$. The average number of left- and right-moving particles with some energy $e$, denoted by $\rho_L$, $\rho_R$, respectively, are

$$\rho_i(e) = \frac{1}{e^{e/T_i} \pm 1}, \quad i = L, R \qquad [19]$$

where the ± sign refers to fermions and bosons, respectively, and we have introduced left- and right-moving temperatures $T_L, T_R$. The physical temperature is

$$\frac{1}{T} = \frac{1}{2}\left(\frac{1}{T_L} + \frac{1}{T_R}\right) \qquad [20]$$

The extensive quantities, such as the energy $E$, momentum $P$, and entropy $S$, then become the sum of left- and right-moving pieces:

$$E = E_L + E_R, \quad P = P_L + P_R, \quad S = S_L + S_R \qquad [21]$$

and the distribution function [19] leads to the following thermodynamic relations:

$$T_i = \sqrt{\frac{3E_i}{L\pi f}} = \frac{4S_i}{\pi f L}, \quad i = \mathrm{L, R} \qquad [22]$$

Since the total momentum $P = P_R + P_L = E_R - E_L$ is nonzero, the lowest-energy state is clearly the one in which all the particles move in the same direction, for example, right moving. This is a BPS state and corresponds to the extremal solution in supergravity. Then $E = E_R = P = P_R$. This approach to the black hole entropy was initiated by Das and Mathur (1996) and Callan and Maldacena (1996).

For our two-charge system, $f = 8, P = 2\pi Q_1/L$, and $L = 2\pi R Q_1 Q_5$. Using [22] we get

$$S_{\text{micro}}^{\text{2-charge-II}} = 2\pi\sqrt{2Q_1Q_5} \qquad [23]$$

This is the microscopic entropy for the fundamental string with momentum in the type II theory. By duality, this is also the microscopic entropy of the D1–D5 system. This is a large number which should agree with the macroscopic entropy calculated from the corresponding classical solution.

The discussion is almost identical for the fundamental heterotic string, except that now we have 24 right-moving bosons, eight left-moving bosons, and eight left-moving fermions, and the BPS state consists only of right movers. If $n_w$ denotes the winding number and $n_p$ the quantized momentum the extremal heterotic string entropy is

$$S_{\text{micro}}^{\text{2-charge heterotic}} = 4\pi\sqrt{n_p n_w} \qquad [24]$$

The supergravity solution for the D1–D5 system may be obtained by substituting $\sigma = 0$ in eqns [8]–[13]. In the extremal limit, the classical Bekenstein–Hawking entropy vanishes as is clear from the expression [15], in which $N = 0$. This appears to be in contradiction with the fact that the state has a large microscopic entropy.

The key point, however, is that the two-charge solution has a singular horizon where the string frame curvature is large. Consequently, low-energy tree-level supergravity breaks down near the horizon and higher-derivative terms (e.g., higher powers of curvature) become important. This issue has been best studied for the fundamental heterotic string compactified on $T^6$. This is dual to the D1–D5 system in type IIB theory compactified on $K3 \times T^2$. The classical supergravity solution is then a singular black hole in four spacetime dimensions. In one of the first papers on the string-theoretic understanding of black hole thermodynamics, Sen (1995) showed that, for large $n_p$, $n_w$, string-loop effects are small near the horizon so that the only relevant corrections are higher-derivative terms coming from integrating out the massive modes of the string at tree level. Furthermore, a robust scaling argument shows that regardless of the detailed nature of the derivative corrections, the macroscopic entropy defined through the horizon area must be of the form $a\sqrt{n_p n_w}$, where $a$ is a pure number. Finally, one can define a "stretched horizon" as the surface where the curvature becomes of the order of the string scale and the area of the stretched horizon is indeed proportional to $\sqrt{n_p n_w}$. This result gives a strong indication that string theory provides a microscopic basis for black hole thermodynamics, although the coefficient $a$ cannot be determined without more detailed knowledge of higher-derivative terms.

## Microscopic Entropy of Extremal Three-Charge System

Brane bound states with three kinds of charge provide examples of black holes whose extremal limits have large horizons with curvatures much smaller than the string scale. In this case, a microscopic count of states in string theory should exactly account for the Bekenstein–Hawking formula, without corrections coming from higher derivatives. This is indeed true, as first found by Strominger and Vafa (1996). In the following, we will outline how this calculation can be done in the D1–D5–$N$ system on $K3 \times S^1$ or $T^4 \times S^1$ following the treatment of Dijkgraaf *et al.* (1996).

D1 branes can be considered as "instanton strings" in the six-dimensional supersymmetric $U(Q_5)$ gauge theory of D5 branes (actually, these should be called solitonic strings rather than instantons, since the configurations are time independent). The total instanton number is the D1-brane charge $Q_1$. The moduli space of these instantons is then a blown-up version of the

orbifold $(T^4)^{Q_1Q_5}/S(Q_1Q_5)$ or $(K3)^{Q_1Q_5}/S(Q_1Q_5)$ and is $4Q_1Q_5$ dimensional. Since any instanton configuration is independent of time $x^0$ and the $S^1$ direction $x^5$, the collective coordinate dynamics is a $(1+1)$-dimensional field theory which lives in the $(x^0, x^5)$ space. At low energies, this flows to a conformal field theory with a central charge $c = 6Q_1Q_5$ since there are $4Q_1Q_5$ bosons each contributing 1 to the central charge and an equal number of fermions each contributing 1/2. The BPS state with momentum $N/R$ is a purely right- or left-moving state in this conformal field theory which has a conformal weight $N$. From general principles of conformal invariance, the degeneracy of such states for large $N$ is given by Cardy's formula

$$d(N) \sim e^{2\pi\sqrt{cN/6}} \qquad [25]$$

so that the microscopic entropy is

$$S^{\text{micro}}_{\text{3-charge}} = \log d(n) = 2\pi\sqrt{cN/6} \qquad [26]$$

Substituting the value of $c = 6Q_1Q_5$, this is in exact agreement with the Bekenstein–Hawking entropy of the classical solution given in [15].

## Nonextremal Black Holes and Hawking Radiation

The BPS property of ground states of D-brane systems enables us to compute the degeneracy of microstates exactly in the regime of parameters where the state can be reliably described as a black hole solution in the low-energy theory. However, extremal black holes have vanishing temperature and do not radiate. To understand the microscopic origins of Hawking radiation, one has to go away from extremality. Such states are not supersymmetric and an extrapolation of weak-coupling calculations to strong coupling is not *a priori* justified. Nevertheless, it turns out that for small departures from extremality, weak-coupling results still reproduce semiclassical answers for entropy, temperature, and luminosity.

### Near-Extremal Entropy

Nonextremal properties are best understood for the D1–D5–$N$ system on $T^4 \times S^1$. In the orbifold limit, the conformal field theory which describes the low-energy dynamics is equivalent to a gas of strings which are wound around the $S^1$ and which can oscillate along the $T^4$. The total winding number is $k = Q_1Q_5$ and may be achieved by sets of strings which are multiply wound in various ways. As argued below, entropically the most favored configuration is a single long string wound around $Q_1Q_5$ times. Thus, the thermodynamics may be analyzed exactly along the lines of the fundamental string in the previous section. The thermodynamic relations are given by [22] with $f = 4$ and $L = 2\pi RQ_1Q_5$. The extremal state consists entirely of right movers and $E = E_R = N/R$. Substituting these values in [22] yields the correct formula for the microscopic entropy

$$S^{\text{3-charge}}_{\text{micro}} = 2\pi\sqrt{Q_1Q_5N} \qquad [27]$$

The same expression follows if $f = 4Q_1Q_5$ and $L = 2\pi R$ corresponding to $Q_1Q_5$ singly wound strings. However, for statistical methods to hold, the entropy must be much larger than the number of flavors. The ratio of the entropy to the number of flavors is $S/f \sim \sqrt{N/Q_1Q_5}$ for multiple singly wound strings and is not guaranteed to be large when all of $Q_1$, $Q_5$, $N$ are large. On the other hand, this ratio is $S/f \sim \sqrt{Q_1Q_5N}$ for the long string. This shows that the long string is always entropically favored.

A departure from the extremal state is achieved by adding a left-moving momentum $2\pi n/L$ as well as a right-moving momentum $2\pi n/L$ to the extremal state, thus adding energy to the system but maintaining the total momentum. For the long string, this yields

$$S_R = 2\pi\sqrt{Q_1Q_5N + n}, \qquad S_L = 2\pi\sqrt{n} \qquad [28]$$

For small departures from extremality, $n \ll N$, the expressions for the total entropy and temperature as a function of the excess energy $\Delta E = 2n/Q_1Q_5$ agree exactly with the near-extremal Bekenstein–Hawking entropy and the Hawking temperature of the classical solution, as shown by Callan and Maldacena (1996) and by Horowitz and Strominger.

The necessity of the long string appears in another important physical consideration. For statistical mechanics to be valid, the specific heat of the system has to be larger than unity. This implies that for the case considered here the energy gap $\Delta E$ must be larger than $1/RQ_1Q_5$, which is precisely what the long string yields.

### Hawking Radiation

A nonextremal state described above is unstable, since a left mover can annihilate a right mover into a closed-string mode which may leave the brane system and propagate to the asymptotic region. The resulting closed-string state will be in a thermal state whose temperature is the physical temperature of the initial state. This process is the microscopic

description of Hawking radiation. The decay rate is related to the absorption cross section of the corresponding mode by the principle of detailed balance, encoded in eqn [4].

From the point of view of the classical solution, the absorption cross section can be calculated by solving the linearized wave equation in the background geometry and calculating the ratio of the incident and reflected waves. It follows from these calculations that at low energies, absorption (and hence emission) are dominated by massless minimally coupled scalars. In fact, for any spherically symmetric black hole in any number of dimensions, there is a general theorem which ensures that the low-energy limit of this absorption cross section is exactly equal to the horizon area.

In the microscopic model for the three-charge black hole, this absorption cross section may be calculated by the usual rules of quantum mechanics. In the long-string limit and in the approximation that the modes on the long string form a dilute gas, the result has been derived by Das and Mathur (1996):

$$\sigma(\omega) = \frac{2\pi G_{10} Q_1 Q_5}{V} \omega \frac{e^{\omega/T} - 1}{(e^{\omega/2T_R} - 1)(e^{\omega/2T_L} - 1)} \quad [29]$$

where $V$ is the volume of the $T^4$ and $T$ is the physical temperature given by [20]. For a near-extremal hole $T_R \gg T_L$, so that $T \sim 2T_L$. Then in the extreme low-energy limit $\omega \ll T_R$, so that the corresponding Bose factor may be approximated as $1/(e^{\omega/2T_R} - 1) \sim 2T_R/\omega$. The cross section [29] becomes

$$\sigma = \frac{4\pi Q_1 Q_5 G_{10} T_R}{V} = \frac{4 G_{10} S_R}{(2\pi R) V} = 4 G_5 S_{\text{extremal}} = A_H \quad [30]$$

where $G_5$ is the five-dimensional Newton's gravitational constant. We have used the relation [22] with $L = 2\pi R Q_1 Q_5$ and $f = 4$. The fact that in the near-extremal limit $S_R$ is simply the extremal entropy and the fact that the extremal entropy reproduces the Bekenstein–Hawking formula has been used as well. Thus, the microscopic cross section exactly reproduces the semiclassical result at low energies. Even more remarkably, the full cross section [29] agrees with the semiclassical answer for the gray-body factor for parameters which correspond to the dilute-gas regime, as shown by Maldacena and Strominger.

It is rather surprising that the results for microscopic absorption cross section calculated at weak coupling agree with the semiclassical answers, since the relevant process involves states which are not supersymmetric and therefore a naive extrapolation to strong coupling is not *a priori* justified. There are strong indications, however, that low-energy nonrenormalization theorems are at work. This agreement has been established not only for black holes with finite-horizon areas, but also for other systems with no horizons – most significantly, a set of parallel 3-branes – and forms the basis for Maldacena's conjecture about AdS/CFT Correspondence (see AdS/CFT Correspondence).

## Effects of Higher-Derivative Terms

The classical low-energy limit of string theory is supergravity. The effects of the massive modes of the string as well as effect of string loops is to add terms to the supergravity action which involve higher number of spacetime derivatives, for example, terms containing higher powers of the curvature. In the presence of such terms, the Bekenstein–Hawking formula for black hole entropy [2] receives corrections which can be calculated in a systematic fashion. It turns out that for a class of extremal black holes, this corrected entropy as computed in the modified supergravity is also in exact agreement with a microscopic calculation.

One example of this agreement is provided by four-dimensional extremal black holes in type IIA string theory compactified on a Calabi–Yau manifold. These are obtained by wrapping D4 branes on three different 4-cycles on the Calabi–Yau and having in addition a number of D0 branes. Let $p^A$, $A = 1, \ldots, 3$ denote the three D4 charges and $q_0$ denote the D0 charge. The microscopic entropy of the BPS state can be computed by embedding this in M-theory:

$$S_{\text{micro}}^{\text{CY-Black hole}} = 2\pi \sqrt{\frac{1}{6} |q_0| (C_{ABC} p^A p^B p^C + c_{2A} p^A)} \quad [31]$$

where $C_{ABC}$ is the intersection number of the 4-cycles and $c_2$ denotes the second Chern class of the Calabi–Yau space. When all the charges $p^A$ are large, the term involving $c_2$ is subdominant. In this case, the result agrees with the Bekenstein–Hawking entropy of the corresponding classical solution. When the charges are not all large (so that the second term is appreciable), the curvatures of the supergravity solution become large at the horizon and higher-derivative corrections to the action cannot be ignored. In this particular case, it turns out that these higher-derivative corrections are string-loop corrections and can be computed using general properties of $N = 2$ supersymmetry, so that one can compute corrections to near-horizon geometry. Furthermore, one has to now modify the

expression for macroscopic entropy using the formalism of Wald. Putting these together, it is found that the macroscopic entropy following from the modified supergravity is in exact agreement with [31]. This subject is reviewed in Mohaupt (2000).

These methods have also been applied to the problem of two-charge black holes in heterotic string theory on $T6$ or, equivalently, type IIA on $K3 \times T^2$ (Dabholkar 2004). Recall that in this case the horizon of the usual supergravity solution is singular. It has been found that leading-order higher-derivative corrections smoothen out the horizon into a $AdS_2 \times S^2$ spacetime and the modified expression for the macroscopic entropy is again in exact agreement with the microscopic answer [23].

## Geometry of Microstates

A satisfactory solution of the information-loss paradox requires a much more detailed understanding of black holes in string theory. The discussion above shows that black holes have microstates which may be described well in the weak-coupling regime. It is interesting to ask whether there is a description of these microstates in the strong-coupling regime in terms of the effective geometry perceived by suitable probes. This question has been answered for the two-charge system in great detail (see Mathur (2004)). It turns out that the D1–D5 microstates can be described by perfectly smooth metrics with no horizons, and they asymptote to the standard two-charge metric discussed above. The location of the erstwhile stretched horizon marks the point where the different microstates start differing from each other significantly. Since each such geometry does not have a horizon, neither does it have any entropy – this is consistent with their identification with nondegenerate microstates. Indeed, the number of such microstates correctly accounts for the microscopic entropy. Whether a similar picture holds for the three-charge system remains to be seen in detail, although there are some indications that this may be true. In this approach, it is not yet fully understood how a horizon emerges and why the entropy scales as the horizon area.

## Outlook

One key feature of the understanding of black hole statistical mechanics from the dynamics of branes is the fact that a problem in gravity is mapped to a problem in a theory without gravity, for example, open-string field theory. In fact, the closed strings in the bulk are already contained in the spectrum of the open strings. This is a consequence of the basic duality between open strings and closed strings. Furthermore, the open-string theory lives in a lower-dimensional spacetime. This is a manifestation of the holographic principle. As argued by Maldacena, the presence of a horizon implies that the low-energy limit retains all the modes of the closed strings near the horizon, while it truncates the open-string theory to a gauge theory. Open–closed duality then reduces to gauge–string duality. This provides a strong evidence that black holes obey the normal laws of quantum mechanics and hence their time evolution is unitary.

One of the most outstanding problems in the subject is a proper understanding of neutral black holes. Most of the quantitative results described above depend on supersymmetry, which allows extrapolation of weak-coupling answers to the strong-coupling domain. Some of these results can be extended to situations which have small departures from supersymmetry, for example, near-extremal black holes. States corrresponding to neutral black holes are, however, far from supersymmetry and known calculational techniques fail. There are good reasons to expect, however, that the general philosophy – in particular the holographic principle – is still valid. Finally, so far string theory has been able to attack problems of eternal black holes. A satisfactory understanding of the information-loss problem requires an understanding of the dynamics of black hole formation and subsequent evaporation. Unfortunately, very little is known about this at the moment.

## Glossary

**ADM** (Arnowitt–Deser–Misner) **mass** – Mass of a gravitational background which is asymptotically flat.

**AdS$_n$** (anti-de Sitter space) – A space (or spacetime) with constant negative curvature in $n$ dimensions.

**BPS state** (Bogomolny–Prasad–Sommerfeld state) – In a theory of extended supersymmetry, a state that is invariant under a nontrivial subalgebra of the full supersymmetry algebra. These states always carry conserved charges, and supersymmetry determines the mass exactly in terms of the charges.

**Calabi–Yau space** – Complex Kahler manifold with vanishing first Chern class.

**Compactify** (n. compactification) – To consider a field or string theory in a spacetime some of whose spatial dimensions are compact.

**Dirichlet boundary condition** – The boundary condition which fixes the value of a field on the boundary.

**Duality** Equivalence of systems which appear to be distinct. For string theories, such equivalences relate string theories on different spacetimes as well as theories with different coupling constants.

**Einstein–Hilbert action** – The standard action for gravity which leads to Einstein's equation, $S = (1/16\pi G)\int d^d x \sqrt{g} R$, where $R$ is the Ricci scalar, $g$ denotes the determinant of the metric, and $G$ is Newton's gravitational constant.

**Instanton** – A classical solution of Euclidean field theory with finite action.

**Kaluza–Klein gauge field** – In a compactified theory, the gauge field which arises from the metric of the higher-dimensional theory.

**K3** – The unique Calabi–Yau manifold in four dimensions having an SU(2) holonomy.

**Loop levels** – In a Feynman diagram expansion of a field theory, terms which contribute in higher orders of the Planck constant $\hbar$.

**Macroscopic entropy** – Entropy associated with gravitational backgrounds via the Bekenstein–Hawking formula or its generalization.

**Microscopic entropy** – Entropy which follows from the degeneracy of states of a system via Boltzmann's relation.

**Minimally coupled scalar** – A scalar field whose equation of motion is the standard Klein–Gordon equation where the derivatives are covariant derivatives.

**Neveu–Schwarz/Neveu–Schwarz states** – In type I and II string theories, bosonic closed-string states whose left- and right-moving parts are bosonic.

**No-hair theorem** – A theorem in general relativity which states that black holes with nonsingular horizons are uniquely characterized by their mass, angular momenta, and charges which can couple to long-range gauge fields.

**Orbifold** – A coset space $M/G$ where $G$ is a group of discrete symmetries of a manifold $M$. If $G$ has a fixed point, the space is singular.

**p-Form** – A fully antisymmetric $p$-index tensor.

**Ramond–Ramond states** – In type I and II string theories, bosonic closed-string states whose left- and right-moving parts are fermionic.

**Reissner–Nordstrom black hole** – Black hole solution of general relativity with electric Maxwell charge.

**$S^n$** – $n$-Dimensional sphere.

**Supergravity** – Supersymmetric extension of general relativity.

**Supersymmetry** – A symmetry between bosons and fermions.

**Threshold bound state** – A bound state which is marginally bound, that is, the binding energy is zero.

**Tree level** – In a Feynman diagram expansion of a field theory, terms which contribute to lowest order of the Planck constant $\hbar$.

**U($N$)** – The group of $N \times N$ unitary matrices. If the determinant is unity, the subgroup is called SU($N$).

# Breaking Water Waves

**A Constantin**, Trinity College, Dublin,
Republic of Ireland

## Introduction

Watching the sea or a lake it is often possible to trace a wave as it propagates on the water's surface. One can roughly distinguish two types of breaking waves. All waves break while reaching the shore but certain waves break far from the shore. In the first case, the change in water depth or the presence of an obstacle (e.g., a rock) seems to cause wave breaking, while for certain waves within the second category, these factors appear not to be essential. It is a matter of observation that for many waves that break in the open water a drastic increase in their slope near breaking is noticeable. This leads us to the following mathematical definition: the wave profile gradually steepens as it propagates until it develops a point where the slope is vertical and the wave is said to have broken (Whitham 1980). Throughout this article, we are concerned with wave breaking that is not caused by a drastic change of the topography of the bottom; for a discussion of wave breaking at the beach we refer to Johnson (1997). The governing equations for water waves (see the next section) are too difficult to be dealt with in their full generality. Therefore, to gain some insight, one has to find simpler models that are more tractable mathematically. Investigating the properties of the model, certain predictions can be made. The conclusions reached will reflect reality only to some limited extent. The value of a model depends on the number and the degree of accuracy of physically useful deductions that can be made from it – the "truth" of the model is meaningless as all experiments contain inaccuracies and effects other than those accounted for (while deriving the model) cannot be totally excluded. We intend to discuss the way in which a recent model due to Camassa and Holm (1993) can lead to a better understanding of breaking water waves. Firstly we survey a few classical nonlinear partial differential equations that model the propagation of water waves over a flat bed (within the confines of the linear theory one cannot cope with the wave breaking phenomenon) and discuss their relevance to the study of breaking waves. We then analyze the breaking of waves within the context of the Camassa–Holm equation: existence of breaking waves, criteria that guarantee that a certain initial shape develops into a breaking wave, specific features of wave breaking (blow-up rate and blow-up set for certain types of breaking waves). We conclude the presentation with a discussion of the way in which solutions to the Camassa–Holm equation can be continued after wave breaking.

## The Governing Equations

The water waves that one typically sees propagating on the surface of the sea or on a lake are, as a matter of common experience, approximately two dimensional. That is, the motion is identical in any direction parallel to the crest line. To describe these waves, it suffices to consider a cross section of the flow that is perpendicular to the crest line. Choose Cartesian coordinates $(x, y)$ with the $y$-axis pointing vertically upwards and the $x$-axis being the direction of wave propagation, while the origin lies at the mean water level. Let $(u(t,x,y), v(t,x,y))$ be the velocity field of the flow, let $y = -d$ be the flat bed (for some fixed $d > 0$), and let $y = \eta(t,x)$ be the water's free surface. Homogeneity (constant density) is a physically reasonable assumption for gravity waves (Johnson 1997), and it implies the equation of mass conservation

$$u_x + v_y = 0 \qquad [1]$$

The inviscid setting is realistic since experimental evidence confirms that the length scales associated with an adjustment of the velocity distribution due to laminar viscosity or turbulent mixing are long compared to typical wavelengths. Under the assumption of inviscid flow the equation of motion is Euler's equation

$$\begin{aligned} u_t + uu_x + vu_y &= -P_x \\ v_t + uv_x + vv_y &= -P_y - g \end{aligned} \qquad [2]$$

where $P(t,x,y)$ denotes the pressure and $g$ is the gravitational constant of acceleration. The free surface decouples the motion of the water from that of the air so that (Johnson 1997) the dynamic boundary condition

$$P = P_0 \quad \text{on } y = \eta(t,x) \qquad [3]$$

must hold if we neglect surface tension, where $P_0$ is the (constant) atmospheric pressure. Moreover, since the same particles always form the free surface, we have the kinematic boundary condition

$$v = \eta_t + u\eta_x \quad \text{on } y = \eta(t,x) \qquad [4]$$

On the flat bed we have the kinematic boundary condition

$$v = 0 \quad \text{on } y = -d \qquad [5]$$

expressing the fact that the flow is tangent to the horizontal bed (or, equivalently, that water cannot penetrate the rigid bed). The governing equations for water waves are [1]–[5]. Other than the fact that they are highly nonlinear, a main difficulty in analyzing the governing equations lies in the fact that we deal with a free boundary problem: the free surface $y=\eta(t,x)$ is not specified *a priori*. In our discussion, we suppose that initially (at time $t=0$), a disturbance of the flat surface of still water was created and we analyze the subsequent motion of the water. The balance between the restoring gravity force and the inertia of the system governs the evolution of the mass of water and our primary objective is the behavior of the free surface.

An important category of flows are those of zero vorticity, characterized by the additional assumption

$$u_y = v_x \qquad [6]$$

The vorticity of a flow, $\omega = u_y - v_x$, measures the local spin or rotation of a fluid element. In flows for which [6] holds the local whirl is completely absent and for this reason such flows are called irrotational. Relation [6] ensures the existence of a velocity potential, namely a function $\phi(t,x,y)$ defined up to a constant via

$$\phi_x = u, \qquad \phi_y = v$$

Notice that [1] ensures that $\phi$ is a harmonic function, that is, $(\partial_x^2 + \partial_y^2)\phi = 0$. In this way, the powerful methods of complex analysis become available for the study of irrotational flows. Thus, while most water flows are with vorticity, the study of irrotational flows can be defended mathematically on grounds of beauty. Concerning the physical relevance of irrotational water flows, experimental evidence indicates that for waves entering a region of still water the assumption of irrotational flow is realistic (Johnson 1997). Moreover, as a consequence of Kelvin's circulation theorem (Acheson 1990), a water flow that is irrotational initially has to be irrotational at all later times. It is thus reasonable to consider that water motions starting from rest will remain irrotational at later times.

## Nonlinear Model Equations

Starting from the governing equations [1]–[6] one can derive a variety of model equations using the nondimensionalization and scaling approach: a suitable set of nondimensional variables is introduced, which, after scaling, leads to the appearance of parameters. The sizes and relative sizes of these parameters then govern the type of phenomenon that is of interest. An asymptotic expansion in one or several parameters yields an equation that is usually of significance in some region of space/time. The aim of this process is to obtain a simpler model that can be used to gain some understanding and to make some predictions for specific physical processes. This scaling method yields the Korteweg–de Vries (KdV) equation

$$\eta_t + \eta\eta_x + \eta_{xxx} = 0, \quad t > 0,\, x \in \mathbb{R} \qquad [7]$$

as a model for the unidirectional propagation of shallow water waves over a flat bed (Johnson 1997). In [7] the function $\eta(t,x)$ represents the height of the water's free surface above the flat bed. We would like to emphasize that the "shallow water" regime does not refer to water of insignificant depth – it indicates that the typical wavelength is much larger than the typical depth (e.g., tidal waves are considered to be shallow water waves although they affect the motion of the deep sea). The KdV model admits the solitary wave solutions

$$\eta_c(t,x) = 3c\,\mathrm{sech}^2\left(\frac{\sqrt{c}}{2}(x-ct)\right), \quad c \in \mathbb{R} \qquad [8]$$

For any fixed $c > 0$, the profile $\eta_c$ propagates without change of form at constant speed $c$ on the surface on the water, that is, it represents a traveling wave. Since the profiles [8] of the traveling waves drop rapidly to the undisturbed water level $\eta = 0$ ahead and behind the crest of the wave, $\eta_c$ are called solitary waves. Notice that [8] shows that taller solitary waves travel faster. They have other special properties: an initial profile consisting of two solitary waves, with the taller preceding the smaller one, evolves in such a way that the taller wave catches up the other, there is a period of complicated nonlinear interaction but eventually both solitary waves emerge completely unscathed! This special type of nonlinear interaction (the superposition principle is not valid since KdV is a nonlinear equation) in which solitary waves regain their form upon collision occurs only for special equations, in which case the solitary waves are called solitons. A further interesting property of the KdV model, relevant for the understanding of the interaction of solitons, is the fact that it is completely integrable (McKean 1998): there is a transformation which converts the equation into an infinite sequence of linear ordinary differential equations which can be trivially integrated. Moreover, the KdV-solitons $\eta_c$ are stable: an initial profile that is close to the form of a soliton will evolve into a wave that at any later times has a form close to that of a soliton (Benjamin 1972). Despite all these intriguing features of the KdV-model, for all initial profiles $x \mapsto \eta(0,x)$ within the Sobolev space $H^1(\mathbb{R})$ of square-integrable functions with a square-integrable distributional derivative, eqn [7] has a unique solution

defined for all times $t \geq 0$ (cf. Kenig *et al.* (1996)) so that the KdV model cannot be used to shed light on the wave breaking phenomenon.

Whitham (1980) suggested the equation

$$\eta_t + \eta\eta_x + \int_{\mathbb{R}} k(x-y)\eta_y(t,y)\mathrm{d}y = 0 \qquad [9]$$

for the free surface profile $x \mapsto \eta(t,x)$, with the singular kernel

$$k(x) = \frac{1}{2\pi}\int_{\mathbb{R}} \left(\frac{\tanh(\xi)}{\xi}\right)^{1/2} \mathrm{e}^{\mathrm{i}\xi x}\mathrm{d}\xi$$

to model wave breaking. It can be shown (see Constantin and Escher (1998) and references therein) that [9] describes wave breaking: there are smooth initial profiles $x \mapsto \eta(0,x)$ such that the resulting unique solution of [9] exists on a maximal time interval $[0,T)$ with

$$\sup_{(t,x)\in[0,T)\times\mathbb{R}} \{\eta(t,x)\} < \infty$$

$$\inf_{x\in\mathbb{R}} \{\eta_x(t,x)\} \to -\infty \quad \text{as} \quad t \uparrow T$$

(the solution remains bounded but its slope becomes infinite in finite time). However, in contrast to the KdV model, eqn [9] is not integrable and does not possess soliton solutions. As emphasized by Whitham (1980), it is intriguing to find models for water waves which exhibit both soliton interaction and wave breaking.

The Camassa–Holm equation

$$\eta_t - \eta_{txx} + 3\eta\eta_x = 2\eta_x\eta_{xx} + \eta\eta_{xxx} \qquad [10]$$

was first obtained by Fokas and Fuchssteiner (1981/82) as a nonlinear partial differential equation with infinitely many conservation laws. Camassa and Holm (1993) derived [10] as a model for shallow water waves, established that the equation possesses soliton solutions and found that it is formally integrable (for a discussion of the integrability issues we refer to Constantin (2001), and Lenells (2002)). Moreover, the solitons of [10] are stable (Constantin and Strauss 2003). An astonishing plentitude of structures is tied into the Camassa–Holm equation: [10] is a re-expression of geodesic flow on the diffeomorphism group (Constantin 2000, Kouranbaeva 1999), a property that can be used to show that the least action principle holds in the sense that there is a unique flow transforming a wave profile into a nearby profile within the class of flows that minimize the kinetic energy (see the discussion in Constantin (2000) and Constantin and Kolev (2003)). Interestingly, the Camassa–Holm equation also models wave breaking. More precisely (see the discussion in Constantin (2000)), for any initial data $x \mapsto \eta_0(x) = \eta(0,x)$ in $H^3(\mathbb{R})$ there is a unique solution of [10] defined on some maximal time interval $[0,T)$ and the solution stays uniformly bounded on $[0,T)$ with

$$\lim_{t\uparrow T}\left(\inf_{x\in\mathbb{R}}\{\eta_x(t,x)\}(T-t)\right) = -2 \text{ if } T < \infty$$

In addition to this, for a large class of initial data, there is precisely one point where the slope of the wave becomes infinite at breaking time (Constantin 2000): if $\eta_0 \not\equiv 0$ is odd and such that $\eta_0(x) - \eta_0''(x) \geq 0$ for all $x \leq 0$, then the corresponding wave $t \mapsto [x \mapsto \eta(t,x)]$ will break in finite time $T < \infty$ and

$$\lim_{t\uparrow T} \eta_x(t,0) = -\infty$$

whereas

$$|\eta_x(t,x)| \leq K + K\frac{\cosh(x)}{|\sinh(x)|}$$

$$t \in [0,T), \quad x \neq 0$$

for some constant $K > 0$. Thus, the Camassa–Holm model is an integrable infinite-dimensional Hamiltonian system with stable solitons and eqn [10] admits also breaking waves as local solutions (see Constantin and Escher (1998) and McKean (1998) and references therein for further results on wave breaking for the Camassa–Holm equation).

We conclude our discussion by pointing out that it is possible to continue solutions of the Camassa–Holm equation past the breaking time. For this purpose it is convenient to rewrite [10] as the nonlinear nonlocal conservation law

$$\eta_t + \eta\eta_x + \frac{1}{2}\partial_x \int_{\mathbb{R}} \mathrm{e}^{-|x-y|}\left(\eta^2 + \frac{\eta_x^2}{2}\right)\mathrm{d}y = 0 \qquad [11]$$

reminiscent to some extent to the form of [7] and [9] and obtained by formally applying the operator $(1-\partial_x^2)^{-1}$ to [10] in view of the fact that

$$(1-\partial_x^2)^{-1}f = P * f \quad \text{for} \quad f \in L^2(\mathbb{R})$$

the kernel of the convolution being

$$P(x) = \tfrac{1}{2}\mathrm{e}^{-|x|}, \quad x \in \mathbb{R}$$

By introducing a new set of independent and dependent variables it is possible to resolve all singularities due to wave breaking in the sense that [11] is transformed into a semilinear system, the unique solution of which can be obtained as a fixed point of a contractive operator (Bressan and Constantin 2005). In terms of [11], a semigroup of global conservative solutions (in the sense that the total energy

$$\frac{1}{2}\int_{\mathbb{R}} (\eta^2 + \eta_x^2)\mathrm{d}x$$

equals a constant, for almost every time), depending continuously on the initial data $\eta(0,\cdot) \in H^1(\mathbb{R})$, is thus constructed.

# BRST Quantization

**M Henneaux**, Université Libre de Bruxelles, Bruxelles, Belgium

## Introduction

The BRST symmetry was originally introduced in the seminal papers by Becchi *et al*. (1976) and Tyutin (1975) for Yang–Mills gauge theories as a tool for controlling the renormalization of the models in a consistent (gauge-independent) way. This symmetry was discovered as a residual symmetry of the gauge-fixed action. It was realized later that, in fact, the BRST construction is quite general, in the sense that it covers arbitrary gauge theories and not just Yang–Mills gauge models. Furthermore, it is intrinsic, in that no gauge choice is actually necessary to define it.

The purpose of this review is to explain the general, intrinsic features of the BRST formalism applicable to "any" gauge theory. The proper setting for discussing these issues is that of homological algebra (Stasheff (1998), and references therein). This article first explains the necessary algebraic material underlying the construction and then illustrates it in the cases of the Hamiltonian BRST formalism and the Lagrangian BRST formalism.

## A Result from Homological Algebra

The main result of homological algebra needed in the BRST construction deals with a differential complex $\mathcal{C}$ with two gradings. The first grading is an $\mathbb{N}$-degree and is called the "resolution degree," or "r-degree." The second grading is a $\mathbb{Z}$-degree and is called the total ghost number. It is denoted by gh. We assume that there are two odd derivations $\delta$ and $s_0$ that have the following properties:

$$r(\delta) = -1, \qquad \mathrm{gh}(\delta) = 1$$
$$r(s_0) = 0, \qquad \mathrm{gh}(s_0) = 1 \qquad [1]$$

and

$$\delta^2 = 0, \quad s_0\delta + \delta s_0 = 0, \quad s_0^2 = -[\delta, s_1] \qquad [2]$$

for some derivation $s_1$ of r-degree 1 and ghost number 1. The bracket $[\cdot,\cdot]$ is the graded commutator – in this specific case, the anticommutator. We also assume that the homology of $\delta$ vanishes at nonzero value of the r-degree, both in the original complex $\mathcal{C}$,

$$H_k(\delta, \mathcal{C}) = 0, \quad k > 0 \qquad [3]$$

(which is equivalent to $\delta a = 0$, $r(a) > 0 \Rightarrow a = \delta b$) and in the space of derivations,

$$[\alpha, \delta] = 0, \quad r(\alpha) \neq 0 \Rightarrow \alpha = [\beta, \delta] \qquad [4]$$

where $\alpha$ and $\beta$ are both derivations in $\mathcal{C}$. The r-degree of a homogeneous linear operator $\alpha$ is defined through $r(\alpha(x)) = r(\alpha) + r(x)$ for any element $x \in \mathcal{C}$ and is negative when $\alpha$ decreases the r-degree.

In $H_0(\delta, \mathcal{C})$, the (odd) derivation $s_0$ defines a differential. The cohomology of $s_0$ modulo $\delta$, denoted $H^k(s_0, H_0(\delta, \mathcal{C}))$, is the cohomology of $s_0$ in $H_0(\delta, \mathcal{C})$. It is explicitly defined through the cocycle condition

$$s_0 a = \delta m \qquad [5]$$

with coboundaries of the form

$$s_0 b + \delta n \qquad [6]$$

The central result underlying the BRST construction is:

**Theorem 1** *Given the above setting, there exists an odd derivation s in $\mathcal{C}$ with the following properties*:

$$s = \delta + s_0 + s_1 + \cdots \qquad [7]$$

$$r(s_k) = k, \qquad \mathrm{gh}(s_k) = 1 \qquad [8]$$

$$s^2 = 0 \qquad [9]$$

*Furthermore, one has*

$$H^k(s, \mathcal{C}) = H^k(s_0, H_0(\delta, \mathcal{C})) \qquad [10]$$

The proof is straightforward (see, e.g., Henneaux and Teitelboim (1992)). In particular, the proof of [10] is a standard spectral sequence argument with a sequence that collapses after the second step. It is interesting to note that, contrary to $s_0$, which is only a differential modulo $\delta$,$s$ is a true differential. The construction of $s$ provides a model for $H^k(s_0, H_0(\delta, \mathcal{C}))$. The differential $s$ is not unique, but this does not affect the subsequent discussion.

In physical applications, the total ghost number is a derived quantity. The primary gradings are the resolution degree and the "filtration degree" called the pure ghost number and denoted pgh. It is an $\mathbb{N}$-degree and one has

$$\mathrm{gh} = \mathrm{pgh} - r \qquad [11]$$

The r-degree is known as the antighost or antifield number, depending on the context (see below). When $r(x) = 0$, one has $\mathrm{gh}(x) = \mathrm{pgh}(x)$. Since the pure ghost number is non-negative, this implies that

$$H^k(s, \mathcal{C}) = 0, \quad k < 0 \qquad [12]$$

## A Geometric Application

### Geometric Setting

Theorem 1 is relevant to the following situation. Consider a surface $\Sigma$ in a manifold $M$, defined by equations

$$f_a = 0 \qquad [13]$$

which may or may not be independent. (We assume for definiteness that the variables in $M$ are bosonic, that is, that $M$ is an ordinary manifold – as opposed to a supermanifold. The graded case can be covered without difficulty by including appropriate sign factors at the relevant places.) Assume that $\Sigma$ is partitioned by orbits generated by vector fields $\boldsymbol{X}_\alpha$ defined everywhere in $M$, tangent to $\Sigma$ and closing on $\Sigma$ in the Lie bracket,

$$[\boldsymbol{X}_\alpha, \boldsymbol{X}_\beta] = C^\gamma{}_{\alpha\beta}\boldsymbol{X}_\gamma + \text{“more”} \qquad [14]$$

where "more" denotes terms that vanish on $\Sigma$. We assume, for simplicity, that the vector fields $\boldsymbol{X}_\alpha$ are linearly independent of $\Sigma$, although this is not necessary. The formalism can be developed in the nonindependent case, but it then requires more variables. We are interested in the quotient space $\Sigma/\mathcal{O}$ of the surface $\Sigma$ by the orbits. To guide the geometrical intuition, we shall assume that this quotient space is a smooth manifold (the fiber of the orbits, etc.), and we shall suggestively adopt notations adapted to this best possible case. The approach, being purely algebraic, is in fact more general. (Accordingly, the notations should be understood with a liberal mind.)

The aim here is to describe the algebra of "observables," that is, the algebra $C^\infty(\Sigma/\mathcal{O})$ of functions on the quotient space $\Sigma/\mathcal{O}$. The terminology "observables" anticipates the physical situation discussed below, where the orbits are the "gauge orbits." In order to describe algebraically the algebra of observables, one observes that this algebra is obtained

through a two-step procedure. First, one restricts the functions from $M$ to $\Sigma$. Second, one imposes the invariance condition along the orbits. To each of these steps corresponds a separate differential.
